As was the case for BWR piping, the 0.2-mg/L oxygenated 288-°C (550-°F) water in the BWR was sufficient to provide the chemical driving force for intergranular SCC of the jet pump beams. To quantify the effects of the environment on Alloy X-750, creviced and uncreviced tensile specimens were tested at constant load in air-saturated 8-mg/L oxygenated water and typical BWR 0.2-mg/L oxygenated water at 288 °C (550 °F) at various applied stress ratios (applied stress/yield stress).

Mitigation of Intergranular SCC in Jet Pump Beams. A two-pronged attack was used to solve the intergranular SCC problem. Both the material and stress factors of the intergranular SCC three intersecting circles shown in Fig. 1 are addressed.

Extensive research and testing revealed that high-temperature annealing (1095 °C, or 2000 °F, for 1 h) can reduce the susceptibility of Alloy X-750 to intergranular SCC in oxygenated water. It is believed that this occurs because of the creation of new grain boundaries that are free of precipitates and impurities. By eliminating the equalizing step (885 °C, or 1625 °F, for 20 h) and retaining the direct aging step at 705 °C (1300 °F) for 20 h, the material attains high strength and is much more resistant to intergranular initiation (Ref 25). This heat treatment is known as high-temperature annealing and aging. It can also be applied to previously heat-treated beams and does not affect performance in hydrogen water chemistry environments (Ref 26).

To address the tensile stress component, evaluations revealed that the preload could be reduced on the newer-type jet pump beam from 133.5 to 111.2 kN (30 to 25 kips). This reduction in stress alone would result in a significant increase in lifetime of the equalized and aged heat-treated Alloy X-750 from a calculated average 13 years to 19 to 40 years or more for a $\leq$2.5% probability of crack initiation. The synergistic combination of lower stress and the high-temperature annealing and aged heat treatment will decrease the probability of cracking even further--to more than 40 years for a $\leq$ 2.5% probability of crack initiation.

Conclusions. The primary conclusions of this case study are as follows:

- The intergranular SCC observed in the Alloy X-750 jet pump beam was a result of simultaneous interaction of a susceptibly heat-treated material, heat treatment, sufficient preload tensile stress, and high-temperature oxygenated water
- The problem has been mitigated by changing the heat treatment of Alloy X-750 beams and reducing the preload
- It is anticipated that the cracking of jet pump beams will not be a concern during future BWR operation, because all BWR utilities have addressed this problem by beam replacement, reheat treatment, or preload reduction

Irradiation-Assisted SCC

Irradiation-assisted SCC is an intergranular SCC phenomenon that can occur in BWR internals. Irradiation-assisted SCC does not require the presence of a sensitized microstructure or high tensile stresses.

The intergranular SCC described in the discussion on "Mechanism of Intergranular SCC in BWR Piping" in this article was the result of the simultaneous interaction of sensitized stainless steel (that is, chromium depletion at the grain boundaries), high tensile stresses (weld residual, pressure, and thermal), and oxygenated high-temperature water. The mechanism of irradiation-assisted SCC appears to involve the simultaneous interaction of highly irradiated nonsensitized material with diffusion of impurities (sulfur, silicon, and phosphorus) to the grain boundaries, low stress (fabrication, irradiation creep) and high-temperature water with short-lived oxidizing species (hydrogen peroxide, H_2O_2), gamma, and neutron flux. It is extremely important to note that irradiation-assisted SCC does not require the chromium depletion sensitization or high tensile stresses that are implicit in the failure of nonirradiated stainless steel components.

Field Experience With Irradiation-Assisted SCC. During the early history of the BWR (1960s), type 304 stainless steel was used as a fuel cladding material. Because this highly stressed material suffered extensive cracking, the type 304 stainless steel was replaced with Zircaloy-2. It is believed that this instance of cracking was the first indication that annealed type 304 stainless steel could suffer intergranular SCC in the BWR core environment. Because this type of intergranular cracking was produced in nonsensitized, highly stressed, highly irradiated components, this form of intergranular SCC is referred to as irradiation-assisted SCC. (As noted above, high tensile stresses are not necessary for irradiation-assisted SCC, but the presence of high tensile stress certainly exacerbates the phenomenon.)

Recently, core components such as type 304 stainless steel neutron source holders, control blade absorber tubes (Fig. 22), and nuclear instrument tube holders have cracked in the BWR environment. Table 1 presents a summary of significant field irradiation-assisted SCC experience. To date, the cracking has been limited to readily replaceable components. It is also important to note that PWRs have also experienced this type of corrosion phenomenon (Ref 27, 28). The results of the field irradiation-assisted SCC experience suggest the following:

- Dynamic strain or high stresses produced irradiation-assisted SCC in fuel cladding and absorber tubing
- More recent results with lower-stressed neutron source holders and instrument tubes indicate that the stress threshold for irradiation-assisted SCC may be lower than initially believed
- No field irradiation-assisted SCC has been observed at a fluence below about $\leq 5 \times 10^{20}$ NVT (neutrons per unit volume multiplied by time) (>1 MeV)
- Cracks may occur at lower stresses for higher fluences

Table 1 Summary of significant field irradiation-assisted SCC experience

Stainless steel component	Fluence (neutrons/cm^2)	Source of stress
Fuel cladding	5×10^{20} to 2×10^{21}	Fabrication; fuel cladding interaction
Neutron source holders	10^{21} to 10^{22}	Welding; beryllium swelling after initial crevice attack
Control rod absorber tubes	5×10^{20} to 3×10^{21}	B_4C swelling
In-core instrument tubes	10^{21} to 10^{22}	Fabrication

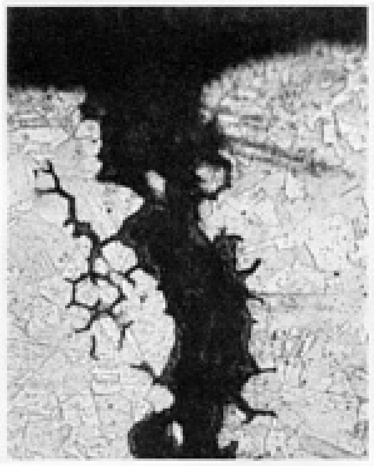

Fig. 22 Irradiation-assisted SCC of a control blade absorber tube. 500×

Mechanism of Irradiation-Assisted SCC. The mechanism of irradiation-assisted SCC appears to involve highly irradiated annealed austenitic stainless steel with diffusion of impurities (sulfur, silicon, phosphorus) to the grain boundaries, low stress (fabrication, irradiation creep), and a highly oxidizing environment associated with the gamma and neutron flux (Ref 27, 28). Partial chromium depletion is also possible. To simulate these highly oxidizing conditions in the core, tests were performed on irradiated annealed type 304 stainless steels at different levels of fluence. The irradiation-assisted SCC phenomenon was reproduced, and the results indicate that the observed field irradiation-assisted SCC fluence threshold is consistent with the laboratory tests.

Mitigation of Irradiation-Assisted SCC. Fortunately, the same environmental solution for the intergranular SCC of piping (hydrogen water chemistry) appears promising for this phenomenon. Table 2 presents the results of SCC tests on highly irradiated commercial-purity annealed type 304 stainless steel in a high-oxygen (32 mg/L) environment simulating the highly oxidizing regions in the core and in hydrogen water chemistry. The difference in SCC response is dramatic. The highly oxidizing environment produced a fracture surface with 99% intergranular SCC, while the more reducing environment characteristic of hydrogen water chemistry produced ductile failure. The reason for this significant disparity may be explained by the electrochemical potential of type 304 stainless steel, which is significantly more oxidizing in the core region ($\sim$250 mV_{SHE}) than in the recirculation piping system ($\simeq$30 mV_{SHE}). Hydrogen water chemistry obtained by lowering the electrochemical potential appears to be a promising method of mitigation for irradiation-assisted SCC if sufficient reduction of electrochemical potential can be achieved in the core.

Table 2 Hot cell SCC test results on irradiated type 304 stainless steel

Environment	Fluence	Fracture
32 ppm O_2	2×10^{21} NVT (>1 MeV)	99% Intergranular SCC
Hydrogen water chemistry	2×10^{21} NVT (>1 MeV)	Ductile

Note: NVT = neutrons per unit volume × time.

The second promising technique for mitigating irradiation-assisted SCC is the use of high-purity materials containing controlled amounts of such impurities as sulfur, phosphorus, and silicon (Ref 27). This mitigation technique is based on early laboratory testing in a highly oxidizing medium, such as boiling nitric acid (HNO_3) with Cr^{6+} ions, and on the highly successful in-reactor performance of high-purity type 348 stainless steel fuel cladding at the La Crosse BWR. In contrast, commercial-purity type 348 stainless steel materials with the nominal commercial levels of sulfur, phosphorus, and silicon installed at the La Crosse BWR suffered irradiation-assisted SCC. Other support for the implementation of high-purity materials is based on in-reactor studies (Ref 29) and on laboratory studies on nonirradiated stainless steel where the presence of these specific impurities increased the intergranular SCC susceptibility (Ref 30). Work is continuing in this area.

Conclusions. The results of in-reactor and laboratory investigations suggest the following conclusions concerning irradiation-assisted SCC in the BWR:

- The irradiation-assisted SCC of components in the BWR core was the result of the simultaneous interaction of irradiation-enhanced impurity segregation, tensile stress, and highly oxidizing environment
- Preliminary studies suggest that hydrogen water chemistry and high-purity materials are promising remedies for mitigating irradiation-assisted SCC

Case History: Corrosion Fatigue in Feedwater Nozzles

Fatigue evaluation of nuclear power plant equipment subjected to cyclic loading conditions is of primary concern to equipment designers and stress analysts. Because the number of loadings resulting in significant stresses that occur over the life of light water reactors seldom exceed several thousand, and in numerous cases do not even exceed several hundred, fatigue usage is generally classified as low cycle. However, in this particular case history on feedwater nozzle cracking, both low- and high-cycle fatigue were involved. Figure 23 shows a cross section of a feedwater nozzle that suffered from cracking of the cladding of the feedwater nozzle bed radii, a problem common to a number of BWRs.

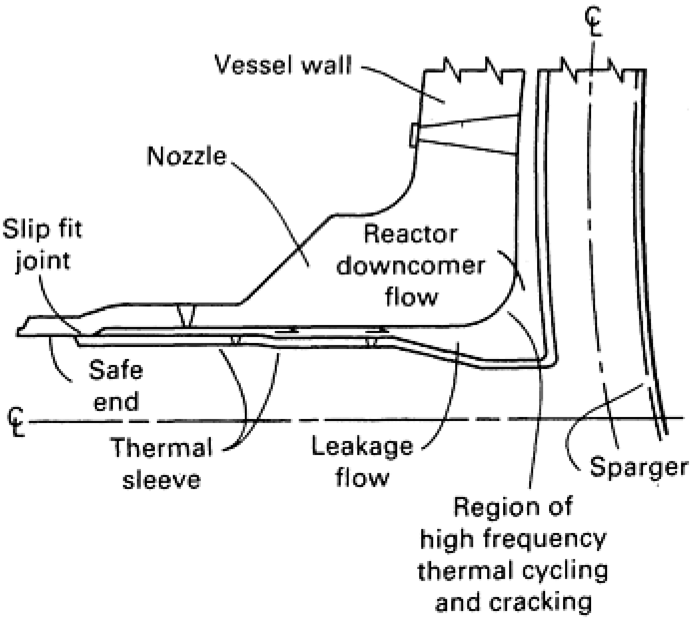

Fig. 23 Cross section of feedwater nozzle with cracking location

Field Experience. Metallurgical examination of a boat sample (a wedge-shaped specimen cut out of a component) removed from the cladding of the feedwater nozzle bend radii revealed that the primary cause of the nozzle crack was thermal-induced corrosion fatigue (Fig. 24). It was further determined that there are two corrosion fatigue mechanisms present: a high-cycle corrosion fatigue mechanism, which initiates the cracks, and a low-cycle corrosion fatigue mechanism, which causes the cracks to propagate.

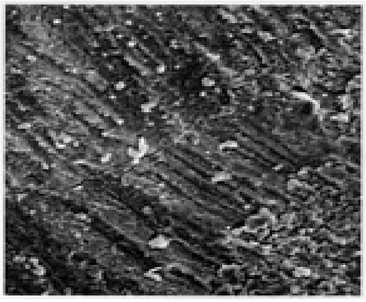

Fig. 24 Example of corrosion fatigue striations in a feedwater nozzle. 1500×

Mechanisms of Corrosion Fatigue in Feedwater Nozzles. The high-cycle mechanism was found to be primarily caused by leakage flow passing between the thermal sleeve and safe end. This leakage flow, which is at feedwater temperature, mixes in a turbulent manner with hot downcomer flow in the annulus between the nozzle and thermal sleeve. The mixing fluid impinges on the nozzle wall, causing thermal cycling of the metal surface. It has been determined by test and by field measurements at two BWRs that the metal temperature cycling, with leakage present, has a magnitude of up to 50% of the difference in temperature between the feedwater and the downcomer water. The cycling occurs with frequencies between 0.1 and 1 Hz and thus can initiate cracking rapidly with little if any environmental contribution. The exact time to crack initiation depends on several factors, including the duration of operation with low feedwater temperature.

The cracks initiated by the high-frequency cycling described above will arrest at a depth of approximately 6 mm (0.25 in.) from the metal surface. This arrest results from the fact that the high-cycle thermal input induces thermal stresses with steep gradients and shallow depths. Cracks that arrest, as described above, present no problem from an engineering

standpoint, because they will not degrade safety or availability and would not have to be repaired under the rules of Section XI of the American Society of Mechanical Engineers Code.

There is another mechanism present in the feedwater nozzles that causes the cracks to continue to grow. This mechanism is the combined pressure and thermal cycles imposed by start-up/shutdown and feedwater on-off transients. These transients, although relatively few in number, produce large stress cycles in the nozzle and in time could drive the cracks to significant depths. This low-cycle fatigue crack propagation is environmentally accelerated under BWR conditions. The deepest cracks observed were up to 18% of wall and relatively short.

Fortunately, the cracking is readily detectable by dye-penetrant examination and/or ultrasonic examination from the outside of the nozzle. The deep cracks require repair and thus can result in a significant impact on plant availability and operating cost.

Leakage between the safe end and thermal sleeve also has an aggravating effect on the crack growth rate because it increases the heat transfer coefficient between the feedwater and the nozzle. The increased heat transfer coefficient increases the stresses in the nozzle during thermal transients, and because crack growth is dependent on stress to the fourth power, a significant effect results.

Mitigation of Cracking. Several solutions were derived to mitigate this problem from both a design and a corrosion/metallurgical viewpoint. The solution consisted of three parts: a revised sparger thermal sleeve design, use of unclad feedwater nozzles, and a revised system of configuration/operating procedures that mitigates the conditions tending to produce crack initiation and growth. Together these three elements constitute a solution to the problem with margin for unexpected conditions. The implementation of hydrogen water chemistry would also mitigate this problem because test results have indicated a decrease in corrosion fatigue crack propagation rate in hydrogen water chemistry (Ref 26).

A sparger thermal sleeve design has been developed that meets the following objectives:

- It can be installed and removed without cutting feedwater piping
- It protects the feedwater nozzle against the high-frequency thermal cycles that initiate nozzle cracks through the use of redundant metal O-ring seals
- It uses materials and processes that make the part immune to intergranular SCC

The resulting design is schematically shown in Fig. 25. The thermal cycling profiles for the previous and the newer-design feedwater spargers are shown in Fig. 26. The marked reduction in thermal cycling is evident.

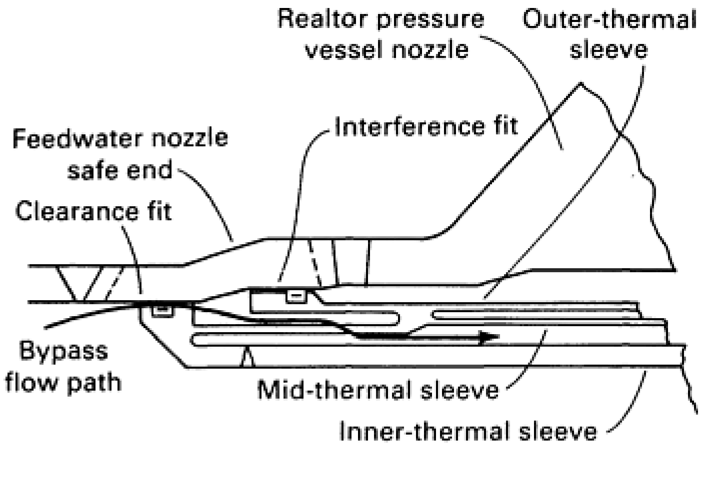

Fig. 25 Improved feedwater thermal sleeve design to eliminate corrosion fatigue

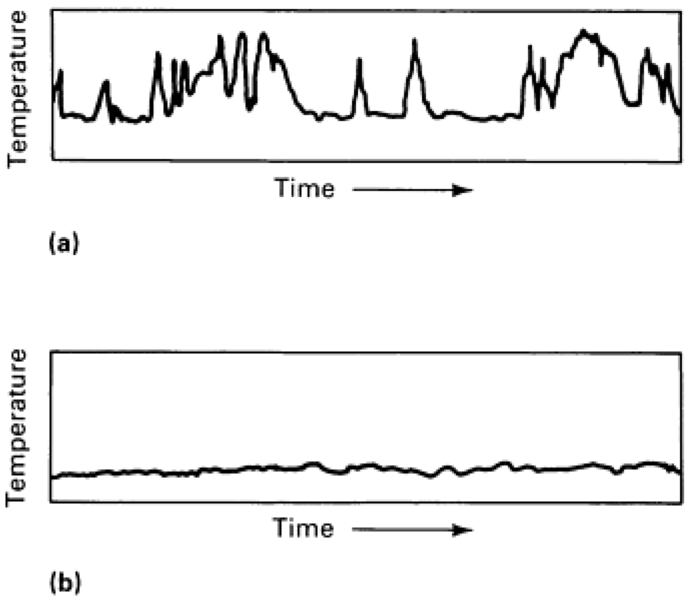

Fig. 26 Temperature variations with (a) and without (b) bypass leakage

The main conclusions concerning the corrosion fatigue cracking of BWR feedwater nozzles are:

- The corrosion fatigue of BWR feedwater nozzles was a result of the interaction of high-cycle fatigue crack initiation due to leakage flow passing between the thermal sleeve and safe end and low-cycle corrosion fatigue crack growth due to start-up/shutdown and feedwater on-off transients
- The cracking problem was mitigated by a redesign of the feedwater thermal sleeve to eliminate leakage and the removal of the nozzle cladding. Hydrogen water chemistry will also provide an additional margin against this phenomenon

SCC in Nitrided Stainless Steel

Positive core reactivity control is maintained in the domestic BWR by the use of movable control rods interspersed throughout the core. The rods are moved vertically by hydraulically actuated, locking-piston drive mechanisms. The drive mechanisms are bottom-entry upward-scramming drives that are mounted on a flanged housing on the reactor vessel bottom head (Fig. 15). The control rod drive mechanism is a double-acting hydraulic piston that uses condensate water as the operating fluid. An index tube and a piston, coupled to the control rod, are locked at fixed increments by a collet mechanism. One of the key components of this device is the collet retainer tube (CRT).

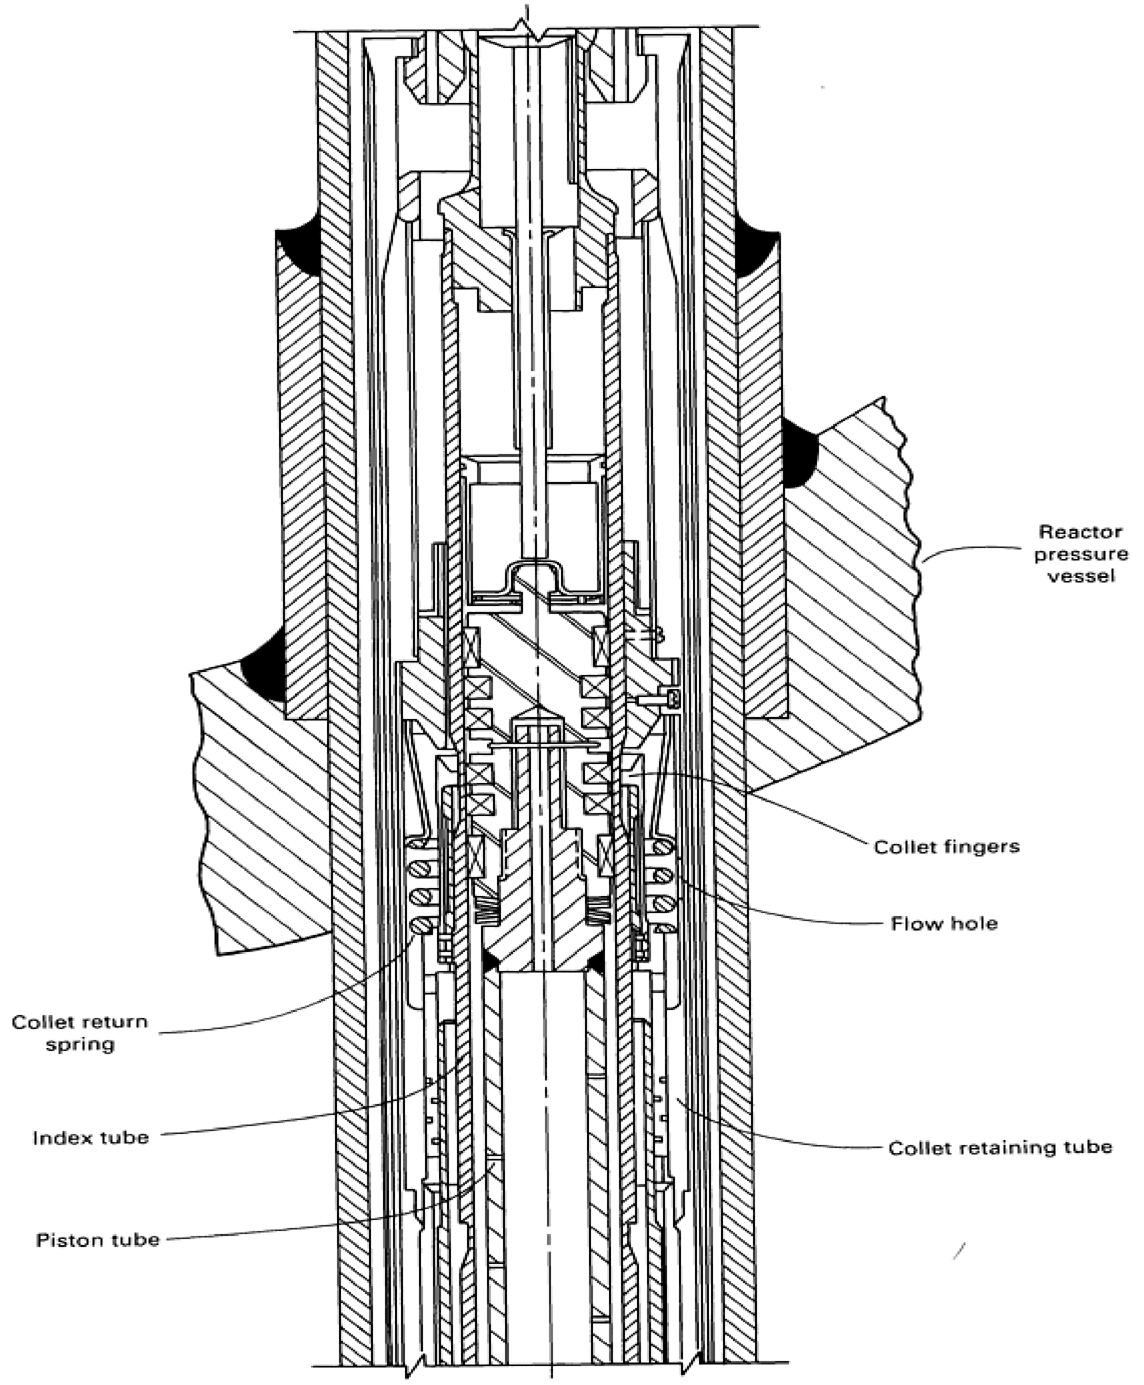

Fig. 15 Control rod drive schematic

The CRT is a short tube welded to the upper end of the drive. Its three primary functions are to carry the hydraulic unlocking pressure to the collet piston, to provide an outer cylinder, with a suitable wear surface for the metal collet piston rings, and to provide mechanical support for the guide cap, a member that incorporates the cam surface for holding the collet fingers open and provides the upper rod guide or bushing.

The CRT (Fig. 16) is fabricated from wrought type 304 stainless steel. The inner surface, where contact is made with the collet piston seal ring, is hard surfaced by nitriding. Under normal conditions, the stresses on the CRT are quite small. However, during rapid (2.5 s) control rod insertions (scrams), the tube experiences high thermal stresses when the outer surface is initially subjected to a sudden flow of 288-°C (550-°F) water. The normal CRT operating range is 65 to 150 °C (150 to 300 °F). The water flow pattern during a scram is such that the inside of the CRT is cold, while the outside has alternating zones of hot and cold water.

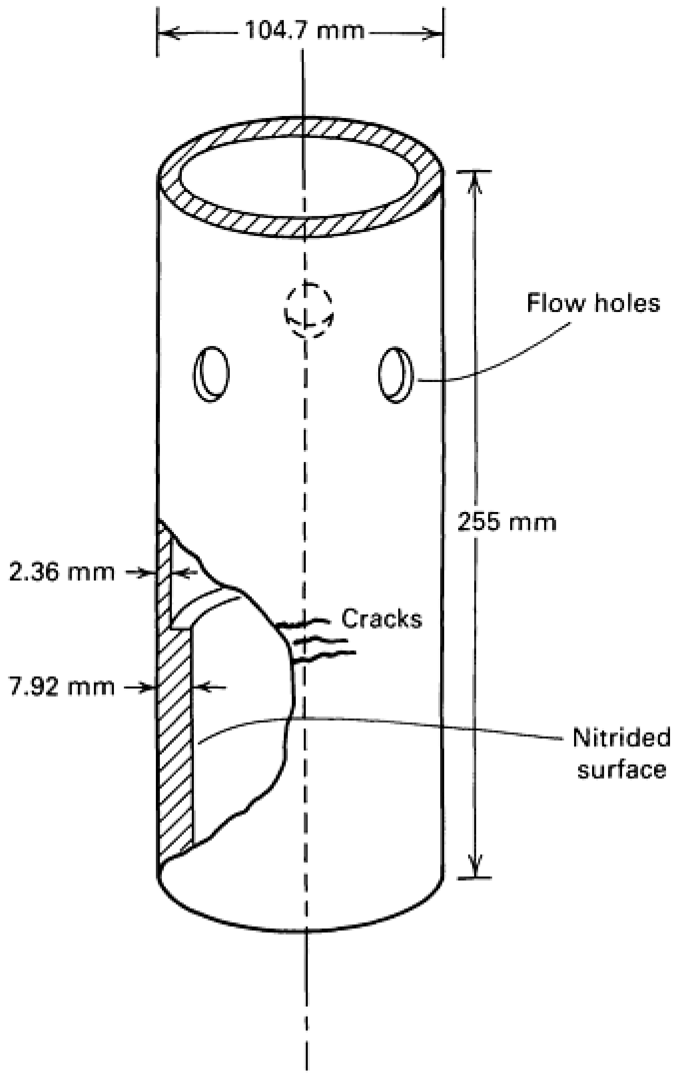

Fig. 16 Geometry of the collet retainer tube

Field Experience With the CRT. During a routine maintenance inspection of disassembled control rod drives at a domestic BWR in June 1975, fine cracks were observed by liquid-penetrant examination in a limited number of CRTs (Fig. 17). Subsequent inspection of drives in other operating BWRs also disclosed occasional occurrences of CRT cracking. Inspection of several test drives having simulated service histories for an excess of the 300 hot scram design life also indicated evidence of cracking. The cracks, which were determined to be intergranular, were generally circumferential and appeared with greatest frequency below and between the cooling ports in the area of the change in wall thickness (Fig. 18).

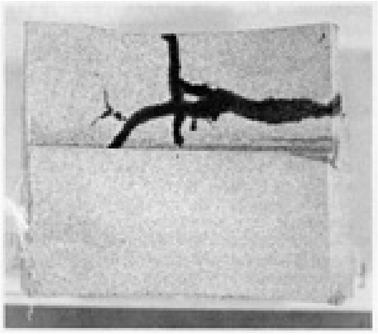

Fig. 17 Intergranular SCC of collet retainer tube revealed by liquid-penetrant examination

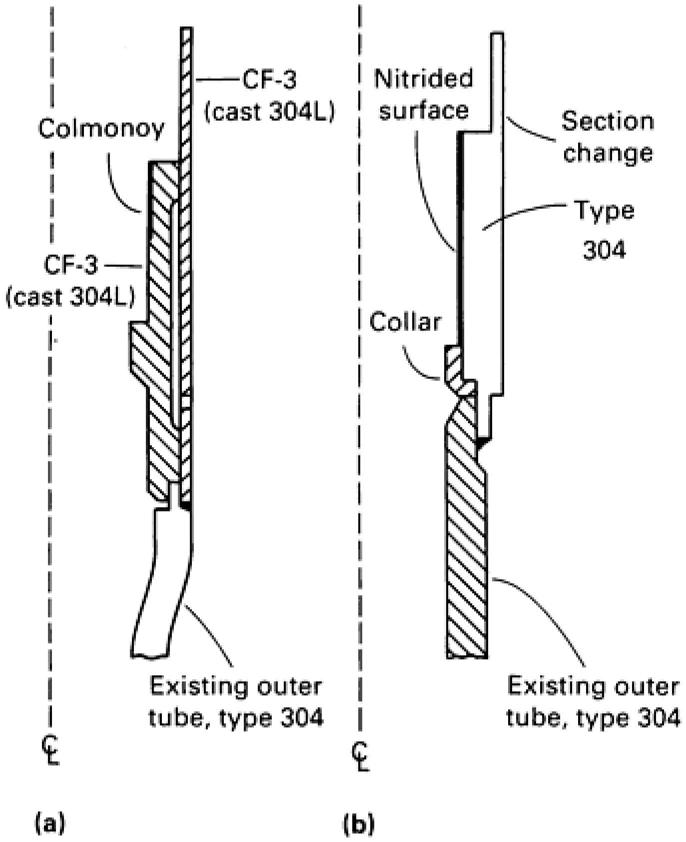

Fig. 18 Collet retainer tube improvements. (a) Improved design. (b) Old design

Mechanism of Cracking of the CRT. A detailed analytical and experimental investigation was performed to determine the cause of cracking and to assess the margin to failure (Ref 14). As was the case with stainless steel piping, the cracking was intergranular SCC produced by the simultaneous combination of sensitization, as discussed above, due to the nitriding thermal cycle, tensile stress, and highly oxygenated water. Specifically, it was determined that there were four sources of thermal stresses near the location of the cracks (Ref 24):

- Thermal shock stresses due to the sudden increase in temperature
- Bending stresses due to the through-wall temperature gradient
- Discontinuity stresses due to the difference in heat-up rates between the thick and thin sections
- Bending stresses due to circumferential temperature gradients

The environment of the control rod drive is typically supplied by the condensate storage tank. This cooling water was often characterized by a conductivity of ~1 μS/cm (25 °C, or 77 °F), and the typical dissolved oxygen content is 5 mg/L. This high-oxygen/high-conductivity environment will accelerate intergranular SCC.

Mitigation of Intergranular SCC in the CRT. It has been shown that the CRT cracking was due to intergranular SCC caused by high thermal stresses with material sensitized by nitriding plus exposure to a high-oxygen water environment. Therefore, the problem can be mitigated by attacking each one of these three necessary factors.

To eliminate the high thermal stresses, the design of the CRT was changed by installing a two-piece CRT, which eliminated the section change and thus reduced the discontinuity stress. To reduce stresses further, the new design (Fig. 18a) has 12 cooling water exit holes rather than the original 3. The effect is to reduce the circumferential variation in temperature below the flow holes during a scram cycle.

The CRT material was changed from wrought type 304 stainless steel to a centrifugally cast CF-3 with ferrite control, a proven BWR material with known resistance to intergranular SCC. The newer-design CRT is also hardfaced with Colmonoy 6, a nickel-base hardfacing material applied by the flame spray process rather than by nitriding.

The environment was changed by a recommendation to BWR operating plant utilities to use high-purity deaerated water (conductivity: ≤0.1 μS/cm, measured at 25 °C, or 77 °F; dissolved oxygen: <5 mg/L) for control rod drive cooling water. This reduction in dissolved oxygen can increase the time to crack initiation of the older CRT by a factor of 100. The recommendation identified approaches to achieving water quality limits, water sampling, and monitoring additions.

The main conclusions of this case study can be summarized as follows:

- The intergranular SCC observed in the CRT was due to the simultaneous interaction of sensitized material, high thermal stresses, and highly oxygenated water
- The problem has been mitigated by eliminating sensitization by a change of material to CF-3, by redesigning to reduce the discontinuity stresses and circumferential stresses, and by reducing the oxygen content and conductivity of the environment
- The intergranular SCC of BWR collet retainer tubes is understood, and a solution is now available

SCC of Alloy X-750 Jet Pump Beams

Jet pumps located within the reactor vessel are used in the BWR recirculation system (Fig. 3). The jet pumps, which have no moving parts, provide a continuous circulation path for a major portion of the core coolant flow. The water from the recirculation system flows up the riser pipe, reverses direction through the 180° bend nozzle, and draws surrounding water in the downcomer region into the jet pump throat, where the two flows mix and then diffuse in the diffuser (Fig. 19).

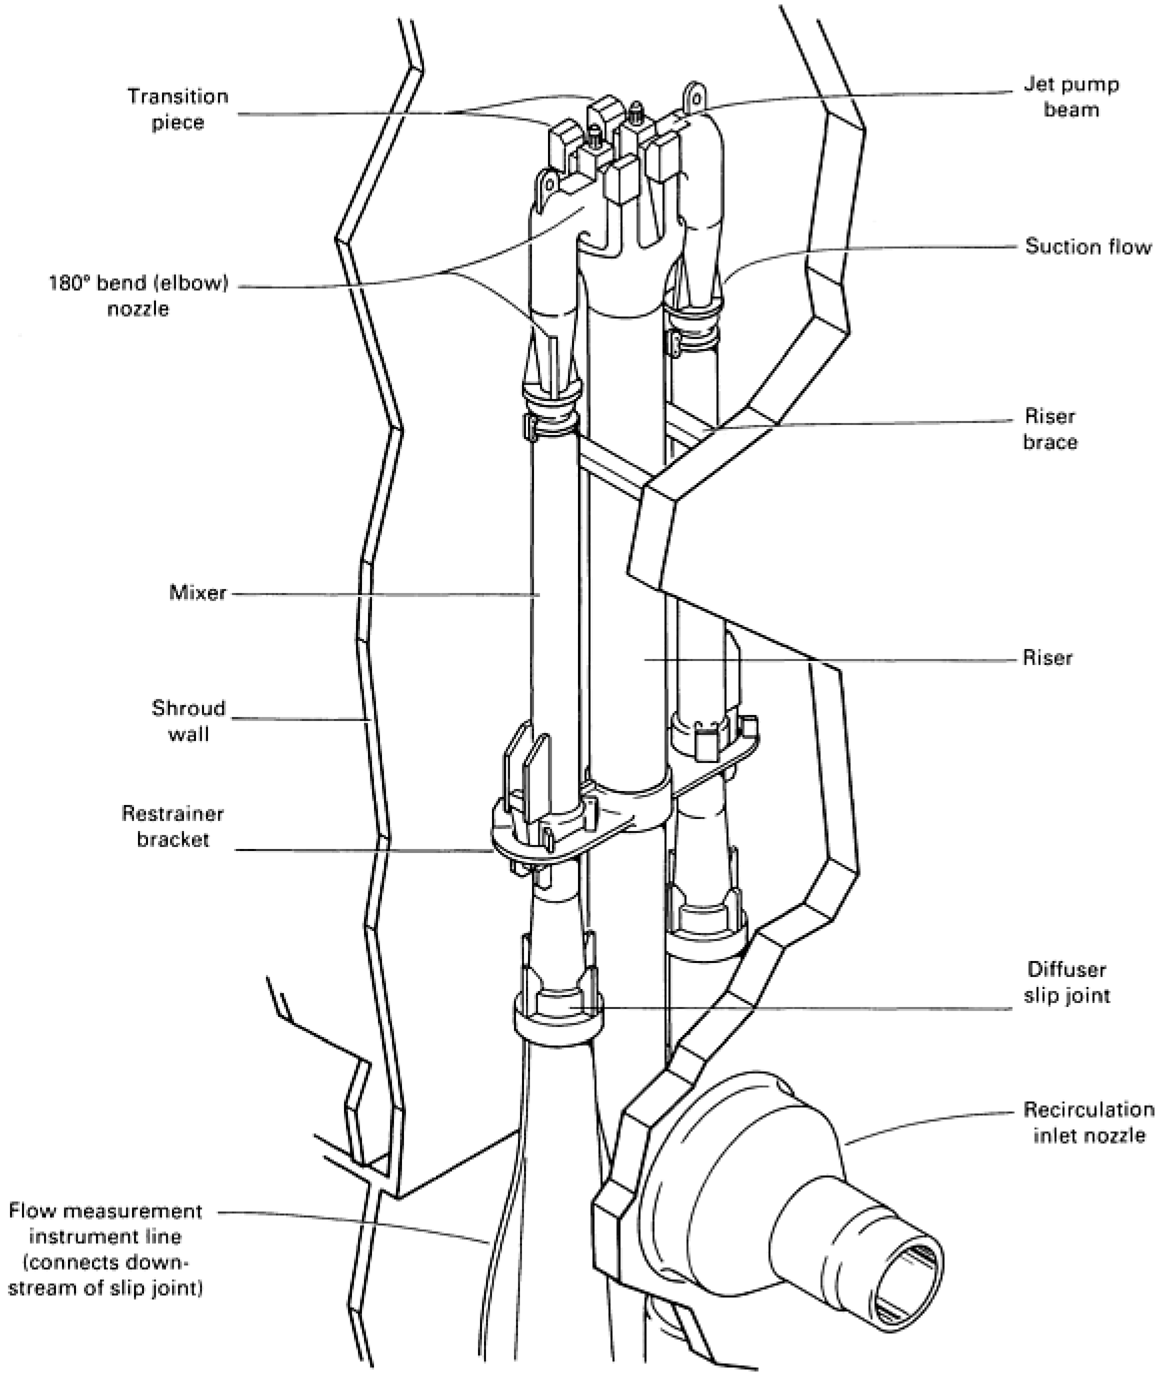

Fig. 19 Jet pump assembly

Field Experience With Jet Pump Beams. The inlet mixer section of each jet pump, from the entrance to the 180° bend to the diffuser slip joints, is removable for inspection. The inlet mixer is held in place by a beam-bolt assembly located in the riser transition piece and is centered in the diffuser by a three-point contact of the restrainer bracket. The beam ends are positioned in pockets in the transition piece, and the beam load is transferred to the elbow through a bolt located in the center of the beam.

In mid-1979 and early 1980, a jet pump hold-down beam fabricated from Alloy X-750 containing 70% Ni (min), 14 to 17% Cr, and 5 to 9% Fe failed during plant operation at one overseas and one domestic BWR plant (Fig. 20). Metallurgical examinations of the failed beams revealed that intergranular SCC under sustained loading was responsible for the failure. Figure 21 shows a detailed illustration of the beam-bolt assembly and the beam top view.

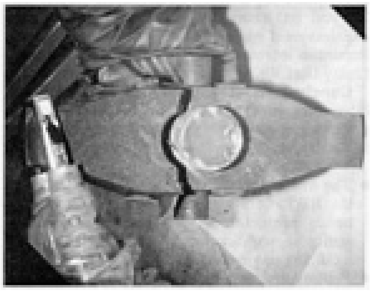

Fig. 20 Failed jet pump beam due to intergranular SCC. Approximately $\frac{1}{3}$ ×

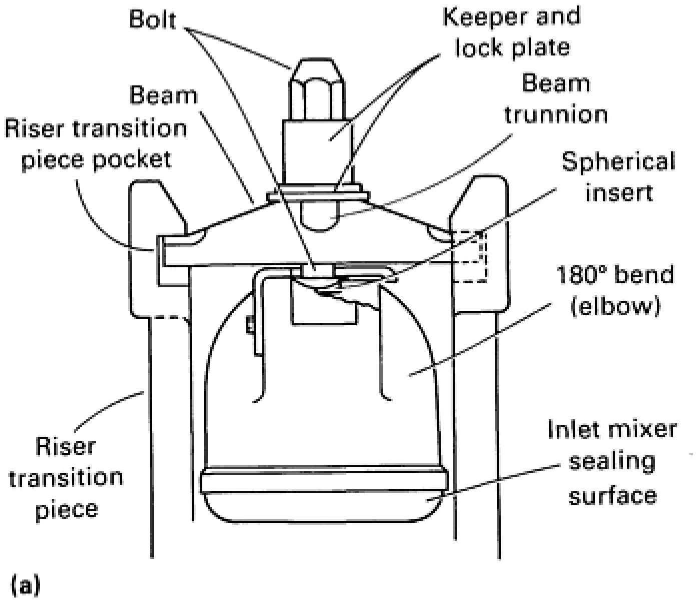

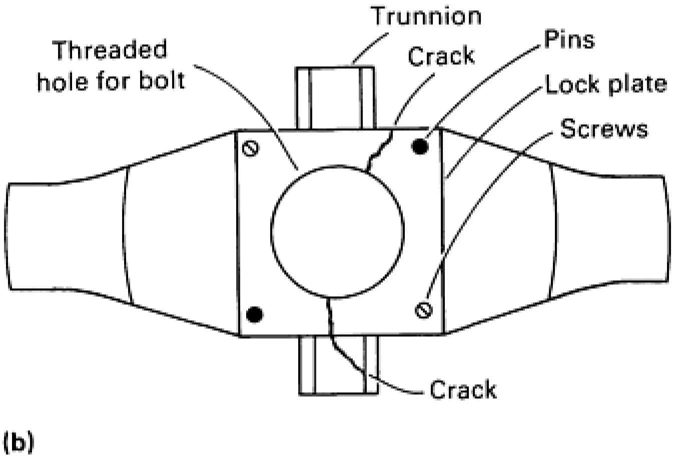

Fig. 21 Jet pump beam/bolt assembly (a) and beam top view (b)

Mechanism of Cracking of the Jet Pump Beam. The Alloy X-750 jet pump beams had received the following heat treatment: heating to 885 °C (1625 °F), holding at this temperature for 24 h (equalizing), followed by aging at 705 °C (1300 °F) for 20 h. This heat treatment is known as equalized and aged.

A stress analysis revealed that the maximum stress occurs at the beam mid-plane top surface. The results of this analysis are consistent with examination of actual beams with cracks in various stages of propagation. The older beam model, using a preload of 111.2 kN (25 kips), resulted in a maximum tensile stress of 593 MPa (86 ksi), but the newer-style beam with a larger cross section, using a preload of 133.5 kN (30 kips), resulted in a maximum tensile stress of 496 MPa (72 ksi).

As was the case for BWR piping, the 0.2-mg/L oxygenated 288-°C (550-°F) water in the BWR was sufficient to provide the chemical driving force for intergranular SCC of the jet pump beams. To quantify the effects of the environment on Alloy X-750, creviced and uncreviced tensile specimens were tested at constant load in air-saturated 8-mg/L oxygenated water and typical BWR 0.2-mg/L oxygenated water at 288 °C (550 °F) at various applied stress ratios (applied stress/yield stress).

Mitigation of Intergranular SCC in Jet Pump Beams. A two-pronged attack was used to solve the intergranular SCC problem. Both the material and stress factors of the intergranular SCC three intersecting circles shown in Fig. 1 are addressed.

Extensive research and testing revealed that high-temperature annealing (1095 °C, or 2000 °F, for 1 h) can reduce the susceptibility of Alloy X-750 to intergranular SCC in oxygenated water. It is believed that this occurs because of the creation of new grain boundaries that are free of precipitates and impurities. By eliminating the equalizing step (885 °C, or 1625 °F, for 20 h) and retaining the direct aging step at 705 °C (1300 °F) for 20 h, the material attains high strength and is much more resistant to intergranular initiation (Ref 25). This heat treatment is known as high-temperature annealing and aging. It can also be applied to previously heat-treated beams and does not affect performance in hydrogen water chemistry environments (Ref 26).

To address the tensile stress component, evaluations revealed that the preload could be reduced on the newer-type jet pump beam from 133.5 to 111.2 kN (30 to 25 kips). This reduction in stress alone would result in a significant increase in lifetime of the equalized and aged heat-treated Alloy X-750 from a calculated average 13 years to 19 to 40 years or more for a $\leq$2.5% probability of crack initiation. The synergistic combination of lower stress and the high-temperature annealing and aged heat treatment will decrease the probability of cracking even further--to more than 40 years for a $\leq$ 2.5% probability of crack initiation.

Conclusions. The primary conclusions of this case study are as follows:

- The intergranular SCC observed in the Alloy X-750 jet pump beam was a result of simultaneous interaction of a susceptibly heat-treated material, heat treatment, sufficient preload tensile stress, and high-temperature oxygenated water
- The problem has been mitigated by changing the heat treatment of Alloy X-750 beams and reducing the preload
- It is anticipated that the cracking of jet pump beams will not be a concern during future BWR operation, because all BWR utilities have addressed this problem by beam replacement, reheat treatment, or preload reduction

Irradiation-Assisted SCC

Irradiation-assisted SCC is an intergranular SCC phenomenon that can occur in BWR internals. Irradiation-assisted SCC does not require the presence of a sensitized microstructure or high tensile stresses.

The intergranular SCC described in the discussion on "Mechanism of Intergranular SCC in BWR Piping" in this article was the result of the simultaneous interaction of sensitized stainless steel (that is, chromium depletion at the grain boundaries), high tensile stresses (weld residual, pressure, and thermal), and oxygenated high-temperature water. The mechanism of irradiation-assisted SCC appears to involve the simultaneous interaction of highly irradiated nonsensitized material with diffusion of impurities (sulfur, silicon, and phosphorus) to the grain boundaries, low stress (fabrication, irradiation creep) and high-temperature water with short-lived oxidizing species (hydrogen peroxide, H_2O_2), gamma, and neutron flux. It is extremely important to note that irradiation-assisted SCC does not require the chromium depletion sensitization or high tensile stresses that are implicit in the failure of nonirradiated stainless steel components.

Field Experience With Irradiation-Assisted SCC. During the early history of the BWR (1960s), type 304 stainless steel was used as a fuel cladding material. Because this highly stressed material suffered extensive cracking, the type 304 stainless steel was replaced with Zircaloy-2. It is believed that this instance of cracking was the first indication that annealed type 304 stainless steel could suffer intergranular SCC in the BWR core environment. Because this type of intergranular cracking was produced in nonsensitized, highly stressed, highly irradiated components, this form of intergranular SCC is referred to as irradiation-assisted SCC. (As noted above, high tensile stresses are not necessary for irradiation-assisted SCC, but the presence of high tensile stress certainly exacerbates the phenomenon.)

Recently, core components such as type 304 stainless steel neutron source holders, control blade absorber tubes (Fig. 22), and nuclear instrument tube holders have cracked in the BWR environment. Table 1 presents a summary of significant field irradiation-assisted SCC experience. To date, the cracking has been limited to readily replaceable components. It is also important to note that PWRs have also experienced this type of corrosion phenomenon (Ref 27, 28). The results of the field irradiation-assisted SCC experience suggest the following:

- Dynamic strain or high stresses produced irradiation-assisted SCC in fuel cladding and absorber tubing
- More recent results with lower-stressed neutron source holders and instrument tubes indicate that the stress threshold for irradiation-assisted SCC may be lower than initially believed
- No field irradiation-assisted SCC has been observed at a fluence below about $\leq 5 \times 10^{20}$ NVT (neutrons per unit volume multiplied by time) (>1 MeV)
- Cracks may occur at lower stresses for higher fluences

Table 1 Summary of significant field irradiation-assisted SCC experience

Stainless steel component	Fluence (neutrons/cm^2)	Source of stress
Fuel cladding	5×10^{20} to 2×10^{21}	Fabrication; fuel cladding interaction
Neutron source holders	10^{21} to 10^{22}	Welding; beryllium swelling after initial crevice attack
Control rod absorber tubes	5×10^{20} to 3×10^{21}	B_4C swelling
In-core instrument tubes	10^{21} to 10^{22}	Fabrication

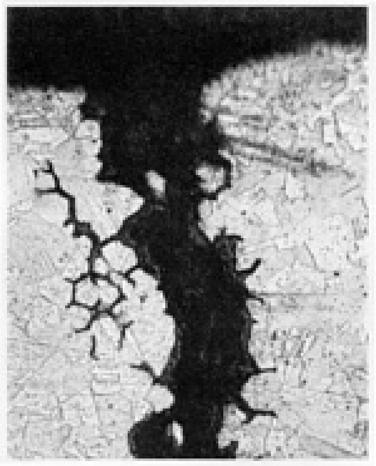

Fig. 22 Irradiation-assisted SCC of a control blade absorber tube. 500×

Mechanism of Irradiation-Assisted SCC. The mechanism of irradiation-assisted SCC appears to involve highly irradiated annealed austenitic stainless steel with diffusion of impurities (sulfur, silicon, phosphorus) to the grain boundaries, low stress (fabrication, irradiation creep), and a highly oxidizing environment associated with the gamma and neutron flux (Ref 27, 28). Partial chromium depletion is also possible. To simulate these highly oxidizing conditions in the core, tests were performed on irradiated annealed type 304 stainless steels at different levels of fluence. The irradiation-assisted SCC phenomenon was reproduced, and the results indicate that the observed field irradiation-assisted SCC fluence threshold is consistent with the laboratory tests.

Mitigation of Irradiation-Assisted SCC. Fortunately, the same environmental solution for the intergranular SCC of piping (hydrogen water chemistry) appears promising for this phenomenon. Table 2 presents the results of SCC tests on highly irradiated commercial-purity annealed type 304 stainless steel in a high-oxygen (32 mg/L) environment simulating the highly oxidizing regions in the core and in hydrogen water chemistry. The difference in SCC response is dramatic. The highly oxidizing environment produced a fracture surface with 99% intergranular SCC, while the more reducing environment characteristic of hydrogen water chemistry produced ductile failure. The reason for this significant disparity may be explained by the electrochemical potential of type 304 stainless steel, which is significantly more oxidizing in the core region ($\sim$250 mV_{SHE}) than in the recirculation piping system ($\simeq$30 mV_{SHE}). Hydrogen water chemistry obtained by lowering the electrochemical potential appears to be a promising method of mitigation for irradiation-assisted SCC if sufficient reduction of electrochemical potential can be achieved in the core.

Table 2 Hot cell SCC test results on irradiated type 304 stainless steel

Environment	Fluence	Fracture
32 ppm O_2	2×10^{21} NVT (>1 MeV)	99% Intergranular SCC
Hydrogen water chemistry	2×10^{21} NVT (>1 MeV)	Ductile

Note: NVT = neutrons per unit volume × time.

The second promising technique for mitigating irradiation-assisted SCC is the use of high-purity materials containing controlled amounts of such impurities as sulfur, phosphorus, and silicon (Ref 27). This mitigation technique is based on early laboratory testing in a highly oxidizing medium, such as boiling nitric acid (HNO_3) with Cr^{6+} ions, and on the highly successful in-reactor performance of high-purity type 348 stainless steel fuel cladding at the La Crosse BWR. In contrast, commercial-purity type 348 stainless steel materials with the nominal commercial levels of sulfur, phosphorus, and silicon installed at the La Crosse BWR suffered irradiation-assisted SCC. Other support for the implementation of high-purity materials is based on in-reactor studies (Ref 29) and on laboratory studies on nonirradiated stainless steel where the presence of these specific impurities increased the intergranular SCC susceptibility (Ref 30). Work is continuing in this area.

Conclusions. The results of in-reactor and laboratory investigations suggest the following conclusions concerning irradiation-assisted SCC in the BWR:

- The irradiation-assisted SCC of components in the BWR core was the result of the simultaneous interaction of irradiation-enhanced impurity segregation, tensile stress, and highly oxidizing environment
- Preliminary studies suggest that hydrogen water chemistry and high-purity materials are promising remedies for mitigating irradiation-assisted SCC

Case History: Corrosion Fatigue in Feedwater Nozzles

Fatigue evaluation of nuclear power plant equipment subjected to cyclic loading conditions is of primary concern to equipment designers and stress analysts. Because the number of loadings resulting in significant stresses that occur over the life of light water reactors seldom exceed several thousand, and in numerous cases do not even exceed several hundred, fatigue usage is generally classified as low cycle. However, in this particular case history on feedwater nozzle cracking, both low- and high-cycle fatigue were involved. Figure 23 shows a cross section of a feedwater nozzle that suffered from cracking of the cladding of the feedwater nozzle bed radii, a problem common to a number of BWRs.

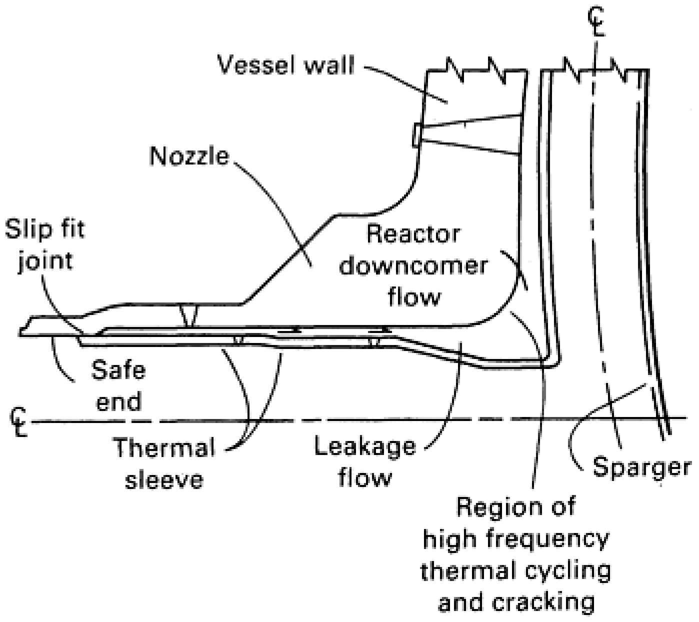

Fig. 23 Cross section of feedwater nozzle with cracking location

Field Experience. Metallurgical examination of a boat sample (a wedge-shaped specimen cut out of a component) removed from the cladding of the feedwater nozzle bend radii revealed that the primary cause of the nozzle crack was thermal-induced corrosion fatigue (Fig. 24). It was further determined that there are two corrosion fatigue mechanisms present: a high-cycle corrosion fatigue mechanism, which initiates the cracks, and a low-cycle corrosion fatigue mechanism, which causes the cracks to propagate.

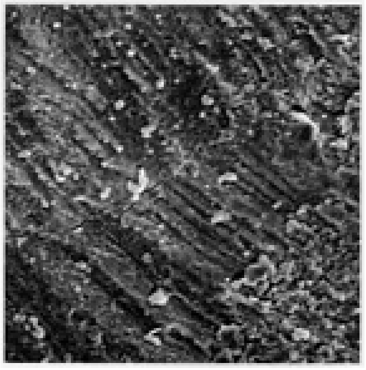

Fig. 24 Example of corrosion fatigue striations in a feedwater nozzle. 1500×

Mechanisms of Corrosion Fatigue in Feedwater Nozzles. The high-cycle mechanism was found to be primarily caused by leakage flow passing between the thermal sleeve and safe end. This leakage flow, which is at feedwater temperature, mixes in a turbulent manner with hot downcomer flow in the annulus between the nozzle and thermal sleeve. The mixing fluid impinges on the nozzle wall, causing thermal cycling of the metal surface. It has been determined by test and by field measurements at two BWRs that the metal temperature cycling, with leakage present, has a magnitude of up to 50% of the difference in temperature between the feedwater and the downcomer water. The cycling occurs with frequencies between 0.1 and 1 Hz and thus can initiate cracking rapidly with little if any environmental contribution. The exact time to crack initiation depends on several factors, including the duration of operation with low feedwater temperature.

The cracks initiated by the high-frequency cycling described above will arrest at a depth of approximately 6 mm (0.25 in.) from the metal surface. This arrest results from the fact that the high-cycle thermal input induces thermal stresses with steep gradients and shallow depths. Cracks that arrest, as described above, present no problem from an engineering standpoint, because they will not degrade safety or availability and would not have to be repaired under the rules of Section XI of the American Society of Mechanical Engineers Code.

There is another mechanism present in the feedwater nozzles that causes the cracks to continue to grow. This mechanism is the combined pressure and thermal cycles imposed by start-up/shutdown and feedwater on-off transients. These transients, although relatively few in number, produce large stress cycles in the nozzle and in time could drive the cracks to significant depths. This low-cycle fatigue crack propagation is environmentally accelerated under BWR conditions. The deepest cracks observed were up to 18% of wall and relatively short.

Fortunately, the cracking is readily detectable by dye-penetrant examination and/or ultrasonic examination from the outside of the nozzle. The deep cracks require repair and thus can result in a significant impact on plant availability and operating cost.

Leakage between the safe end and thermal sleeve also has an aggravating effect on the crack growth rate because it increases the heat transfer coefficient between the feedwater and the nozzle. The increased heat transfer coefficient increases the stresses in the nozzle during thermal transients, and because crack growth is dependent on stress to the fourth power, a significant effect results.

Mitigation of Cracking. Several solutions were derived to mitigate this problem from both a design and a corrosion/metallurgical viewpoint. The solution consisted of three parts: a revised sparger thermal sleeve design, use of unclad feedwater nozzles, and a revised system of configuration/operating procedures that mitigates the conditions tending to produce crack initiation and growth. Together these three elements constitute a solution to the problem with margin for unexpected conditions. The implementation of hydrogen water chemistry would also mitigate this problem because test results have indicated a decrease in corrosion fatigue crack propagation rate in hydrogen water chemistry (Ref 26).

A sparger thermal sleeve design has been developed that meets the following objectives:

- It can be installed and removed without cutting feedwater piping
- It protects the feedwater nozzle against the high-frequency thermal cycles that initiate nozzle cracks through the use of redundant metal O-ring seals
- It uses materials and processes that make the part immune to intergranular SCC

The resulting design is schematically shown in Fig. 25. The thermal cycling profiles for the previous and the newer-design feedwater spargers are shown in Fig. 26. The marked reduction in thermal cycling is evident.

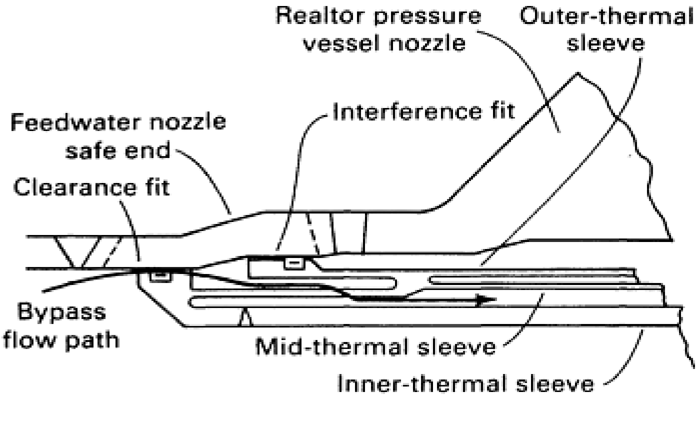

Fig. 25 Improved feedwater thermal sleeve design to eliminate corrosion fatigue

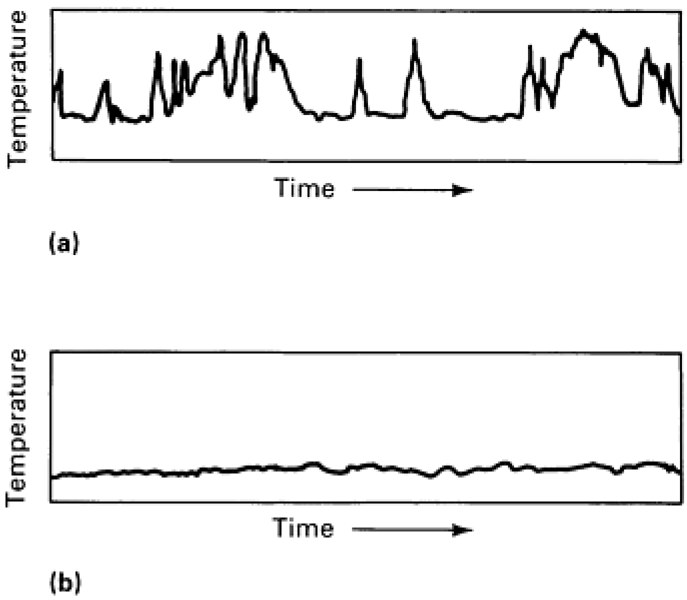

Fig. 26 Temperature variations with (a) and without (b) bypass leakage

The main conclusions concerning the corrosion fatigue cracking of BWR feedwater nozzles are:

- The corrosion fatigue of BWR feedwater nozzles was a result of the interaction of high-cycle fatigue crack initiation due to leakage flow passing between the thermal sleeve and safe end and low-cycle corrosion fatigue crack growth due to start-up/shutdown and feedwater on-off transients
- The cracking problem was mitigated by a redesign of the feedwater thermal sleeve to eliminate leakage and the removal of the nozzle cladding. Hydrogen water chemistry will also provide an additional margin against this phenomenon

Steam Generator Failure or Degradation

Stanley J. Green, Electric Power Research Institute

Steam generators in PWR power plants transfer heat from a primary coolant system (pressurized water) to a secondary coolant system. Primary coolant water is heated in the core and passes through the steam generator, where it transfers heat to the secondary coolant water to make steam. The steam then drives a turbine that turns an electric generator. Steam is condensed and returns to the steam generator as feedwater.

Two types of PWR steam generators are in use: recirculating steam generators (RSGs) and once-through steam generators (OTSGs). Most of the units are vertical, and this Section will be limited to vertical units. Some of these steam generators have operated with a minimum of problems while other steam generator designs have experienced a variety of corrosion-induced and mechanically induced problems. The discussion will focus more on those designs that have experienced problems and where effort has been expended to correct them. The corrosion problems include denting, wastage, intergranular attack, SCC ad pitting on the outside surfaces of the tubes, and SCC from the inner surfaces of the tube. The mechanical concerns have included water hammer, thermal stratification in feedwater pipes, fretting and water of the tubes caused by excessive tube vibration, and erosion-corrosion. These problems have caused unscheduled outages and expensive repairs. Where most extensively affected, some steam generators have been replaced after 8 to 12 years of operation, which is far short of the expected plant operating period of 40 years.

The scope of this Section will be limited to the corrosion-related issues. A brief summary of other degradation phenomena is given at the end of this Section, and previous summaries of these issues are available in Ref 31, 32, 33, and 34. Also, specific preventive and corrective actions are discussed in Ref 35.

Steam Generator Design

A typical vertical recirculating steam generator (feedring-type) is shown in Fig. 27. (Other designs employ preheat features, where the cold feed is introduced into the lower part of the bundle.) Water is fed into the downcomer, where it is mixed with two to five volumes of recirculating water from the moisture separators. The downcomer water flows to the bottom of the steam generator, across the tubesheet, and then upward through the tube bundle where steam is generated.

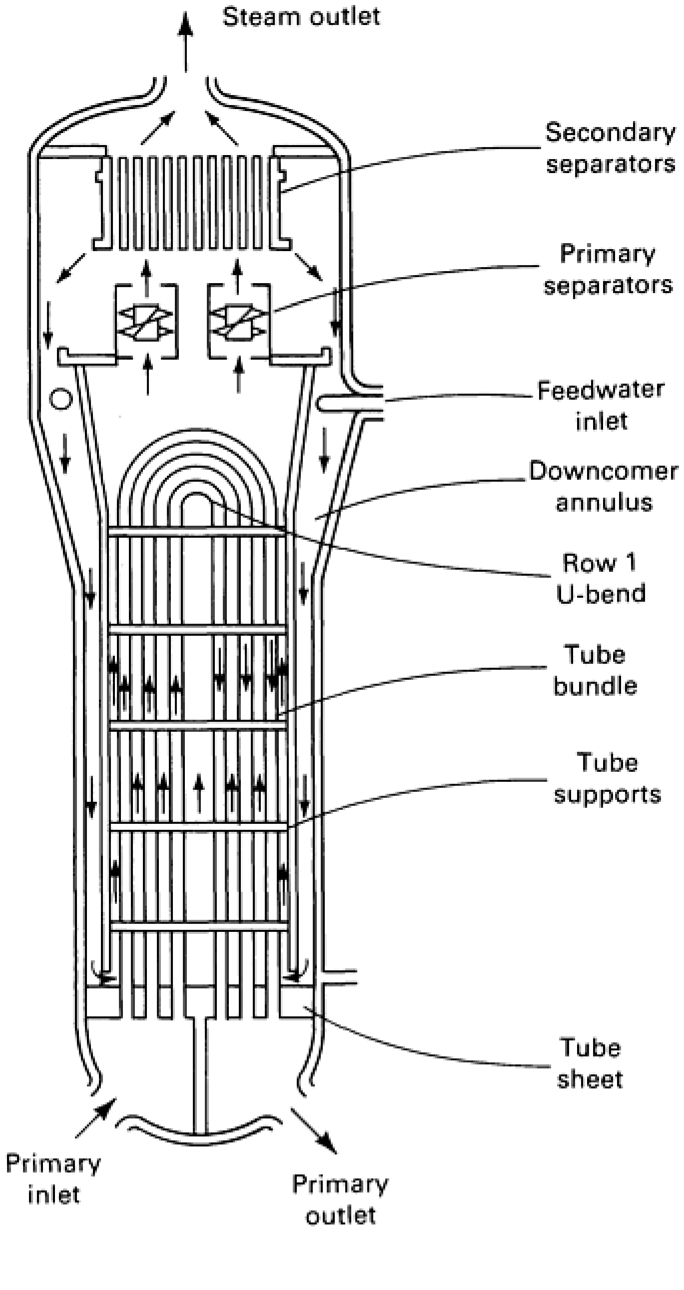

Fig. 27 Recirculating steam generator

The thermodynamic quality of the water-steam mixture at the top of the bundle is about 17 to 33% when it enters the steam separators, which corresponds to a circulation ratio in the range of 6:1 to 3:1. The pressure on the secondary side is about 4135 to 7240 kPa (600 to 1050 psia). The primary coolant flows through U-tubes at a pressure of about 9655 to 15515 kPa (1400 to 2250 psia). It enters the steam generator at about 310 to 325 °C (590 to 620 °F) and leaves at about

255 to 290 °C (495 to 550 °F). At the primary inlet, the temperature difference across the tube wall is about 35 to 50 °C (65 to 90 °F), corresponding to a heat flux of 315,460 to 441,640 W/m^2 (100,000 to 140,000 Btu/h·ft^2). At the primary outlet or cold side, the temperature difference between the primary and secondary sides is about 10 to 15 °C (20 to 25 °F), corresponding to a heat flux of about 94,640 W/m^2 (30,000 Btu/h·ft^2). The Westinghouse, Combustion Engineering, Kraftwerk Union (KWU), Framatome, and Mitsubishi designs have comparable operating parameters, while the Babcock and Wilcox (B&W)/Atomic Energy of Canada Limited (AECL) design operates at lower temperatures and pressures.

Knowledge of the materials, water chemistry, and tube support arrangements used in RSGs is required to understand the problems that have occurred. The tubes have been made primarily of Alloy 600, a nickel, chromium, iron alloy. In KWU and later B&W/AECL designs, the tubes have been made of Alloy 800, an iron-base superalloy. The mill-annealing conditions vary among the manufacturers, while B&W/AECL have used stress-relieved (605 °C, or 1125 °F, for 8 h) tubing for their Alloy 600 tubed steam generators. Some of the more recent designs using Alloy 600 tubing have thermally treated the tubing (705 °C, or 1300 °F, for 15 h) to improve resistance to SCC.

The tube support structures for most of the early units were made of carbon steel, while later units have switched to type 405, 409, and 410 stainless steels for additional corrosion resistance. Type 347 stainless steel has always been used for KWU steam generator tube support structures.

Tube support structures of early units used tube support plates with drilled holes (Fig. 28a and b), plates with broached holes (Fig. 28c), and lattice bars or egg crates (Fig. 28e). When the drilled-hole support plates were found to promote accumulation of corrodents, they were changed to a quatrefoil design hole with lands (Fig. 28d) or to a lattice support structure (Fig. 28e).

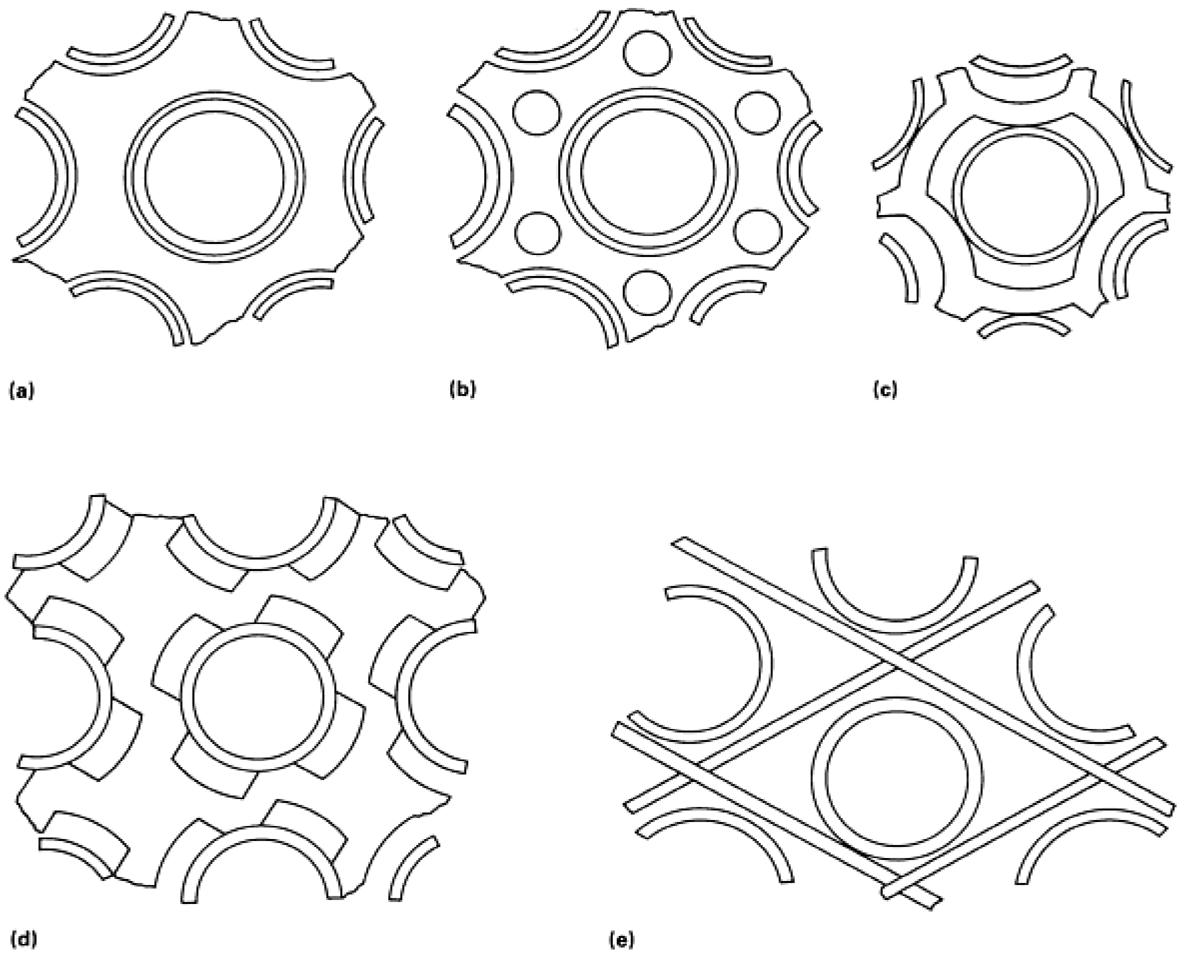

Fig. 28 Tube support device designs. (a) Drilled, without flow holes. (b) Drilled, with flow holes. (c) Broach-trefoil. (d) Broach-quatrefoil. (e) Egg crate

In some of the early designs, the tubes were only partly expanded into the lower end tubesheet, leaving a crevice between the outside diameter of the tube and the inside diameter of the hole in the tubesheet, that is, in the upper part of the tubesheet; in other designs, the tubes were expanded into the tubesheet along its full length. The tubes have been expanded into the tubesheet by mechanical, hydraulic, and explosive expansion methods. Generally, the tubes have been expanded for the full length of the tubesheet in the later designs. Most of the early RSGs employed coordinated sodium phosphate water treatment for the secondary side, which is the conventional water treatment method for fossil-fired boilers with similar steam pressures.

An OTSG is shown in Fig. 29. Water enters a feed annulus above the ninth tube support plate level. There it is mixed with steam aspirated from the tube bundle area and preheated to saturation. The saturated water flows down the annulus, across the lower tubesheet, and upward into the tube bundle, where it becomes steam. It reaches 100% quality (on the average) in the ninth and tenth support plate region, and achieves about 20 to 35 °C (40 to 60 °F) of superheat at about 6370 kPa (924 psia) at the top of the unit. The superheated steam flows radially outward and then down the annulus to the steam outlet connection. The primary coolant flow is from top to bottom. It enters at about 315 to 325 °C (600 to 620 °F) and leaves at about 290 to 295 °C (555 to 560 °F). The temperature difference between the primary and secondary sides at the bottom of the steam generator is similar to that an the cold leg of a recirculating steam generator.

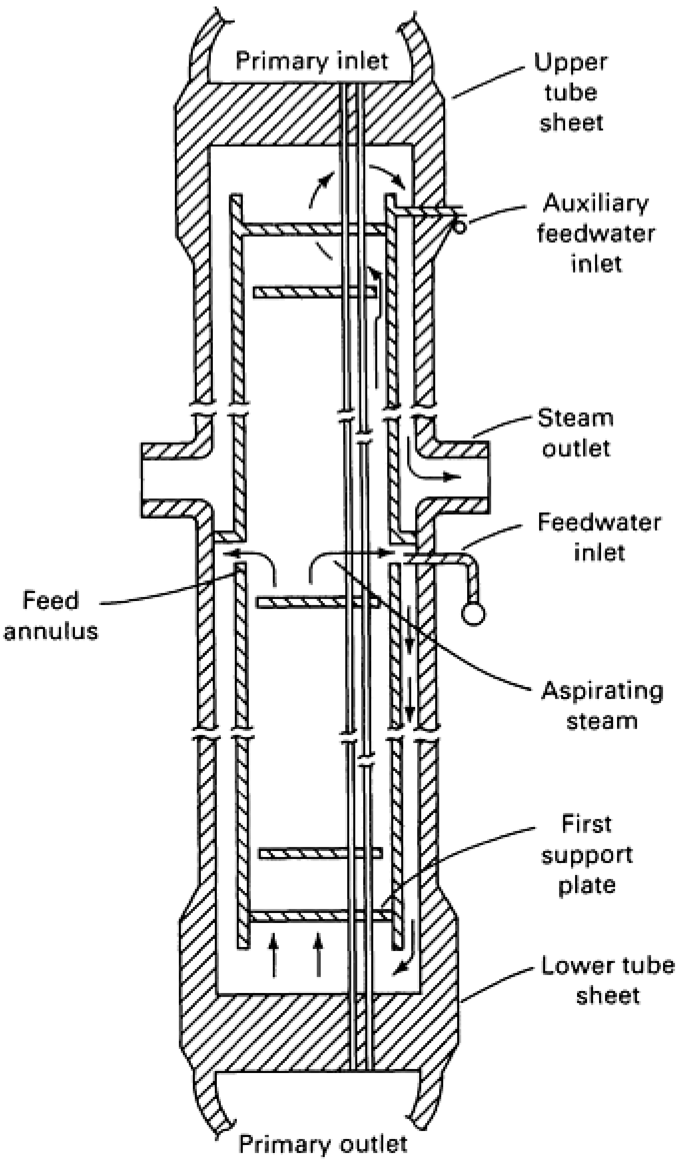

Fig. 29 Once-through steam generator

Once-through steam generator materials are similar to those used in RSGs. Tubes are Alloy 600 in a mill-annealed plus a stress-relieved condition, which sensitizes the tubing (causes chromium-depleted grain boundaries). Tube support plates are carbon steel. However, the holes are not drilled round holes as in the early RSGs, but trefoil holes with three lands supporting the tubes (Fig. 28c). Tubesheets are low-alloy steel. Once-through steam generators have always used all-volatile water treatment water chemistry.

Prevention of Steam Generator Corrosion Problems

As noted above, these steam generators have experienced a variety of corrosion-induced and mechanically induced problems. The types of damage and the number of units affected are presented in Table 3, which indicates that essentially no units have operated trouble-free for more than 5 years. The industry has made a very substantial effort to prevent and minimize these steam generator problems. This includes a major program by the Steam Generator Owners Group, managed by the Electric Power Research Institute (EPRI), and substantial programs carried out by steam generator suppliers and utilities.

Table 3 Units affected by steam generator problems

Total units: 121 (65 units having >5 years of operation and 56 units having <5 years of operation)

Problem	Units affected (as of 1984)
Denting	
Denting at support plates	42
Denting at tubesheet	18
Tubing corrosion	
Wastage	31
Pitting	11
Outside-diameter initiated SCC	31
Inside-diameter initiated SCC	33
Outside-diameter initiated intergranular attack	28
Inside-diameter initiated intergranular attack	2
Mechanical damage	
Fretting	30
High-cycle fatigue	5
Erosion	2
Water hammer	10
Moisture carryover	6
No problems	37
No problems (for 65 units >5 years of operation)	1

The approaches used to correct or prevent corrosion for both new and operating units are based on addressing the causes. Thee corrective measures can be divided into the following three categories:

- Modifying the environment
- Modifying the materials
- Modifying the stresses

The corrosion problems and the types of corrective action developed for each issue are listed in Table 4. Each of the problems and corrective actions is discussed below.

Table 4 Corrective actions for steam generator corrosion problems

(a) By sleeving

Tube Wastage

Causes. Tube wastage, or thinning, was once of the first corrosion problems that occurred in recirculating steam generators operating with sodium phosphate as a secondary water treatment. Phosphate wastage was first observed in commercial PWR plants when phosphate treatment was changed to a low sodium-to-phosphate molar ratio control, in which the molar ratio of Na/PO_4 was maintained at about 2.0. This change was in response to a series of caustic SCC events attributed to operation with uncontrolled high Na/PO_4 ratios (above 2.8), from which free caustic could result. The incidence of caustic SCC dropped markedly, but the general corrosion, now known as phosphate wastage, began to be observed within approximately 1 year after the change. Some phosphate wastage observations are discussed in Ref 36; a detailed report of such events at two specific nuclear power installations is provided in Ref 37.

The phosphate wastage in PWR steam generators of the Westinghouse design occurred for the most part at the interfaces between hot leg tubes and the tops of sludge piles that accumulated on top of the tubesheet. Where the sludge pile was deep, the zone of wastage extended about 25 mm (1 in.) into the pile; in most cases, it did not penetrate appreciably into the tube/tubesheet crevice. Wastage was first noted in steam generators of the Combustion Engineering design. It was most extensive in the vicinity of antivibration straps, which were relatively wide and oriented in such a way as to define a region of steam blanketing. Corrosion was concentrated at the boundaries of this region, where a liquid/vapor interface presumably fluctuated over a short length of tubing.

As recognition grew that this new phenomenon was widespread and of a generic nature, major laboratory investigations were launched by the two United States vendors of RSGs. It was demonstrated in pot boilers that the location of attack was related to the concentration of aggressive species at steam/water interfaces. Emphasis was placed on investigating the chemistry of sodium phosphate solutions in high-temperature water, in addition to corrosion studies and model boiler tests. The laboratory work showed that the corrosivity of concentrated sodium phosphate solutions was related to both concentration and the Na/PO_4 molar ratio.

The laboratory results led to recommendations for Na/PO_4 molar ratio control in the relatively narrow band of 2.3 to 2.6. The lower limit was related to the rapidly increasing rate of wastage at lower ratios, and the higher limit was selected to avoid free caustic and concomitant caustic SCC. A number of plant operators were successful in controlling their steam generator chemistries within this restricted range of compositions, but eddy-current inspections indicated that the rate of attack was only slowed, not stopped. It appeared that attack could not be stopped unless the operators consistently operated within a narrow control band at the high end of the allowed range. Furthermore, a constantly increasing sludge burden, augmented by precipitated phosphate compounds, made such control increasingly difficult.

Corrective Actions. The above difficulties led the vendors of the affected plants to recommend that the operators adopt an all-volatile water treatment based on the use of ammonia and hydrazine. This recommendation was almost universally followed in the United States except for two plants. Steam generators manufactured by KWU continued to use phosphate water treatment. These steam generators, tubed with Alloy 800 material, have experienced a slower rate of wastage corrosion. It is not clear whether the slower rate is a function of the alloy, the low concentration of phosphate used, the relatively low Na/PO_4 ratio, or the relatively good impurity control history at several of these units. It is probable that all of these factors are involved. However, KWU has switched to all-volatile water treatment for their new units.

Thus, the cause for wastage was determined to be an aggressive environment, and the corrective action involved a change in the environment for operating units from a phosphate chemistry to all-volatile water treatment. However, as discussed below, this change led to other corrosion problems, namely denting.

Denting

Causes. Denting was discovered in 1975 when eddy-current probes were prevented from passing through tube/tube support plate intersections by tube diameter restrictions. By 1977, denting had become a widespread problem and had resulted in the formation of the Steam Generator Owners Group as a concerted effort to address the problem (Ref 38).

Denting is a term used to describe the localized tube diameter reduction that occurs when the hole of a carbon steel tube support plate corrodes to the point at which the corrosion products deform the steam generator tubing (Fig. 30). The cause of denting is best explained by Potter-Mann-type linear accelerated corrosion, in which a nonprotective oxide layer is formed as the corrosion progresses. These corrosion products, which have a bulk volume considerably larger than the volume of metal corroded, fill the original tube/tube support plate crevice and deform the tube and the tube support plate simultaneously.

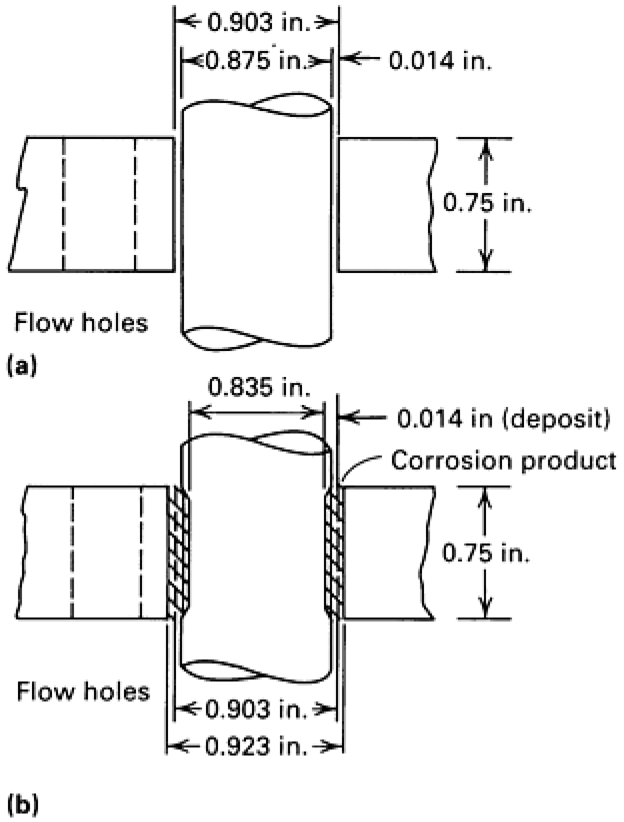

Fig. 30 Denting at tube/tube support plate intersection. (a) Normal tube/tube support plate intersection. (b) Dented intersection. Denting results in a reduction in tube diameter and thinning and cracking of support plate ligaments. 1 in. = 25.4 mm

Sample intersections of tubes and support plates removed from dented steam generators have shown local chloride concentrations of over 4000 ppm in the dented region. The high local chloride concentration is caused by local thermal-hydraulic conditions within the crevice between the tube and the tube support plate. The source of chloride is generally condenser leakage, particularly at plants cooled by seawater.

Tube deformation has been reported in some steam generators with carbon steel egg crate supports, implying that concentration of chemicals and carbon steel corrosion may also be occurring with this design. Similarly, distorted eddy-current signals (dings) have been observed at the ninth and tenth support plates of OTSGs that use a trefoil design support plate. This is a most likely region for corrosion because it is the region where dryout and most of the deposition of any chemicals present in the feedwater occur. It is the region corresponding to approximately 95 to 100% quality on the average. However, it is possible that these dings may be caused by tube vibration and impact on the tube support plates.

Denting has also been observed at the top of the tubesheet crevice in several RSGs, but it has progressed at a slower rate. Whether this is due to different geometry the presence of sludge, or different materials (different grades of low-alloy or carbon steel are used in the tubesheet and the support plate) is not known at this time. Denting has not been reported in the KWU steam generators where the support structures are fabricated of type 347 stainless steel or in the B&W/AECL units that have used lattice bars and broached hole plates with both carbon steel and type 410 stainless steel.

Several major consequences can result from the uncontrolled progression of denting: tube cracking and leaking at U-bends, tube cracking and leaking of a highly concentrated acidic and oxidizing environment at the constricted crevices, tube support ligament failure, and gross deformation of tube support plates. Laboratory tests proved that denting is caused by the presence of a high concentration of chlorides in the support plate crevice and the presence of an oxidizing environment outside the crevice (Ref 39, 40, 41). This aggressive environment is brought about by the introduction of acid-forming impurities via the feed into the steam generator and subsequent concentration at the tube/tube support crevice. Concentration factors of greater than 20,000 times within the crevice have been observed in laboratory tests.

Corrective Actions. Based on this knowledge of the causes of denting, the corrective actions for operating plants have been to modify the environment and make it less aggressive. This has been accomplished by establishing secondary water chemistry guidelines based on laboratory and field data that recommend reduced levels of impurities in the steam generator (Ref 42) and by recommending methods for achieving these greatly lowered impurity levels. These methods include reducing condenser in-leakage (Ref 43, 44), reducing air in-leakage (Ref 45), producing purer makeup water, and using condensate polishers to purify the water. Another method employed to modify the environment is the addition of boric acid, which inhibits the acid chloride attack (Ref 46, 47). The application of these methods has led to greatly reduced denting rates. The PWR Secondary Water Chemistry Guidelines were prepared by a committee of industry experts under the sponsorship of the Steam Generator Owners Group (Ref 42). The guidelines combine the results of laboratory corrosion studies and evaluation of good PWR operating practice. The PWR Secondary Water Chemistry Guidelines consist of chapters covering:

- Management Responsibilities
- Recirculating Steam Generators
- Once-Through Steam Generators
- Analytical Methods
- Data Management and Surveillance

These guidelines have been endorsed by the Steam Generator Owners Group and have been generally adopted by the utilities. They have also been endorsed by the NRC and the Institute for Nuclear Power Operations.

For new plants, one vendor minimized the potential of formation of the aggressive environment by switching from drilled to broached support plates having flat lands. With this design, the concentration of chemicals within the tube/tube support crevice is greatly reduced. For new plants, the corrosion was reduced by the use of more corrosion-resistant materials. Types 405 and 409 stainless steels, which are more corrosion resistant, have replaced the use of carbon steel for United States manufacturers of RSGs (Fig. 31). (Type 410 stainless steel replaced carbon steel in the B&W/AECL units.) The differences in corrosion between carbon steel and type 405 stainless steel is less at higher salt concentrations (Ref 48, 49).

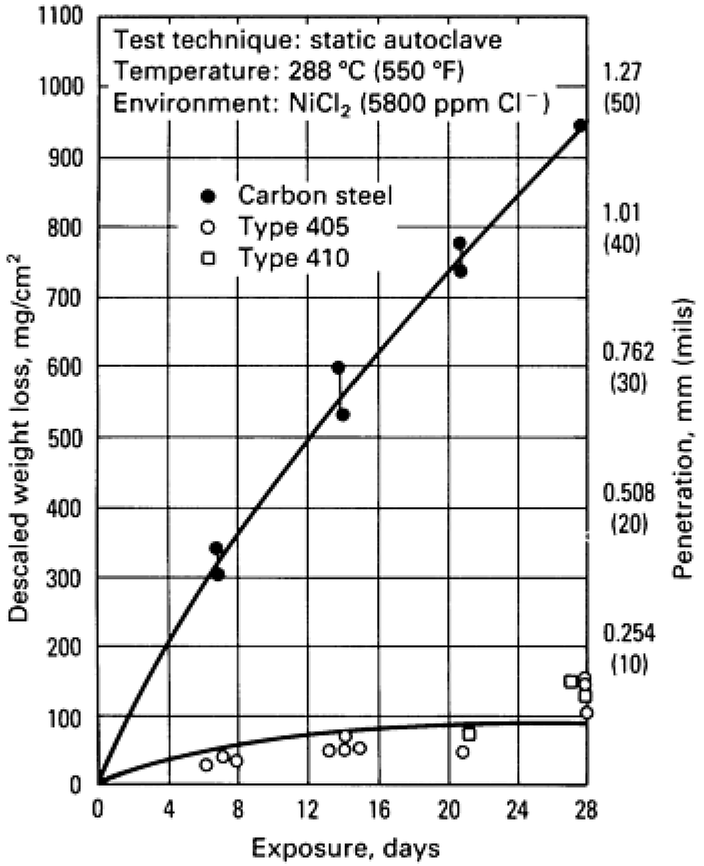

Fig. 31 Corrosion of carbon steel and 12% Cr stainless steels in nickel chloride ($NiCl_2$) solutions

In summary, denting, brought about by the corrosion of carbon steel, is caused primarily by concentration in the tube/tube support crevices of impurities in the secondary coolant. The corrective actions include modifying the environment by reducing, inhibiting, or neutralizing the impurities in the steam generator; by using a tube support design that reduces the concentrating mechanism; and by using more corrosion-resistant materials.

Inside Surface (Primary-Side) SCC

Causes. Primary-side SCC of Alloy 600 steam generator tubing evolved from a laboratory prediction during the 1950s and 1960s to a major degradation mechanism during the 1970s and 1980s in operating steam generators. As early as 1957, cracking of high-nickel alloys in high-purity water at 350 °C (660 °F) was reported (Ref 50). During the following years, numerous laboratory tests were performed in different environments in an attempt to duplicate and explain these observations. This work was summarized in 1975 (Ref 51), in 1981 (Ref 52), and in 1983 (Ref 53). In 1971, the laboratory cracking phenomenon in high-purity water became an in-service degradation mechanism, with the first confirmed primary-side cracking of hot leg roll transition regions at the tubesheet and suspected primary cracking in U-bends (Ref 54). Leakage at U-bends was experienced in Obrigheim steam generators, manufactured by KWU, after only 2 years of operation.

In recent years, cracking of Alloy 600 tubes from the primary side has become a problem of increasing importance. As of early 1985, this type of cracking has been experienced by a number of plants (Table 5) of some steam generator designs.

Table 5 Plants affected by primary-side cracking

Type of primary-side attack[a]	Number of plants affected (as of 1985)
U-bend tangent cracks	16
Roll transition cracks	16
Roll expansion cracks	10
Explosive expansion transition cracks	1
Total number of plants affected	**29**

(a) Excluding those caused by denting

Cracking in the U-bend has occurred mainly on the inner row at the apex and at the tangent points (Fig. 32). Cracks have also occurred in the tubesheet at transition expansion and roll expansion regions (Fig. 33).

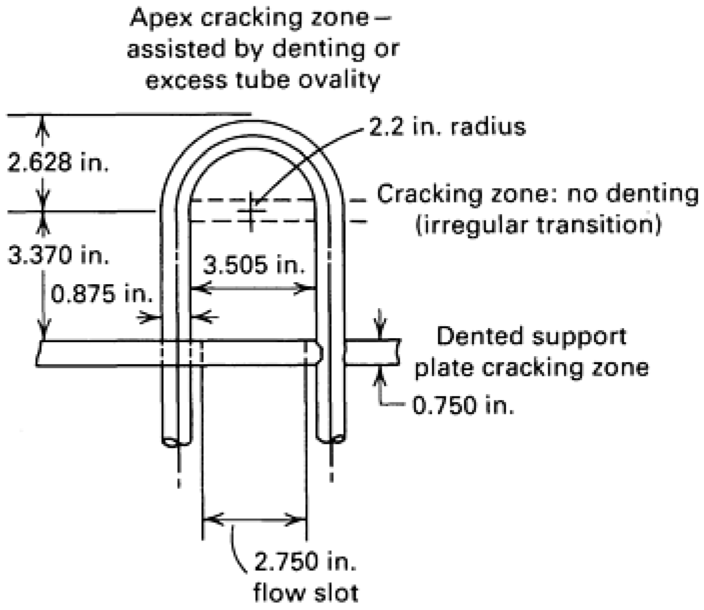

Fig. 32 Location of cracking in steam generator inner row U-bends. 1 in. = 25.4 mm

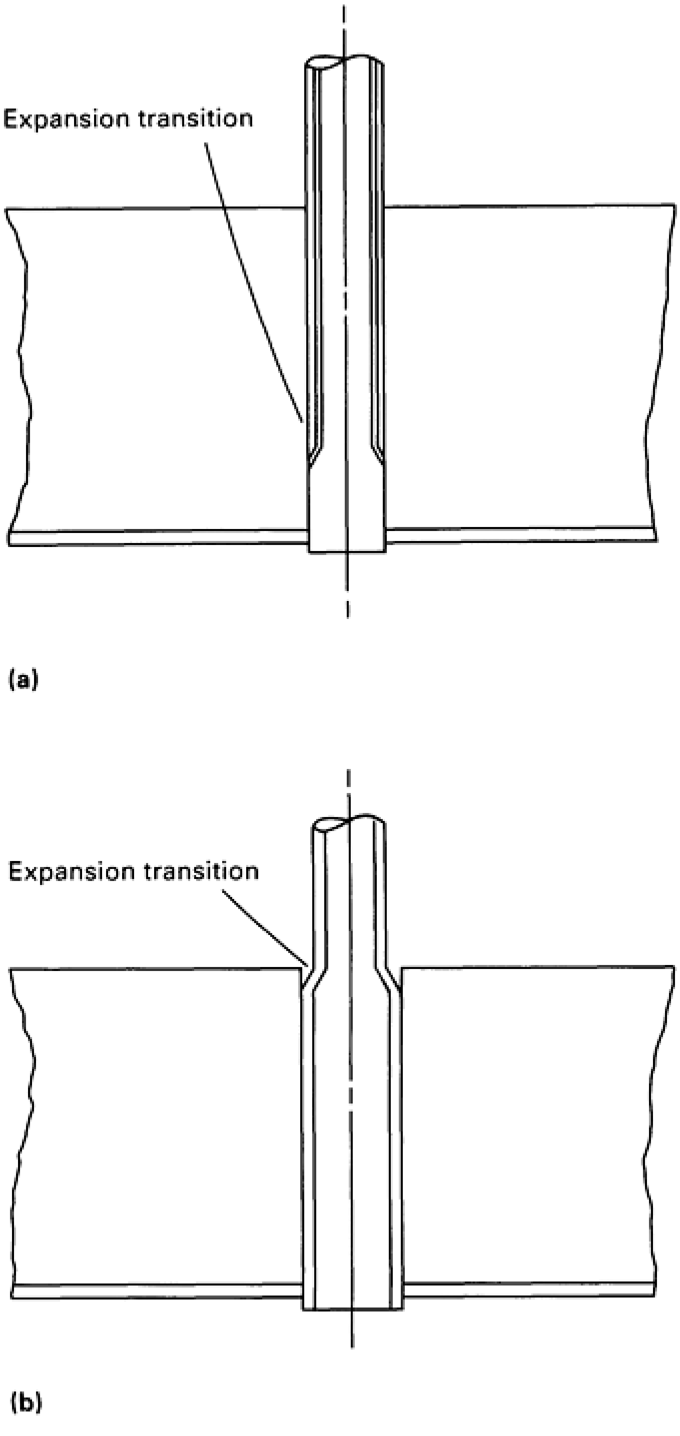

Fig. 33 Details of tubesheet expansion transition region. (a) Partial tubesheet expansion transition region. (b) Full tubesheet explosive, hydraulic, or roller expansion transition region

Primary-side cracking is a form of intergranular SCC. This type of intergranular SCC, in common with other forms of SCC, occurs when certain environmental, tensile stress, and material susceptibility factors are sufficiently severe.

Environmental factors influence the initiation of primary-side SCC; of these, temperature must be considered a major factor. The first roll transitions experiencing SCC were located on the hot leg side. Because the hot leg at 320 °C (610 °F) is 30 to 40 °C (55 to 70 °F) hotter than the cold leg at 280 °C (535 °F), it would appear that temperature has a significant influence on SCC initiation, indicating a thermally activated process. The reaction rate can be characterized by an Arrhenius factor, exp ($-Q/kT$), where Q is an apparent activation energy, k is the Boltzmann constant, and T is absolute temperature. Thus, the influence of temperature can be graphically represented by an Arrhenius plot of reciprocal

temperature versus the logarithm of crack growth rate (Ref 55) or time to failure (Ref 56). At a typical temperature difference of 30 °C (55 °F) between hot and cold legs, this energy of activation could account for a factor of four to five increase in the time to the onset of cracking.

Other environmental factors that might influence crack initiation are hydrogen gas and chemical contaminants. Various investigations have shown that dissolved hydrogen gas can make an environment more aggressive (Ref 55, 57, 58). It has also been determined that the addition of lithium hydroxide and boric acid along with hydrogen (simulating PWR primary water) appears to produce results intermediate between pure water (least aggressive) and pure water with hydrogen added (most aggressive) (Ref 55). Primary water is less aggressive than pure water at the same hydrogen concentration.

Tensile stresses also have a major impact on the initiation of SCC. The main source of stress is residual stress from tube manufacture and installation. Pressure and thermal stresses also play significant secondary roles. To date, only the most highly strained regions of steam generator tubing (that is, row-one U-bends, roll transition regions, expanded regions, and dented areas) have exhibited SCC. This has also been demonstrated by the results of numerous laboratory tests, which show that plastically deformed samples, that is, split tube U-bends, accelerate crack initiation (Ref 50, 55, 57, 58, 59, 60, 61). Stresses in excess of yield can lead to rapid cracking in susceptible material. A threshold stress, below which cracking will not occur, of roughly 0.8 yield for high-temperature water (Ref 55) and 0.5 yield for concentrated sodium hydroxide (Ref 61) has been determined.

Material susceptibility, in combination with the factors mentioned above, can cause SCC. However, it is important to emphasize that there is not a single product called "mill-annealed" Alloy 600 tubing. Each tubing manufacturer employs a different process to produce "mill-annealed" tubing, and the resistance to SCC varies greatly with the process. Some of the mill-annealed tubing has not experienced any SCC over extended periods of operation, which SCC has occurred in other tubing after 1 to 2 years of service.

This microstructural aspect of cracking involves mostly the final mill-annealing temperature and whether precipitation of grain-boundary carbides occurs during the annealing treatment. The most susceptible microstructures are those produced by low mill-annealing temperatures (Ref 57, 62) that develop fine grain size (ASTM 9 to 11) and a copious quantity of intragranular carbide. The grain boundaries of these materials usually contain little, if any, carbide phase (Ref 57, 58, 63).

The beneficial influence of grain-boundary chromium carbides on primary-side SCC resistance has received extensive evaluation over the past several years. As far back as 1973, results were published indicating that Alloy 600, given a heat treatment to precipitate grain-boundary chromium carbide, developed improved SCC resistance in high-purity water (Ref 59). Recent work has demonstrated that grain-boundary carbides improve primary-side SCC resistance with or without grain-boundary chromium depletion (Ref 57, 58, 60, 61). Annealing temperatures in the range of 980 to 1010 °C (1800 to 1850 °F) will avoid undue grain growth and provide enough dissolved carbon so that carbide precipitation will occur during cooling and subsequent thermal treatment for 15 h at 705 °C (1300 °F). The 15-h treatment provides enough time for grain-boundary chromium content to recover (Ref 58).

Corrective Actions. Preventive measures against SCC are discussed in Ref 64 and are summarized below.

Reduction of temperature in the inner row U-bends is one possible corrective action. By orificing the inlet, the flow to these tubes is reduced, which would cause the primary coolant temperature to reach the cold-side temperature at the apex and thus reduce the time to crack by factors of about two to three.

Stress Relief. For operating plants and for plants already built but not operating, reduction of tensile stresses by stress-relief heat treatment and peening (discussed below) of the inside-diameter surface are the most practical approaches. Stress relief includes the use of resistance heaters, induction heaters, and global heat treatment.

Resistance heaters can provide *in situ* stress relief of U-bends according to laboratory tests; during the stress-relieving process, the heater is pulled up to and around the bend (Ref 65). It is believed that temperatures in a fairly broad range, even for a short time, would significantly reduce stress and improve resistance to attack.

Induction heaters can be used to reduce stresses sufficiently in roll transitions to increase resistance significantly to primary-side attack (Ref 65, 66). This type of stress relief would have the advantage of decreasing both residual stresses at inner and outer surfaces in the roll transition area without causing significant sensitization. Induction heating equipment has been developed for use in brazing sleeves inside tubes and is thus available for *in situ* treatment. One question that still needs to be resolved is the extent of high-temperature corrosion that would occur from any residual salts that would

be present in the gap created between the tube outside diameter and the tubesheet in the area that reaches high temperature. According to preliminary evaluation, the gap is acceptable because the crevice depth is relatively shallow (for example, 6 mm, or $\frac{1}{4}$ in.) and comparable to tube support plate crevices already present in the generator. Another question that needs to be resolved is whether unacceptable tube axial stresses could be developed by the stress relief.

Global heat treatment as a means of stress relief involves heating the entire tubesheet area to a temperature of about 610 °C (1130 °F) in order to relieve residual stresses and to obtain microstructural improvement (carbide precipitation at the grain boundaries). It would be performed by using heaters placed under the tubesheet and along the outside of the shell up to about one shell diameter above the tubesheet. Separately controlled heaters would be located along the divider plate and around the channel head in order to ensure that large thermal expansion stresses do not develop at divider plate junctions. This procedure would require only a few weeks of critical path time and would minimize the amount of high-radiation exposure work required in the channel head.

Before application, plant operators should resolve specific questions, such as the effect of residual salts, the factor of improvement expected from the stress relief, and whether the carbide precipitation obtained during the stress relief could cause Alloy 600 to become susceptible to attack by sulfur species such as polythionic acid. This would require increased care in water chemistry control. In the evaluation of various stress-relieving methods, plant operators need to assess the benefits and risk factors connected with the different corrective measures.

Shot peening to produce residual surface compressive stresses is a well-known approach for providing resistance to stress corrosion. Shot peening has been investigated for use inside tubes in the tubesheet area of steam generators (Ref 67) and has been performed in a number of plants. Shot are blow up the tube so that the shot impinge on a conical deflector located in the area to be peened. It is possible that the same approach could be used for U-bends. Before applying this method to the U-bend and/or tubesheet region it is necessary to ensure that a compromise can be reached between the induced inside-diameter compressive stresses and the resultant outside-diameter tensile stresses. Thus, the total tube SCC resistance, inside and outside diameter, would be optimized.

Rotopeening has been performed for both radioactive and nonradioactive plants to reduce the stresses in the expansion transition and expanded areas. It is performed by using beads bonded to fabric flappers that are rotated in a flapper wheel arrangement such that the beads impact the tube inside-diameter surface.

The compressive stresses developed on the tube inside diameter by the peening must be balanced by tensile stresses in the remaining wall thickness. Excessive inside-diameter peening could lead to significant tensile outside-diameter surface stresses. These stresses, combined with applied pressure and thermal stresses, might then aggravate attack at the outer surface. This possibility needs to be evaluated in relation to water chemistry and possible sludge pile accumulation.

If cracks are already present at the time peening is performed, the effects of the stresses induced by the peening on crack growth need to be assessed. It is suspected that peening will serve to prevent initiation of new cracks, but will not prevent growth of existing cracks through the wall thickness. If this is correct, then peening will be most useful in cases in which most tubes have either no cracks or only very small ones.

Sleeving is another repair method for modifying the tubing material in operating plants. Sleeves up 1120 mm (44 in.) long have been installed in the region between the lower face of the tubesheet and the first support plate as a corrective measure against pitting and intergranular attack at the outer surface. In some cases, even longer sleeves have been installed. The sleeves bridge the damaged area and are attached to sound material beyond either end of the damage. The ends of the sleeves are expanded hydraulically or explosively and are in most cases sealed by rolling, welding, or brazing (examples of sleeves are shown in Fig. 34). A discussion of tube sleeving development for OSTGs is presented in Ref 68.

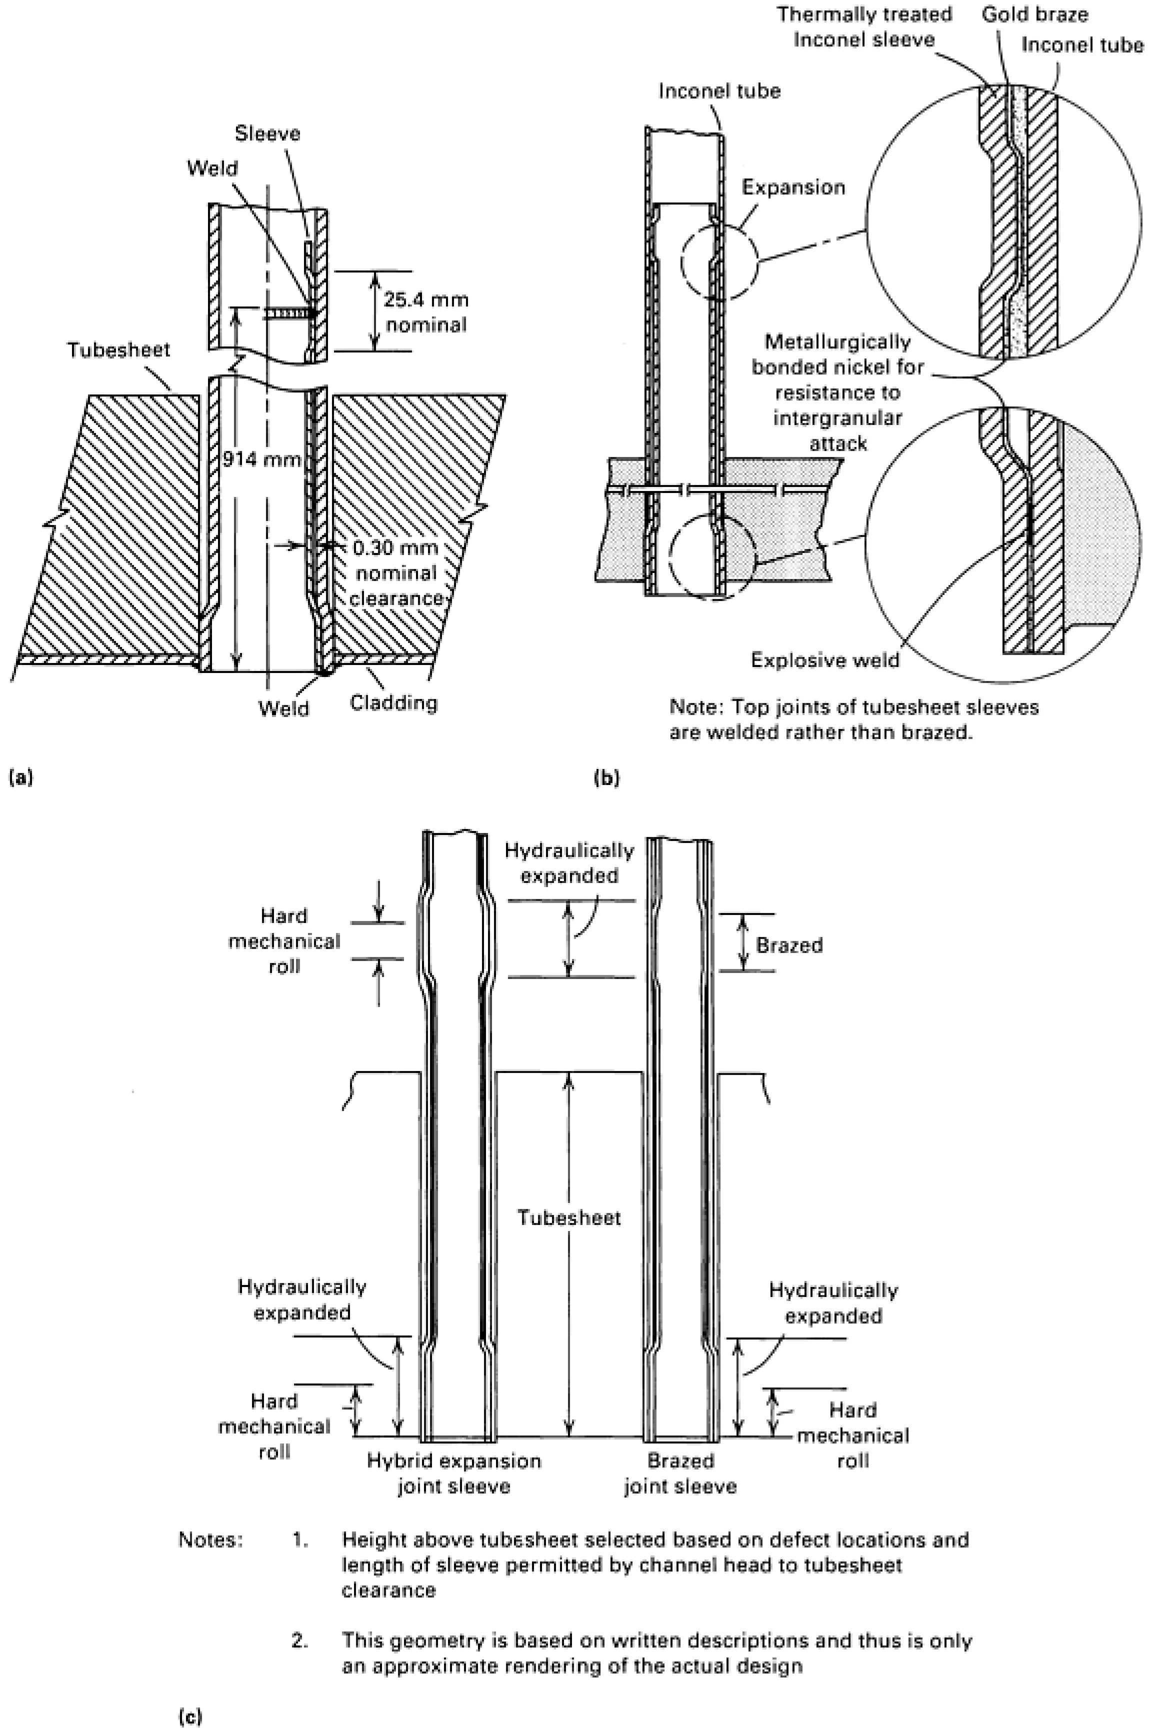

Fig. 34 Example of sleeve designs for protecting tubing material. (a) Combustion Engineering welded sleeve. (b) B&W regular length sleeve. (c) Westinghouse-type sleeve

For more recent plants, the corrective action has been to use tubing made of thermally treated Alloy 600. Extensive tests have shown this material to be greatly superior to mill-annealed Alloy 600 (Ref 57, 58, 61). The thermal treatment involves a final mill-annealing temperature of 980 to 1010 °C (1800 to 1850 °F), followed by a 705-°C (1300-°F) treatment for 15 h to produce a semicontinuous grain-boundary precipitation (Ref 58). More recent steam generators are being fabricated by using thermally treated Alloy 690. It has been reported that this alloy is superior to thermally treated Alloy 600 from the standpoint of resistance to SCC.

Intergranular Attack and SCC at the Outside Surface

Causes. Intergranular corrosion in one or another of its various forms has been experienced in many steam generators operating with seawater- or freshwater-cooled locations. The rate of propagation has been shown to vary widely, depending on the form of the attack. Progression rates in some cases have been sufficiently rapid to require mid-cycle inspections and unscheduled outages to plug or repair leaking tubes and to cause significant economic loss to the PWR operator. Fortunately, most of the corrosion has been confined to crevice locations so that leaks have been small and without risk of a large rupture. Intergranular corrosion has been found to take various forms, such as intergranular SCC, intergranular attack, and intergranular penetration.

Intergranular SCC in Alloy 600 steam generator tubing is illustrated in Fig. 35. In the case of intergranular SCC, the corrosion morphology consists of single or multiple major cracks with minor-to-moderate amounts of branching. Cracks propagate intergranularly in essentially all cases in Alloy 600 tubing. Experience suggests that intergranular SCC requires stresses greater than 0.5 yield in order to propagate rapidly. At lower levels, propagation rates may approach 0, or the corrosion may take another intergranular form.

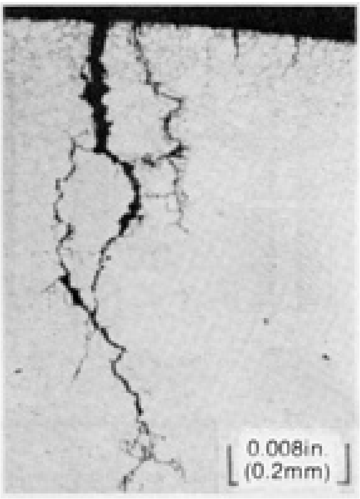

Fig. 35 Intergranular SCC in Alloy 600 C-rings. Source: Ref 69

Intergranular attack, a second form of intergranular corrosion, has been described as general intergranular attack or volumetric intergranular attack (Fig. 36). Its morphology is characterized by a uniform or relatively uniform attack of all grain boundaries over the surface of the tubing. In the purest case, stress does not contribute to the morphology of intergranular attack, which distinguishes this phenomenon from intergranular SCC. However, the close relationship between intergranular attack and intergranular SCC is apparent in Fig. 36, in which a stress-assisted finger of corrosion penetrated from the layer of intergranular attack into the tube material.

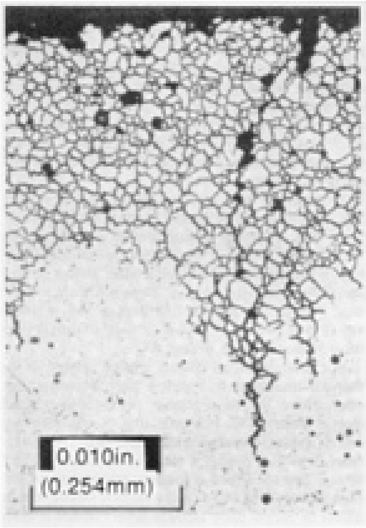

Fig. 36 Integranular attack of Alloy 600 steam generator tubing. Etched sample. Source: Ref 70

Intergranular penetration, the third form of intergranular corrosion, has been variously described as a mixture or a hybrid of the other two forms.

Within the steam generator, intergranular corrosion has been found in a variety of locations. The most important of these locations are the tube/tubesheet crevice (an annular gap remaining after steam generator manufacture), as shown in Fig. 37 , and the tube/tube support plate crevice. Intergranular corrosion at this latter location has been found at several Japanese sites, but has not occurred widely in the United States. Corrosion has also been observed in the sludge region above the tubesheet. All of the steam generators experiencing secondary-side intergranular corrosion are tubed with mill-annealed Alloy 600. In laboratory tests, however, intergranular corrosion has been produced in mill-annealed Alloys 600, 690, and 800. Based on these findings, there appears to be little difference in performance among these alloys in the mill-annealed condition (Ref 33, 34).

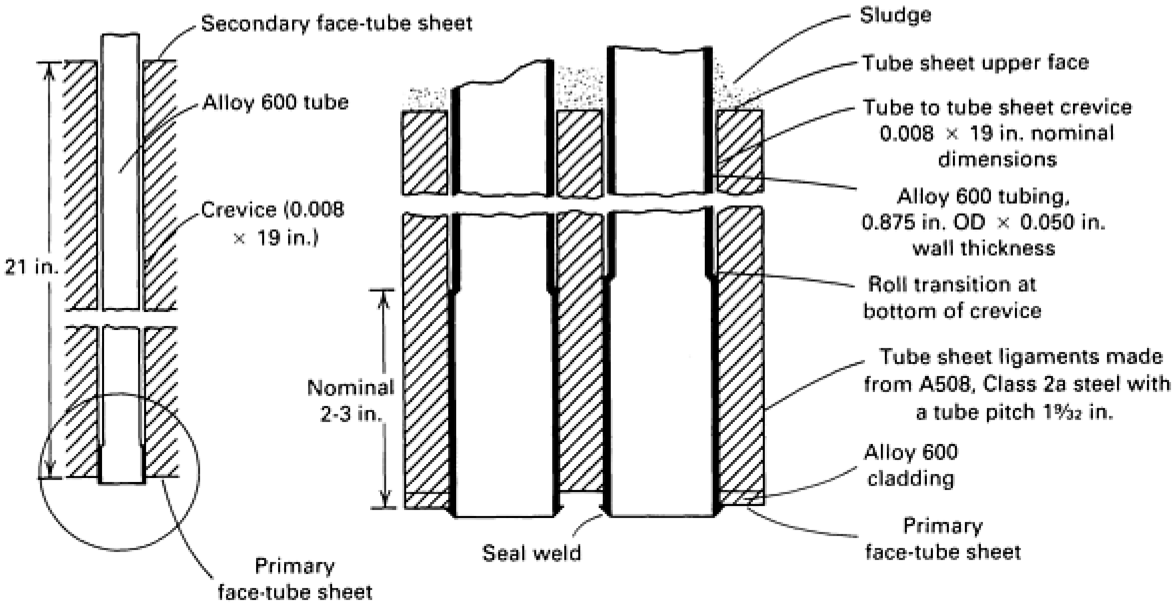

Fig. 37 Typical steam generator tube showing the tubesheet annular crevice. 1 in. = 25.4 mm

Tests have shown how aggressive chemicals can concentrate in these crevices and in the sludge under heat transfer conditions (Ref 71, 72); alternate wetting and drying is a particularly effective concentration mechanism. Five classes of environmental contaminants have been postulated to explain the occurrence of intergranular corrosion (Ref 33). These include high concentrations of sodium hydroxide (NaOH) and/or potassium hydroxide (KOH), the products from the reaction of sulfate ions with hydrazine or hydrogen (reactive sulfur-bearing species are postulated), the products of thermal decomposition of ion exchange resins (sulfates and organic residuals), highly concentrated salt solutions at neutral or nearly neutral pH (these salt solutions are the natural consequences of condenser leakage concentrated to high levels of salt by the boiling processes in the steam generator), and alkaline carbonates and/or their reaction or hydrolysis products (believed to affect the nature of the passive film on the alloy surface).

Corrective Actions. It has been shown with reasonable certainty that increased service stress, dynamic strain, and a high residual stress level can all be major factors in accelerating initiation or propagation of intergranular SCC. A similar statement for intergranular attack cannot be made, because experimental results have shown that intergranular attack can develop even with compressive stress (Ref 58).

Stress-relief treatment of tubing in new steam generators is accomplished by installing thermally treated Alloy 600 tubing that has been aged at 705 °C (1300 °F) for 15 h. Also, one manufacturer uses a full bundle stress relief after steam generator fabrication to provide stress relief. No practical procedure for the application of thermal stress relief to the secondary side of in-service tubing has yet been proposed.

For new plants, modification of the materials by thermal treatment to improve the microstructure can reduce the susceptibility to caustic-induced intergranular SCC. For operating plants, sleeving can be applied to mitigate the effect of intergranular corrosion. The modified material or sleeve should be resistant to faulted secondary environments; for example, sleeves have used a duplex sleeve with a nickel or nickel alloy outside layer (which is considered immune to caustic attack).

Modification of the crevice environment appears to be the most straightforward method of preventing or arresting intergranular attack and may apply equally to the intergranular SCC. Modification can include several factors, such as lowering the temperature, adding a pH neutralizer, removing the corrodent by flushing or soaking, and changing the concentration and/or ratio of bulk water contaminants. Laboratory studies have confirmed the benefit of several of these corrective measures; some of the modifications have been applied to operating steam generators.

The operating temperature of one unit was lowered for several years, which effectively reduced the rate of progression of the intergranular attack. The hot leg temperature was lowered to approximately the normal cold leg temperature. A necessary side effect of significant temperature reductions is loss of power. Based on the experience of one utility, it is judged that the temperature must be reduced to 300 °C (575 °F) or lower to have a major impact on corrosion rate.

Boric acid has been added during off-line crevice-flushing operations to reduce the pH level. The pH neutralizer was used on the basis of limited laboratory data regarding its effectiveness. Tubes subsequently removed from one of the steam generators were found to have boric acid present over the full length of the tube surface within the tubesheet crevice. No estimate can be made as to effectiveness. Equilibrium calculations suggest that high levels of boric acid (equivalent to an Na/B ratio approximately equal to 1) will be required to reduce the pH significantly when the pH is held in the alkaline range by NaOH or KOH (very strong bases). On-line addition of boric acid has been employed at several plants.

Flushing or soaking off-line maintenance procedures have been used with varying results at several plants. The flushing procedures are based on laboratory tests and involve a depressurization that causes boiling within the tube/tubesheet crevice and ejection of concentrated solutions from the crevice. Optimization of crevice-flushing procedures for each unit and periodic repetitive application of the optimized procedures are recommended. It should be recognized that flushing or adding a pH neutralizer may be difficult if denting has occurred at the top of the tubesheet or if the annulus is fouled with corrosion products, thus blocking access to the crevice.

The concentration of contaminants accessible to the crevice may be controlled by eliminating or reducing the entry of contaminants to the steam generator and by controlling the concentrating capability of the sludge pile above the crevice. Reducing the entry of contaminants is best accomplished by preventing condenser leaks, routing drains to the condenser (if condensate is subsequently treated), and properly treating makeup water sources. Use of full-flow condensate polishers for control of ionic species has not been shown to be effective in controlling the species that are

probably responsible for intergranular attack and intergranular SCC, as was shown for control of chloride responsible for denting. Polishers are potential sources of sulfates (SO_4) and sodium (Na^+) if operated or regenerated improperly, and they do not effectively remove silica or organics. However, some plants have used these condensate polishers very effectively to minimize impurity entry into the steam generators.

Control of the sludge pile, which is an effective concentrating mechanism, requires three courses of action:

- Effective, periodic sludge lancing
- Minimization of particulate transport by preventing air entry and/or providing for feedwater filtration, such as by powdered resin condensate polishers
- Preventing the entry of chemical species that tend to promote agglomeration

Chemical cleaning has been used to remove the sludge on the tubesheet. One group of utilities has attempted to modify the aggressive environment in the tube/tubesheet crevices by fully expanding the tubes in the tubesheet, thus eliminating the crevice.

Pitting

Causes. Extensive pitting on the outer surfaces of tubes has been observed in two units. The pitting occurred primarily on the cold leg between the tubesheet and the first support plate in regions where sludge or tube scale was present. Figure 38 shows a typical steam generator pit. The laminar appearance is caused by the presence of metallic copper layers. In addition, the corrosion deposit is enriched in chromium and depleted in nickel and iron compared to the base metal. Laboratory tests have shown that pits can be formed in the presence of high chloride ion concentration from either seawater or copper chloride (Ref 74). Thus, it is concluded that the pits are caused by chloride, low pH, and an oxidant such as cupric chloride ($CuCl_2$) or oxygen. Temperatures above about 150 °C (300 °F) are required to form pits such as those observed in the operating units. It is further believed that sludge and scale act as a medium in which the bulk impurities are concentrated to higher levels by the boiling action.

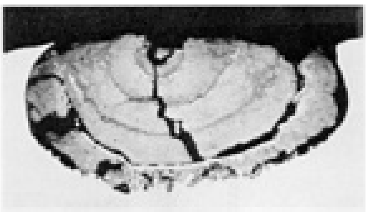

Fig. 38 Pitting of a steam generator tube. Source: Ref 73

Corrective Actions. For existing plants, the tubing is repaired and retained in service by the use of sleeves. Sleeves may be of one alloy or a bimetallic alloy in which the outer alloy is selected for resistance to pitting corrosion and the inner alloy is selected for primary-side corrosion resistance. The principal corrective action is to modify the environment to make it less corrosive. One approach is to reduce the sludge and scale by minimizing the entry of solids (higher pH and reduced air in-leakage), by sludge lancing, and by chemical cleaning. All of these methods are now being used. Another approach is to minimize the entry of soluble contaminants (principally chlorides and oxidants) by following the Secondary Water Chemistry Guidelines (Ref 42), by quickly repairing leaky condensers, and by deaerating auxiliary feedwater used for hot standby.

Corrosion Fatigue

Causes. Cracking of some tubes from the outer surface has occurred in the upper regions of several OTSGs. It is believed that these cracks are caused by corrosion fatigue resulting from small-amplitude vibration combined with the transport of impurities into the upper regions of the OTSG units, particularly in the open lane. Laboratory tests have shown a decrease in Alloy 600 fatigue strength in the presence of chemicals that are judged to be present in these upper regions (Ref 75).

In these tests, a substantial decrease in fatigue resistance of Alloy 600 was observed in acid sulfate/silicate solution. The environment was selected to be consistent with that postulated to exist in the region of interest at the top of an OTSG. Figure 39 shows the response of Alloy 600 in an aggressive (pH 2) sodium sulfate/sodium silicate/sulfuric acid environment. The fatigue strength at 10^7 cycles at 289 °C (552 °F) was found to be approximately 56% of the value measured in air at about the same temperature. Aerated acid sulfate/silicate and alkaline sulfate/silicate environments had a less deleterious effect.

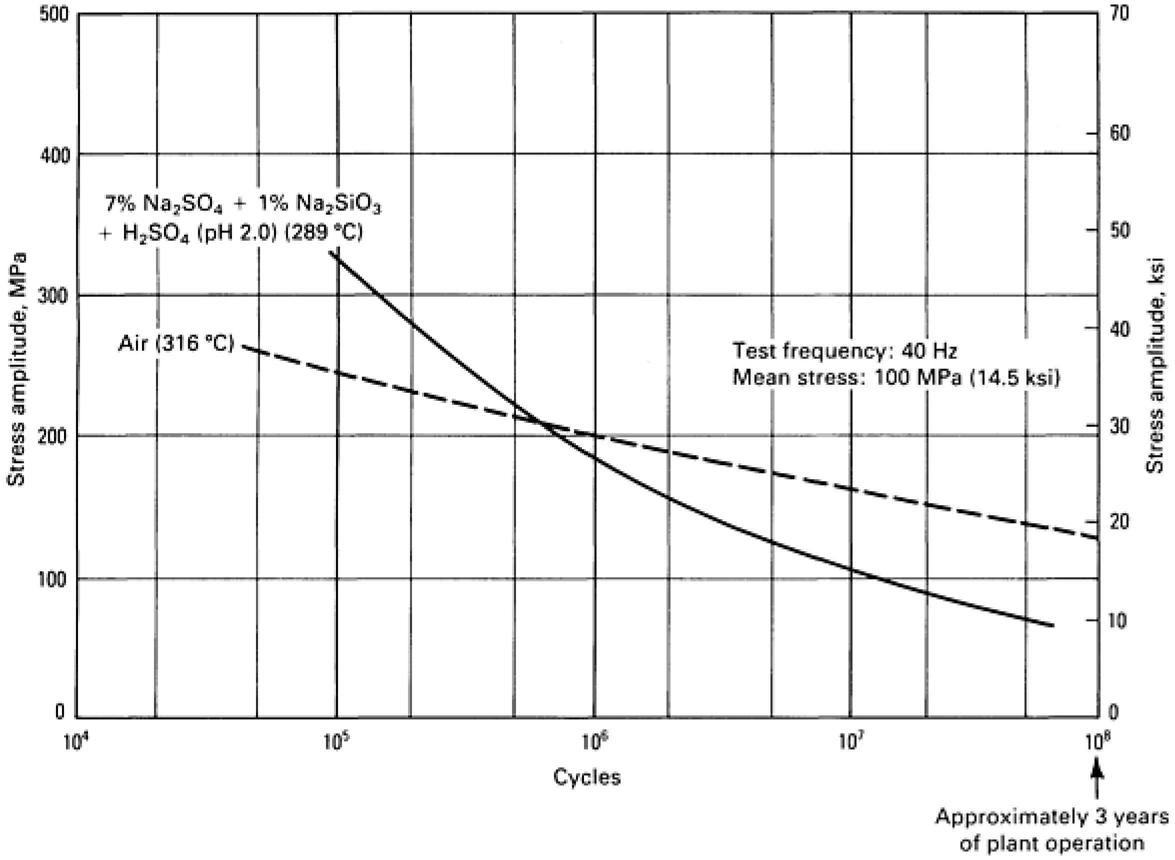

Fig. 39 Corrosion fatigue effects of Alloy 600

Corrective Action. The corrective action is to modify the environment to make it less aggressive. This can be done by minimizing the entry of these impurities into the steam generator. Also, the use of mechanical flow-diverting lane blockers has been tested and shown to be a useful steam generator modification; they reduce the flow of liquid droplets to the upper regions via the open lane (Ref 76). In new plants, the open lane has been eliminated.

Other Phenomena

A variety of additional factors have contributed to lower-than-desired steam generator availability or have caused the utility operators to incur repair costs. These phenomena will not be discussed in this section. Some of the mechanical problems and proposed or actual corrective actions are summarized briefly in Table 6. References 77 and 78 provide information that is particularly useful to those utility operators that are assessing whether to repair or replace their steam generators.

Table 6 Corrective actions for steam generator mechanical problems

Problem	Corrective action
Erosion-corrosion of feedwater nozzles	Higher pH coolant; replace with higher chromium tubing
Loose parts fretting and wear	Inspection; keep loose parts out
Wear at antivibration bar locations	Replace with wider bars, improved materials; reduce tube-to-bar gap
Wear in preheat units	Improved flow distribution baffle; reduced tube to support plate clearance
	Split feed flow
Water hammer	Modify feed design and feed rings to avoid drainage of feed ring

Corrosion of Zircaloy-Clad LWR Fuel Rods

A.J. Machiels, Electric Power Research Institute

Almost all power reactors in the world are cooled by either normal or heavy water and are termed light water reactors (LWRs) or heavy water reactors (HWRs), respectively. The heat-generating fuel elements, or fuel rods, are made of stacks of uranium dioxide (UO_2) pellets clad or sheathed in hermetically sealed tubes. Fuel rods are grouped together in assemblies whose designs differ markedly according to the type of reactor (Ref 79).

A primary fuel assembly reliability consideration is the ability to maintain optimum power generation over the design lifetime of the assembly without releasing the radioactive by-products of the nuclear fission process into the primary coolant (water). Therefore, the cladding or sheathing tubes separating the coolant water from the nuclear fuel and its by-products must resist the corrosive attacks of both environments while meeting all mechanical loads present or anticipated during power and fuel-handling operations.

Although the first LWRs in the United States used stainless steel as a cladding material, the economics of LWR-generated electricity favor the use of zirconium-base alloy (Zircaloys) wherever possible in the high-flux regions of the reactor core. The reason for this is the low neutron absorption cross section of zirconium. As a result, tubes and other assembly structural components are for the most part made of zirconium alloys.

The primary zirconium alloys are known as Zircaloy-2 and Zircaloy-4. They are mostly zirconium (~98 wt%) with low amounts of alloying elements (tin, iron, chromium, nickel, and oxygen), which confer to the alloys the desirable mechanical and corrosion properties. Zirconium-niobium alloys are also used in Canada and Russia.

Zircaloy-2 and Zircaloy-4 were selected during the early days of the U.S. Nuclear Navy program on the basis of relatively few data (Ref 80), and it is now generally accepted that the formation of these alloys is not optimized with regard to their corrosion resistance to water, which is the topic of this Section. The discussion that follows is restricted to the water-side corrosion properties of Zircaloy under normal operating conditions in LWRs. Oxidation during high-temperature transients leading to core damage is beyond the scope of this Section, but was recently reviewed (Ref 81). A brief introduction to corrosion under isothermal conditions in high-temperature water is first presented. The applications to pressurized PWRs and BWRs are then discussed. Also, given the large number of reviews already devoted to the topic, this discussion is limited to the more recent developments that have, or will have, an impact on the corrosion performance of the Zircaloys. For additional information on the corrosion performance of Zircaloy alloys, see the article "Corrosion of Zirconium and Hafnium" in this Volume.

Corrosion in High-Temperature Water

Light water reactors normally operate with a coolant temperature between 250 and 350 °C (480 and 660 °F) at a pressure of either approximately 7 MPa (1000 psi) (BWRs) or 15 MPa (2200 psi) (PWRs). Therefore, out-of-reactor corrosion studies are usually conducted in high-pressure autoclaves, in which the water is either in the liquid state at temperatures up to approximately 360 °C (680 °F) or in the gaseous state (steam) at temperatures of approximately 400 °C (750 °F) and higher. Under these conditions, the attack of Zircaloy by water is generally uniform. With steam at high temperature

(typically 500 °C, or 930 °F) and high pressure (typically 10 MPa, or 1500 psi), this uniform attack can be accompanied by a more localized form called nodular corrosion.

The reaction between Zircaloy and water can be written as:

$$Zr + 2H_2O \rightarrow ZrO_2 + 2(1 - x)H_2 + 4 \times H \quad \textbf{(Eq 1)}$$

where the first and second left-hand terms represent zirconium (of which Zircaloy is mostly made) and water, respectively; the right-hand terms represent zirconium oxide, hydrogen that is released into the corroding water, and hydrogen that is picked up by the Zircaloy; *x* is the pickup fraction. The pickup of hydrogen by the Zircaloy substrate leads to changes in its mechanical properties and, in particular, to a loss of ductility.

The formation of zirconium oxide results in a loss of metallic Zircaloy. Because the Pilling-Bedworth ratio is equal to 1.56 at ambient temperature, a given loss in metal thickness results in a larger gain in oxide thickness (the Pilling-Bedworth ratio is explained in the article "Fundamentals of Corrosion in Gases" in this Volume). In Fig. 40, the positions of the Zircaloy/ZrO_2 and ZrO_2/H_2O interfaces are shown relative to the position of the original Zircaloy/H_2O interface.

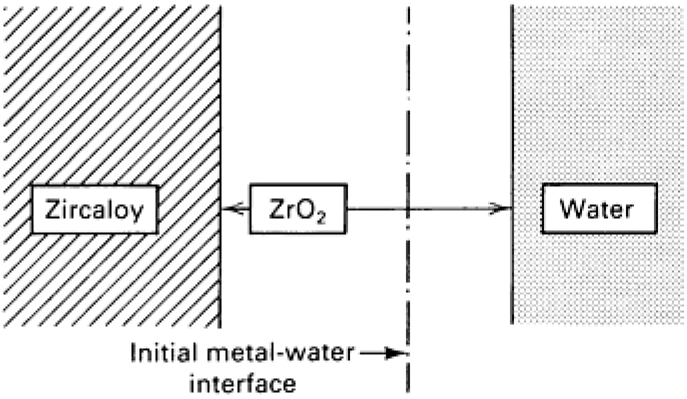

Fig. 40 Zircaloy/zirconium oxide/water interface

The kinetics of the uniform corrosion reaction can be conveniently divided into two main periods, referred to as pretransition and posttransition. In the first of the periods, a black coherent oxide film is formed, and the corrosion rate diminishes with time according to a rate law given by the simplified form: (weight gain) = constant *x* $(\text{time})^n$, with the exponent *n* in the range of 0.25 to 0.5. A transition follows to a period where the rate law is closer to linear ($n \simeq 1$). This transition is eventually accompanied by a conversion of the black oxide to a gray or white oxide. The corrosion kinetics of Zircaloy in high-temperature water actually follow a periodic behavior, and the apparently linear dependence of the posttransition rate is obtained by averaging the time-dependent rates over several periods (Ref 82). A progressive acceleration of the posttransition rate, especially after sufficiently long reaction times, has also been shown (Ref 83).

Given that zirconium is a most reactive metal, it should readily corrode according to Eq 1. However, because of the protective nature of at least part of the oxide film, Zircaloy belongs to the group of extremely corrosion-resistant alloys. The film acts as a barrier through which the reactive species (oxygen ions, electrons, etc.) must diffuse to sustain the corrosion reaction (Ref 84). During pretransition, reaction rates are determined by diffusion through a surface film of increasing thickness. At transition, which typically occurs when the oxide layer is 2 to 3 μm thick, part of the film undergoes a change in morphology and becomes nonprotective (Ref 85). During posttransition, the thickness of the protective part of the oxide film successively increases and abruptly decreases, yielding cyclically time-dependent kinetics. As discussed in the previous paragraph, linearization over a sufficiently long period of time can be readily performed. This is equivalent to assuming the existence of a protective barrier of constant thickness. Under typical high-temperature water autoclave conditions, this equivalent thickness is about 1 μm (Ref 86).

The out-of-reactor corrosion properties of Zircaloys are, in general, strongly dependent on the material microstructure and on temperature. In some cases, these properties also depend on the water chemistry conditions.

Zircaloy Material. The corrosion resistance of Zircaloys depends on a number of factors that include the concentration and distribution of alloying elements and impurity elements. These factors in turn depend on the thermomechanical processing history, which is an essential part of the manufacturing sequence. Other manufacturing variables that are of significance in determining corrosion resistance are related to the surface treatment of the final component, such as grinding, grit blasting, or pickling.

The fabrication variables or the manufacturing variables involved in the production of zirconium sponge are not considered in this section. However, corrosion properties are very sensitive to a number of key manufacturing parameters, such as quenching rates and annealing times and temperatures (Ref 87). Moreover, some variability in these parameters always accompanies the large-scale production of Zircaloy components, even under nominally identical conditions. Therefore, the corrosion performance of a given population of Zircaloy components is generally characterized by a range of corrosion behaviors, the extent of which can be very significant.

Temperature. Corrosion studies in autoclaves under isothermal conditions have led to a number of mathematical expressions, such as (Ref 88):

$$\text{Pretransition } \Delta W^3 = 5.07 \cdot 10^{13} \cdot \exp\left(\frac{-32\,289}{RT}\right)t \qquad \textbf{(Eq 2a)}$$

$$\text{Posttransition } \Delta W = \Delta W_t + 2.21 \cdot 10^9 \cdot \exp\left(\frac{-28\,200}{RT}\right)(t - t_t) \qquad \textbf{(Eq 2b)}$$

$$\text{Transition } \Delta W_t = 3.21 \cdot 10^8 \cdot \exp\left(\frac{-10\,763}{RT - 1.17 \cdot 10^2 \cdot T}\right) \qquad \textbf{(Eq 2c)}$$

where ΔW is the specimen weight gain (in mg/dm^2); ΔW_t is the specimen weight gain at transition (in mg/dm^2); t is the total exposure time (in days); t_t is the time to transition (in days); R is the gas constant, 1.987 cal/(mol·K); and T is the absolute temperature (in degrees Kelvin). In the temperature range of 280 to 400 °C (535 to 750 °F), the pretransition rates increase by a factor of two for each 45- to 50-°C (80- to 90-°F) temperature increment; more important, the posttransition corrosion rates increase by a factor of two for each 16- to 20-°C (29 to 36-°F) temperature increment.

Water Chemistry Conditions. The protective nature of the diffusion barrier can be drastically altered by the presence of some species in the corroding water. Most autoclave experiments use pure water only. However, because of its relevance of LWR technology, lithium hydroxide (LiOH) is sometimes added to the water. At sufficiently high concentrations, the presence of LiOH can lead to rapid corrosion of the Zircaloys (Ref 89).

Corrosion in LWRs

Early experiments on zirconium-alloy corrosion in reactors showed that significant differences in corrosion behavior could occur (Ref 90, 91). Compared to a high-temperature water autoclave, the reactor environment is characterized by the presence of an intense radiation field, the existence of large temperature gradients across the Zircaloy-water contact layers, and the presence of impurities and soluble chemical additives that are usually not present in high-temperature water autoclaves. Subsequent investigations have shown that each of these factors, separately or in combination, can be important.

Water Chemistry. Boiling water reactors normally operate with high-purity water. However, radiolytic decomposition of the water eventually results in the production of stoichiometric amounts of hydrogen and oxygen. Partitioning of those two gases occurs between the steam phase, which is continuously extracted from the system, and the liquid phase, which

is recirculated. Typical steady-state concentrations of hydrogen and oxygen in the recirculation loops are, respectively, 20 and 200 ppb. Pressurized water reactors operate with a hydrogen overpressure sufficient to inhibit the formation of radiolytic oxygen in the coolant, a basic additive (LiOH) to control the release of corrosion products into the coolant and their deposition on fuel surfaces, and a chemical shim (orthoboric acid, H_3BO_3) to control the nuclear reactivity. Under these conditions, typical hydrogen and oxygen concentrations are maintained at >2000 ppb and less than 5 ppb, respectively.

In both systems, the structural components of the reactor system are the source of corrosion products generally characterized by low solubilities. As they are transported throughout the system by the coolant, they tend to form deposits on both in-core and out-of-core surfaces. These deposits, along with the coolant-borne impurities, are referred to as crud. Crud deposits consist mostly of iron oxides with high porosities (65 to 85%). Magnetite (Fe_3O_4), in which the iron is partially replaced by the other constituents (such as nickel or chromium) of the alloys exposed to the coolant, and hematite (Fe_2O_3) are the most common crud constituents in PWRs and BWRs, respectively. Formation of crud deposits on fuel element surfaces is largely dictated by solubility and heat transfer considerations. Under conditions that favor negative solubility temperature coefficient (that is, solubility decreases when temperature increases), or the formation of concentration cells created by boiling heat transfer, or both, crud deposition readily occurs.

Therefore, the important water chemistry parameters include:

- Concentrations of dissolved oxygen and hydrogen
- Concentrations of chemical additives (PWR technology only)
- Concentrations and precipitation characteristics of the coolant-borne impurities

The effects of these parameters can be very important in the presence of a reactor radiation field, or a large enough temperature gradient, or both.

Effect of Radiation. Radiation can affect the corrosion behavior of Zircaloys by modifying the aggressivity of water through the formation of highly reactive, oxygenated radicals; by modifying the diffusive properties of the protective oxide layer through the formation of point defects; and by modifying the microstructure of the Zircaloy substrate by changing the concentration and distribution of some elements in the Zircaloy material close to the Zircaloy/zirconium oxide interface. Effects due to the second item appear to be relatively minor. Effects due to the last item are potentially important, but little is known in this area. Therefore, these radiation effects will not be considered any further in this section.

As already discussed, the BWR and PWR environments lead to significantly different oxygen concentrations in the coolant. In BWRs, where the oxygen content of the coolant water is classified as high, irradiation clearly enhances the oxidation rate. The formation of a uniform oxide layer proceeds at a rate greater than that measured under similar temperature conditions in an autoclave and is generally accompanied by the appearance of locally thicker patches of zirconium oxide having the form of nodules or pustules (Fig. 41). Initially, the nodules appear as white patches on the black pretransition oxide surface (Fig. 42); with exposure, they grow in diameter as well as in thickness, and they eventually cover the entire exposed surface.

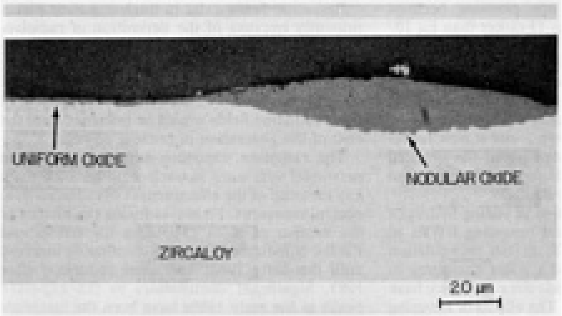

Fig. 41 Photomicrograph showing the uniform and nodular oxides

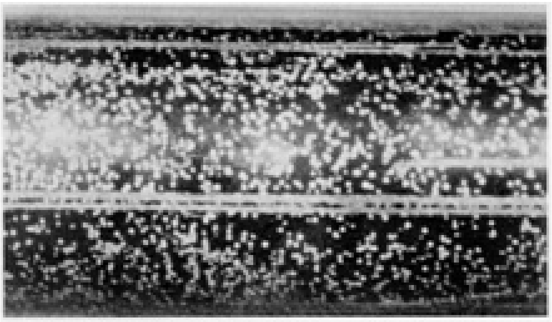

Fig. 42 White oxide nodules on a black, pretransition oxide

In PWRs, where the oxygen content of the coolant water is very low, only the formation of a uniform film is observed. There remains some disagreement as to whether or not irradiation enhances oxidation under those PWR conditions (Ref 92). Estimates of the magnitude of acceleration generally vary between none and a factor of four. Up to oxide thicknesses of 5 μm, no acceleration is detected; however, for oxide thicknesses greater than 15 to 25 μm, some acceleration is usually observed.

Effect of Heat Flux. The transport of heat from the nuclear fuel pellets to the coolant produces large surface heat fluxes. Both the magnitude of the heat flux and the mode of heat transfer between the fuel element outer surface and the coolant have significant effects on the corrosion performance of the Zircaloy cladding. Temperature gradients in the cladding itself influence the distribution of the hydrogen picked up by the alloy during the corrosion process (Eq 1), and temperature gradients across the cladding/coolant interface increase the temperature of the protective oxide layer.

Acceleration of the corrosion process by the hydrogen produced by the corrosion reaction is a possibility, but the existence and magnitude of this effect under operating conditions applicable to nuclear fuel elements remain to be established. The thermal acceleration obtained by increasing the interface temperature is, in principle, more straightforward to evaluate. With reference to Fig. 43, which schematically represents the temperature profile across the Zircaloy/coolant interface at some axial elevation of a heat-generating fuel element, it can be seen that the average temperature of the protective oxide layer, T_I, located at the metal/oxide interface is given by:

$$T_I = T_B + \Delta T_{CO} + \Delta T_{CR} + \Delta T_{OX} \qquad \textbf{(Eq 3)}$$

where T_B is the bulk coolant temperature and ΔT_{CO}, ΔT_{CR}, and ΔT_{OX} denote the temperature differences across the crud/coolant interface, the crud layer of thickness ρ, and the oxide layer of thickness δ, respectively.

Because the oxide thickness, , varies between 0 at the beginning of power generation to its maximum value, $_{MAX}$, at the end of power generation, T_{OX} is a function of time and is given by:

$$\Delta T_{OX}(t) = q''(t) \cdot \frac{\delta(t)}{k_{OX}} \qquad \textbf{(Eq 4)}$$

where t denotes time q" is the surface heat flux, and k_{OX} is the thermal conductivity of the oxide. Assuming steady-state reactor operating conditions resulting in constant T_B, T_{CO}, and T_{CR}, that is:

$$T_B + \quad T_{CO} + \quad T_{CR} = T_O \equiv \text{constant} \qquad \textbf{(Eq 5)}$$

where T_O is the temperature of the outer surface of the oxide layer. Eq 3 can be rewritten as:

$$T_I(t) = T_O + q'' \cdot \frac{\delta(t)}{k_{OX}} \quad \textbf{(Eq 6)}$$

Transforming Eq 2b from weight gain to oxide thickness and differentiating with regard to time leads to:

$$\frac{d\delta}{dt} = K \exp\left(\frac{-Q}{RT}\right) \quad \textbf{(Eq 7)}$$

where K and Q are two constants that can be readily evaluated.

Substituting Eq 6 into Eq 7 yields after some manipulation:

$$\frac{d\delta(t)}{dt} \simeq \left(\frac{d\delta}{dt}\right)_{T = T_O} \cdot A(t) \quad \textbf{(Eq 8a)}$$

where $A(t)$ is a time-dependent thermal acceleration factor equal to:

$$A(t) = \exp\left[\beta_O \cdot q'' \cdot \delta(t)\right] \quad \textbf{(Eq 8b)}$$

with

$$\beta_O = \frac{Q}{k_{OX} R T_O^2} \quad \textbf{(Eq 8c)}$$

Therefore, in the presence of a heat flux, oxidation rates are obtained by multiplying the oxidation rate calculated at a temperature T_O by a time-dependent thermal acceleration factor that depends exponentially on the oxide layer thickness and on the surface heat flux.

$T_O < T_{SAT}$. When T_B is significantly lower than the saturation temperature, T_{SAT}, corresponding to the system pressure, as it is for the major part of a PWR core, T_O, is given by:

$$T_O = T_B + q'' \cdot \left(\frac{1}{\alpha} + \frac{\delta}{k_{CR}}\right) \quad \textbf{(Eq 9)}$$

where α is the convective heat transfer coefficient; α is a strong function of the local flow turbulence and assumes typical values of 3 to 6 W/cm^2·K (Ref 88). The thermal conductivity of the crud is denoted by k_{CR} and assumes typical values of approximately 1 W/m·K (Ref 93). Equation 9 predicts that large heat fluxes produce large temperature differences; as a result, T_O can be significantly higher than T_B, especially when substantial amounts of crud deposits are present. Under present recommended operating practices for PWRs, crud accumulation is nominal ($\leq$10 μm); therefore, its impact tends to be small.

$T_O \simeq T_{SAT}$. When T_B is not significantly lower than T_{SAT}, as it is in BWRs and in parts of some PWRs, boiling heat transfer dominates. Except when dense crud deposits are present, the maximum value for T_O ($T_{O,MAX}$) is given by:

$$T_{O,MAX} = T_{SAT} + \Delta T_1 \quad \textbf{(Eq 10)}$$

where ΔT_1 represents the amount of superheat needed to sustain the boiling process. The evaluation of ΔT_1 is complicated by the fact that boiling heat transfer promotes the concentration of coolant impurities and additives, especially when the change of phase occurs at fixed locations along the heat transfer surface. These conditions may exist with noncrudded rods when steam bubbles originate from the same sites (Ref 94), as well as with crudded rods when wick

boiling is present (Ref 93). For example, a simple evaluation of the maximum concentration factor, F_{MAX}, that can be obtain under wick-boiling conditions is given by (Ref 95):

$$F_{MAX} = \frac{C_{MAX}}{C_B} = \exp\left(\frac{q'' \cdot \rho}{D \cdot p \cdot L_{VAP} \cdot d}\right) \quad \textbf{(Eq 11)}$$

where C_B is the bulk coolant concentration of a given species, and C_{MAX} is its maximum concentration in a crud of thickness . The diffusivity of the species in water is given by D, p is the crud porosity, L_{VAP} is the latent heat of evaporation, and d is the density of water. Soluble species may lead to an elevation of the boiling point when C_{MAX} is large enough. When this is the case, T_1 is given by:

$$T_1 = T_{BPE} + T_2 \quad \textbf{(Eq 12)}$$

where T_{BPE} represents the boiling point elevation, and T_2 is the superheat calculated from boiling heat transfer considerations. The value T_2 is typically small (a few degrees Celsius). The value T_{BPE} is expected to be negligible in BWRs, but not necessarily so in PWRs, because of the additives present in the coolant.

Species with a low-to-moderate solubility may precipitate for C_{MAX} large enough. A few impurities, most notably copper, lead to the formation of dense cruds, through which heat can be transferred by conduction only. The value $T_{O,MAX}$ is then given by:

$$T_{O,MAX} = T_{SAT} + \Delta T_1 + q'' \cdot \frac{\rho}{k_{CR}} \quad \textbf{(Eq 13)}$$

Large amounts of dense cruds (~100 m) can result in cladding temperatures that are approximately 50 °C (90 °F) higher than those obtained in the presence of porous cruds for typical heat fluxes in BWRs.

Boiling also influences the radiolytic conditions existing in the outer layers of the heat-generating fuel elements. A quantitative description of the effect of boiling on Zircaloy corrosion is proposed in Ref 96.

Application to BWRs. In BWRs, the temperature is practically constant along the length of a fuel element, and $T_{O,MAX}$ is approximately equal to the system saturation temperature, typically about 290 °C (555 °F). Under these conditions, uniform corrosion rates are low, even when an enhancement factor is factored in to take into account the oxygenated conditions of the coolant. The formation of a uniform film is accompanied by the nucleation and growth of oxide nodules. The nodular oxide thickness is mainly a function of burnup with a tendency to saturation (Ref 97).

Zircaloy corrosion in BWRs has not been a problem except in reactors characterized by high concentrations of soluble copper in the reactor water. Failures have been observed, in particular with fuel claddings having high nodular corrosion susceptibility (Ref 98, 99). Those claddings develop nodular oxide layers that contain sizable cracks through which heat transfer appears to be occurring by wick boiling. As discussed above, although wick boiling itself leads to negligible superheats, it can produce large concentration effects. When copper concentrations (C_{MAX}, Eq 11) are large enough, copper compounds precipitate and progressively plug the network of cracks necessary to sustain the wick-boiling process. This condition eventually leads to a significant temperature increase of the cladding because $T_{O,MAX}$ is now given by Eq 13 rather than Eq 10. Thermal acceleration of the corrosion reaction can eventually lead to fuel failures. As can be seen from Eq 11, C_{MAX} is linearly dependent on C_B, but depends exponentially on the heat flux, q", and the nodular corrosion properties of the cladding through /p, where and p now represent the thickness and porosity of the cracked nodular oxide. The latter depend on the corrosion properties of the Zircaloy material.

The recent implementation of adding hydrogen to the feedwater of several operating BWRs to prevent intergranular SCC in the recirculation system piping has created a water chemistry in the BWR core that is outside the experience base of either BWRs or PWRs. The effects of lowering the concentration of oxygen in the reactor water should be beneficial as

far as oxidation rates are concerned. The effects on hydriding rates are more difficult to assess because the pickup fraction could be directly influenced by the hydrogen dissolved in the water. Overall, the effects of hydrogen addition on oxidation and hydriding are expected to be small (Ref 100). After 1 cycle of hydrogen water chemistry at Dresden-2, the fuel examination results show that cladding oxidation is well below any performance concerns. Also, for the Zircaloy components that were examined, it does not appear that, within the limits of experimental uncertainties, hydriding rates are directly influenced by the presence of hydrogen in the coolant. Additional examinations after 2 and 3 cycles of hydrogen water chemistry are planned (Ref 101).

Application to PWRs. Because boiling heat transfer also occurs locally in PWRs--especially in the more recently designed ones--$T_{O,MAX}$ is given by Eq 10, in which T_{SAT} is typically 340 °C (645 °F). The evaluation of T_1 is complicated by the presence of LiOH and boric acid in the reactor coolant. Because boiling promotes the concentration of these additives on the outer surfaces of the fuel elements, some local elevation of the boiling point is likely. Lithium hydroxide has a weak effect on the boiling point elevation of water, but the impact of boric acid may be more significant (Ref 93). Uncertainties associated with the accurate evaluation of the interface temperature have hampered efforts to quantify the effects of other phenomena, such as those resulting from the presence of a radiation field.

Zircaloy corrosion in PWRs has become an area of prime concern from a fuel performance point of view. In particular, fuel failures and plant derating due to corrosion have occurred in plants that combine high coolant temperature and high heat flux. Therefore, the full economic benefits associated with high thermal efficiency, high burnup, higher-pH coolant (by adding greater amounts of LiOH), and higher fuel utilization (by fuel rod design changes) may not be obtainable in many existing plants without some improvement in the corrosion properties of the current zirconium alloys.

Influence of Corrosion on Radiation Fields

Robert A. Shaw, Electric Power Research Institute

Radiation fields exist in nuclear power plants primarily because of the deposition of radioisotopes on the surfaces of pipes and other components. These radiation fields can significantly influence the operation and maintenance of nuclear power plants. Consequently, the control of these radiation fields wields an influence over the cost of the generation of nuclear power.

The radiation exposure experienced by the personnel who work in nuclear power plants is a key measure of the effectiveness of radiation field control measures. Figure 44 traces the history of the media of plant exposures for BWRs and PWRs. It indicates a regular, continuing increase until the early 1980s and some reduction after 1983. Significant contributors to the exposure peaks in the early 1980s have been the materials problems experienced in these plants. Pipe cracking and the consequent inspection and replacement of such pipes caused larger-than-normal radiation exposures to be experienced in BWRs. For PWRs, steam generator materials degradation caused significant increase in inspection and, in some cases, replacement of steam generators, causing a similar increase in exposure at roughly the same time.

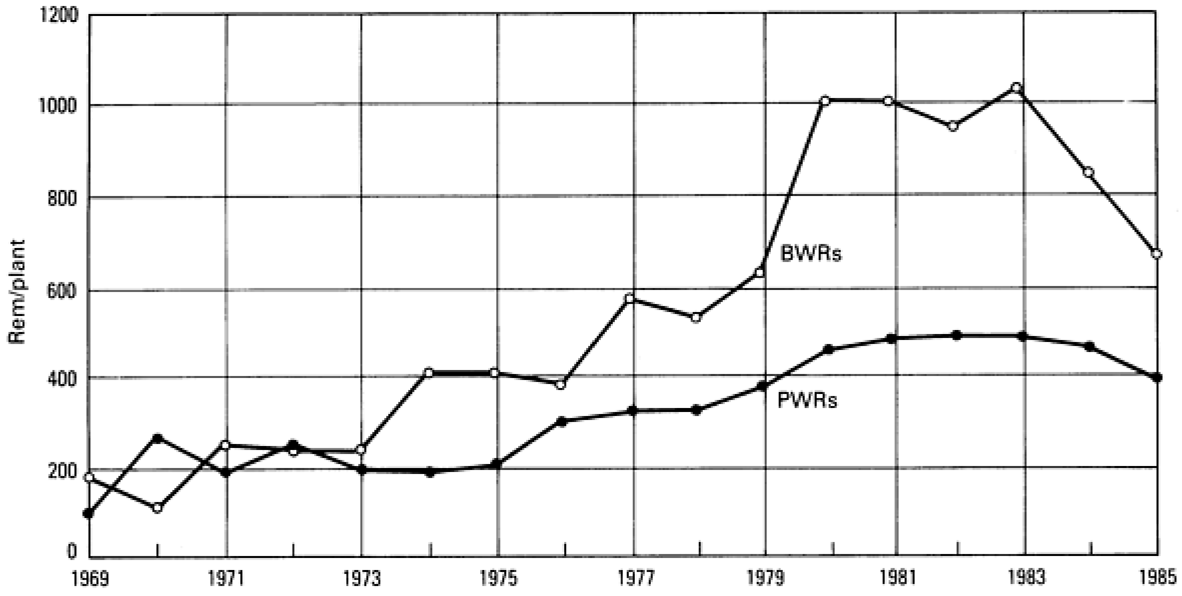

Fig. 44 Median of U.S. nuclear power plant radiation exposures. Rem, roentgen equivalent man

Concurrent with these problems, which caused increase in exposure, has been the application of a number of techniques for reducing radiation exposure in plants. These have included techniques for reducing the radiation fields such as water chemistry control techniques, materials selection emphasizing replacement of cobalt alloys and decontamination to remove radioisotopes from surfaces. In addition to these techniques for reducing radiation fields, radiation exposures have been reduced through the use of remote equipment, shielding, and extensive planning and training for high exposure tasks.

A second measure of expenditure of radiation exposure is presented in Fig. 45 and 46. These diagrams show the man rem/MW·yr, an expression of the radiation exposure that has been required in order to generate electrical energy at nuclear power plants. These two figure compare the experience of the United States with PWRs and BWRs, respectively, to that of other countries. It shows the experience in other countries to be superior to that of the U.S. and stresses the need for effective radiation control programs at U.S. plants. For additional information on techniques to control radiation fields in nuclear reactors, see Ref 102, 103, 104, 105, 106.

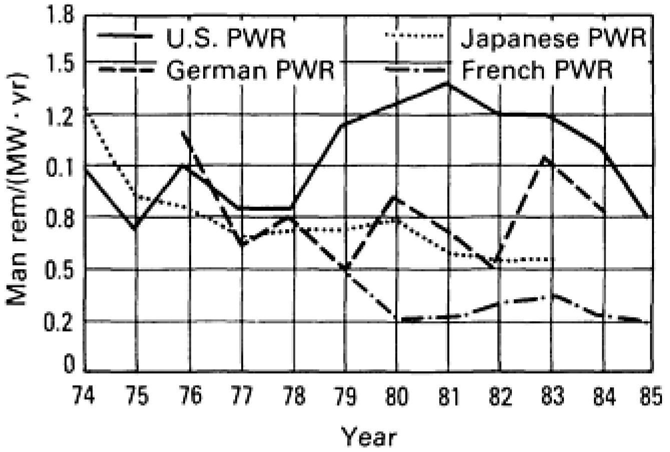

Fig. 45 Occupational radiation exposure per unit electricity generated by PWR nuclear power plants

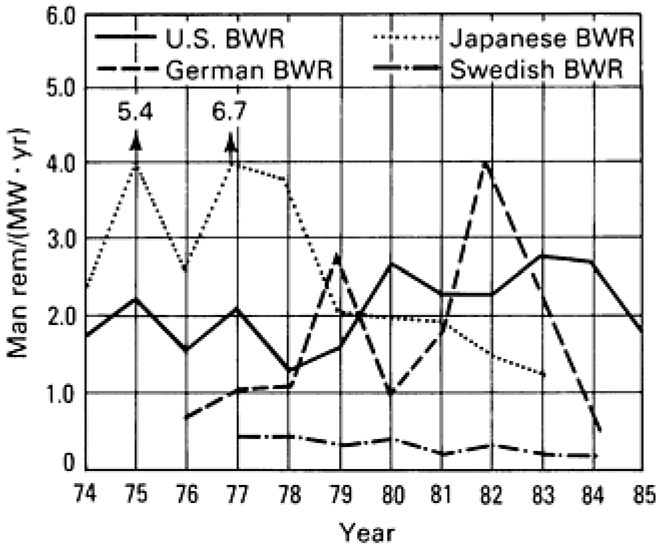

Fig. 46 Occupational radiation exposure per unit electricity generated by BWR nuclear power plants

Radiation Sources

There are two primary sources of radioisotopes generated in nuclear power plants. The first is within the fuel itself where the fissioning process creates fission products and their decay products, which are radioactive. In modern nuclear power plants, fission products are effectively constrained to remain within the Zircaloy cladding present on each fuel rod. Occasionally, in some plants, a few rods will experience pin hole or other types of penetrations through the Zircaloy, permitting the release of fission products into the reactor coolant. Two of the major constituents of fission product radioisotopes--radioactive iodine and radioactive cesium--are useful to illustrate the transport processes, which are typical for fission product.

Iodine, when released to the coolant, will predominantly shift toward the volatile gaseous species. As such, it will processed and monitored with the gases that are removed from the reactor coolant. Iodine generally makes an insignificant contribution to the total exposure experienced at nuclear power plants, although there have been occasional situations in which iodine, which has dissolved in the coolant at the time of shutdown, has delayed shutdown operations pending its removal from the coolant systems by ion exchange. Cesium, on the other hand, is readily soluble in reactor water, and therefore is removed from this water by the purifications system. These purification systems generally use an ion exchange process, which removes the dissolved cesium from the coolant. Subsequently, the cesium ends up in the radioactive waste, where it is processed and packaged on site and shipped off site for disposal. For each of these particular isotopes, and similarly for most fission product isotopes, due to their chemical behavior and/or their low concentration in the coolant water, they contribute relatively insignificantly to the radiation fields that are present from deposition on the surfaces of the components of the reactor coolant system.

The other primary source of radiation fields is from the corrosion products generated at the surfaces of the iron-nickel alloys present as the primary constituent of the pressure boundary. The general corrosion that takes place on these surfaces releases dissolved metallic constituents, such as iron, nickel, manganese, chromium, and cobalt, into the cooling water. Some of these metallic ions are deposited either by particle deposition or by precipitation on hot fuel element surfaces in the core. There they are exposed to neutrons that are generated as a result of the fission process generating the power within the cores. These neutrons will cause the stable radioisotopes of these various metallic constituents to be transmuted into radioactive species. Two of the primary radioactive constituents generated here are ^{60}Co and ^{58}Co.

Cobalt-60 is generated as a result of neutron absorption on naturally occurring ^{59}Co. Although cobalt is present generally as an impurity in the iron-nickel alloys used in reactor power plants, its high susceptibility to neutron adsorption and the high energy of the radioactive emissions from ^{60}Co cause it to predominate over other radioisotopes formed from other

elements that are present in higher concentrations. Cobalt-58 is formed as a result of a neutron knocking a proton from the nucleus of ^{58}Ni, a naturally occurring isotope of nickel.

Following the generation of radioisotopes from the deposits present on the surface of the fuel, various processes such as adsorption, dissolution, and erosion can cause these isotope to be released from the fuel surface, returning them back to the reactor coolant. Transport with the reactor coolant will allow some of these to be deposited later and then incorporated into the growing corrosion films on the surfaces in the reactor coolant system.

To understand the various operational and design parameters that influence the buildup of radiation fields, it is necessary to discuss separately the BWR and PWR. Such influencing features as materials present in the systems, the operational chemistry used in the systems, and the filtration and removal processes used differ sufficiently between these two to warrant separate discussion of these systems.

Boiling Water Reactors

In BWRs, the pressure in the reactor coolant system is maintained sufficiently low to allow boiling to take place. Consequently, the steam generated is fed directly to the turbine and is then condensed in the condenser. This condensate, which is collected in the hot well, is then purified through a condensate polisher. Such a condensate polisher can be either a deep bed ion exchange resin or a powdered resin. The former is more effective in removing dissolved material, whereas the latter is more effective in removing particulate material. This polished condensate water is then delivered through the feedwater heater section, where steam from the various turbine sections is used to preheat the feedwater prior to its return to the reactor vessel. Water in the reactor vessel that is not vaporized as steam is recirculated through a recirculation pipe and pump system back to the bottom of the reactor core, where it is fed upward through the core for cooling the fuel elements.

In considering the generation of corrosion products within a BWR in Fig. 47, a reasonable starting point is in the hot well. Here in the condensate, the primary species will be Fe_2O_3, which is produced primarily from steam impingement on the walls of the hot well. In addition, dissolved forms of other metallic species can be present, particularly from the condenser tubes, which may contain zinc, copper, aluminum, and other elements different from those found in the stainless steel used throughout the rest of the system.

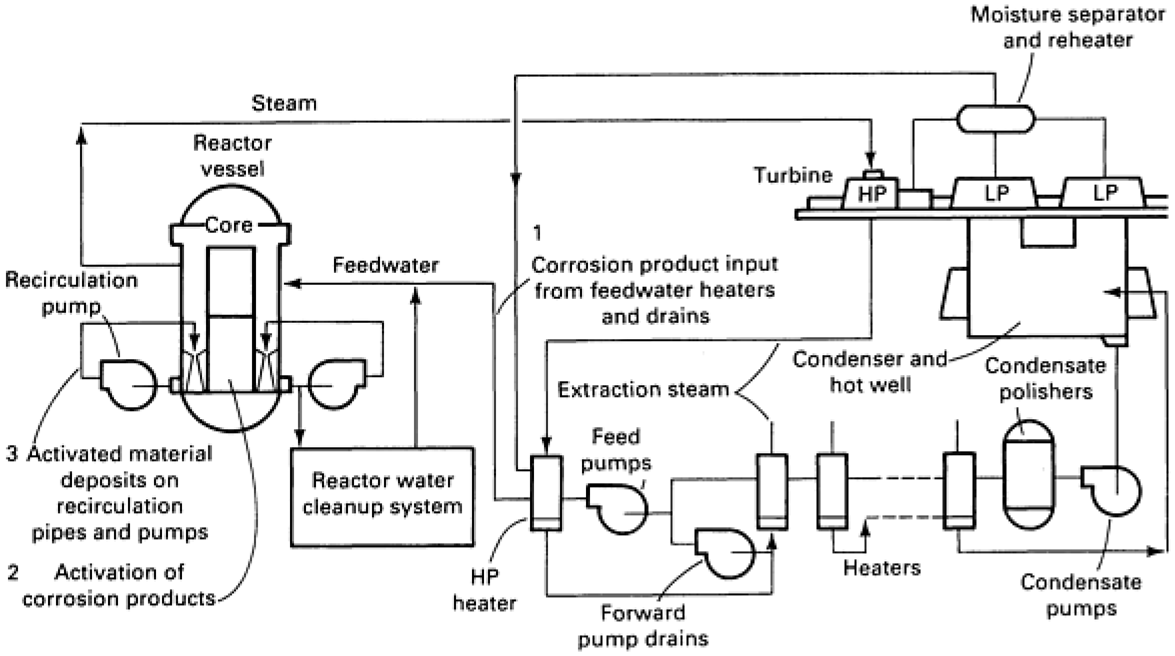

Fig. 47 Diagram of BWR circuit showing origin of radioactive contamination. HP, high pressure. LP, low pressure. Numbered areas indicate sequence of events.

The chemistry of the water exerts significant influence over the form and the amount of the corrosion products present. In the BWR, there are generally no additives. The objective is to keep the water as pure and clean as possible. The result is a neutral water chemistry with regard to pH and an intention of keeping the conductivity as low as possible. The latter is a measure of the impurities present in the system. In addition, as the water passes through the core, radiolysis (the dissociation of molecules by radiation) occurs, causing a small portion of the water molecules to be decomposed into its constituent elements--hydrogen and oxygen. The presence of these gases plus small amounts of air in-leakage, which occurs mostly in the region of the condenser and hot well, create an oxidizing condition in the cooling water.

The condensate polisher serves to remove impurities that are present in the condensate in the hot well. It generally performs its function quite effectively. The accepted measure of its effectiveness in the BWR is the conductivity of the outlet of the polisher.

As the feedwater proceeds up along the feedwater train, some of the impurities will deposit on surfaces and corrosion and other processes will cause materials to be leached from the system surfaces to the water. In addition, in some plants, the condensate in some of the feedwater heater drains is forward pumped into the system. That is, the drains are pumped directly into the feedwater lines at an appropriate point for the purpose of increasing thermal efficiency of the nuclear power plant. In so doing, this forward-pumped water has bypassed the condensate polisher, meaning that its impurities have not been removed by such a system. The result of all these processes is that at the final feedwater location, where the water is pumped into the reactor vessel, there is a concentration of impurities. The primary constituent will still be Fe_2O_3, but the presence of cobalt, nickel, copper, and zinc can influence the subsequent processes that determine radiation field buildup on pipe surfaces.

Hematite is the primary constituent of the deposit on the fuel surfaces. It also acts as the absorption medium for other constituents, including copper, zinc, and cobalt. For the BWR, ^{60}Co is the primary constituents of radiation fields, which generally contributes more than 95% of the radiation fields coming from plant surfaces. In addition to being present as an impurity in stainless steel, which makes up almost all the surface area outside of the Zircaloy core cladding, cobalt is present in small surface area cobalt-base alloy materials used in valves, pumps, and control rods. Table 7 shows the distribution of cobalt sources within a BWR.

Table 7 Estimates of principal sources of ^{59}Co for a BWR

System/component/alloy	^{59}Co input, g/yr
Forward-pumped heater drains	
Main steam valves + HP Turbine	95
Other valves	22
Nickel in carbon steel	2
Stainless steel	11
Total	**130**

Control blade pins/rollers	29
Jet pumps	23
Recirculating system valves	18
Stainless steel + nickel-chromium-iron alloy corrosion	7
Control rod drives	8
Total	**85**
Total	**224**
Off-line valve maintenance	30-90

Cobalt-60 has a relatively long half-life of 5.27 years. This means that any ^{60}Co generated in the system that is incorporated in the growing corrosion film on system surfaces will influence radiation fields in the system for quite a few years unless it is removed from such surfaces. The currently accepted model for corrosion product incorporation in a growing corrosion film on stainless steel surfaces is illustrated in Fig. 48. This illustration shows the particles of Fe_2O_3 and ^{60}Co being deposited on the surface and slowly incorporated in the growing thin film on the stainless steel. Steps 3

and 4 then show the development of the two layers and the corresponding ionic diffusion processes, finally resulting in an outer layer of Fe_2O_3 with an inner layer of Fe_3O_4. The Fe_3O_4 is generated in the oxygen-depleted region near the surface of the stainless steel.

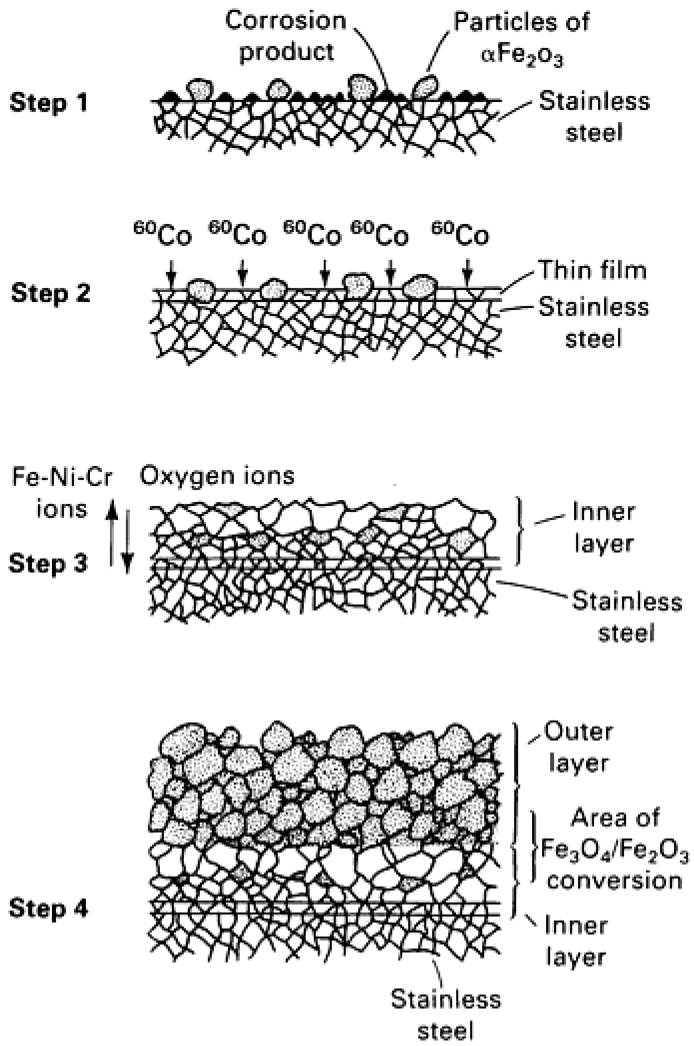

Fig. 48 Crud growth model for BWRs

The ^{60}Co and other impurity ions that are present in very low concentrations could be incorporated into this film in a variety of ways, including adsorption, crystallization, precipitation, and substitution. However, their presence is in such low concentration that chemical analyses have thus far been unable to determine the particular form of the ^{60}Co in this film.

It is important to note that the ^{60}Co is not in a volatile form and therefore stays in the water in the region near the reactor core. This means that the turbine, hot well, condenser, and feedwater systems are not significantly contaminated by this radioisotope or any other for that matter. Radiation fields in a BWR are predominantly, and almost exclusively, from the reactor pressure vessel, recirculation pipes and pumps, and the surfaces of the reactor water cleanup system.

Pressurized Water Reactors

In the PWR, higher pressure is sustained in the system; this prevents gross boiling so that the system is maintained liquid. The water is cooled by its passage through steam generator tubes. These tubes are made of Alloy 600 in U.S. PWRs.

Secondary-side coolant on the outside of these steam generator tubes boils, creating steam that is used to turn the turbines in the system. In the primary circuit, after the water has passed through the steam generator tubes and through the pump, it is driven back through the core, where it is heated again. The interconnecting piping and the cladding of the pressure vessel are all of stainless steel. Therefore, in the PWR, the major surface areas are the zirconium alloy of the fuel cladding and the Alloy 600 of the steam generator tubes, with a secondary surface area of stainless steel. This system is illustrated in Fig. 49.

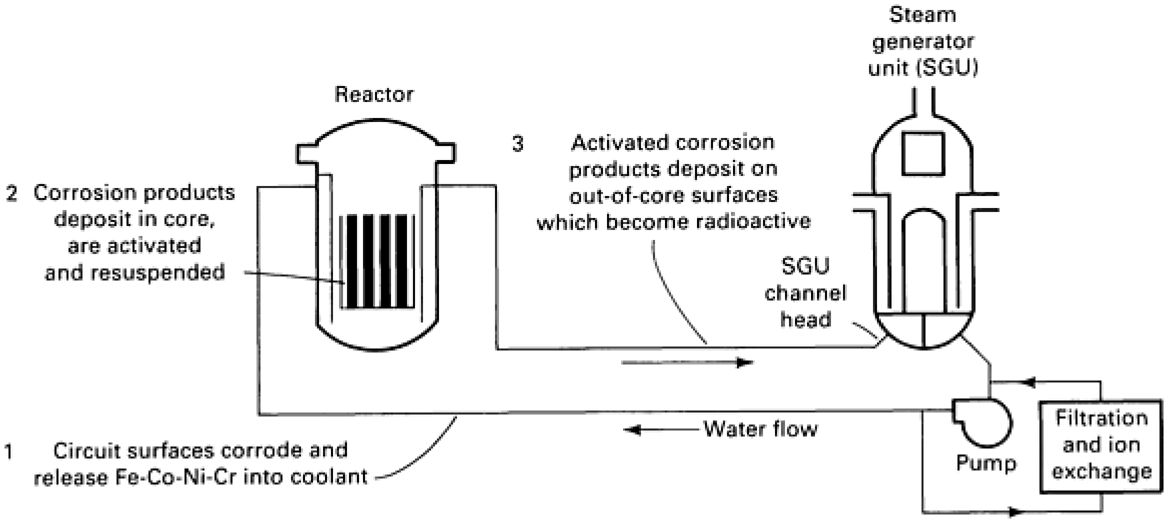

Fig. 49 Diagram of a PWR primary circuit showing the origin of plant-surface radioactive contamination. Numbered areas indicate sequence of events.

The water chemistry of the system is distinct from that in the BWR. In the PWR, boric acid is added as a neutronic control, and LiOH is added to create a basic pH condition in the primary loop coolant. In addition, a hydrogen overpressure is maintained on the coolant circuit, which creates a dissolved hydrogen concentration sufficient to recombine with the oxygenating species formed by radiolysis within the core. This creates a reducing condition in the PWR primary coolant.

The primary constituents released from the corrosion of the surfaces present in the PWR are iron and nickel. This fact, combined with the reducing condition present in the primary coolant, results in a deposit on the fuel that is nickel ferrite, where nickel replaces one of these iron atoms in Fe_3O_4 in a fraction of the lattice positions. Nickel will commonly replace one of the iron atoms in Fe_3O_4 in 30 to 60% of the molecules. Similar to the BWR, cobalt occurs within this deposit on the fuel. As a result of the presence of both cobalt and nickel on the fuel, ^{58}Co and ^{60}Co are both significant sources of radiation in the PWR system. Cobalt-58, however, has a much shorter half-life of 71 days and consequently is not retained from one refueling outage to the next as is ^{60}Co, but will be newly generated from fuel cycle to cycle.

The transport processes that conduct the cobalt radioisotopes to the out-of-core surfaces are similar to those for the BWR except that in the PWR, dissolution and precipitation probably play a much more significant role. These radioisotopes, however, will be transported to the out-of-core Alloy 600 and stainless steel surfaces, where they are incorporated in the corrosion product film as it develops on those surfaces.

The most significant region in the PWR for radiation control is within the channel heads of the steam generators. This is the region where maintenance and nondestructive examination of steam generator systems takes place. Consequently, this is also the region where most of the radiation exposures associated with primary circuit maintenance occur.

Radiation Control Techniques

There are a number of techniques that have been developed over the last few years that permit the operators of nuclear power plants to effect a reduction in the rate of buildup of radiation fields within their plants. These fall into four categories: water chemistry control, materials selection, surface treatment, and decontamination.

Water Chemistry Control. In BWRs, as was previously mentioned, the control of the amount of iron in the coolant is a key to reducing the deposition on the fuel and subsequent radiation field buildup. Control of the iron in the coolant is determined by the operation of the condensate polisher. The electrical conductivity of the water is used as the measure of determining how effective the condensate polisher is performing and is an indicator of any change in the performance of the polisher. Similarly, the reactor water cleanup system provides a kidney-type purification circuit for the water in reactor vessel.

Dissolved oxygen also plays a role in BWRs. It has been determined that extremely low concentrations of oxygen, below of the order of 20 ppb, forms a corrosive that is very easily released form the steel surface. Consequently, it has been found desirable in BWRs to maintain the oxygen in concentration in the feedwater lines of 20 to 200 ppb.

Recent information indicates that certain metallic constituents can significantly influence the sites available for cobalt in the growing crystal lattices. In particular, the presence of zinc in the water has been found to interfere with the absorption of cobalt ions into the growing film. Consequently, small concentrations of zinc of the order of 5 to 10 ppb can reduce the deposition of ^{60}Co on pipe surfaces and therefore reduce the radiation field buildup in BWRs.

In PWRs where precipitation and dissolution from fuel surfaces have been shown to be a significant influencing factor in radiation field buildup, the pH of the coolant can be controlled in a manner to reduce the amount of precipitate on the fuel surfaces. LiOH that is added to the coolant is controlled so that as the boric acid is reduced through the fuel cycle, the LiOH is similarly reduced to maintain constat pH throughout the cycle. When this pH is high enough, in the region of 7.1 to 7.4 at operating temperatures, the thermodynamics of the solubility of nickel ferrite are such that nickel ferrite will not precipitate on the fuel at this pH. This reduction in the fuel deposition concurrently reduces the generation of cobalt isotopes and the subsequent buildup of radiation fields in the steam generator and on other surfaces.

Materials Selection. High-cobalt alloys are present in most nuclear reactor systems, usually in valves, pumps, and control rods. New materials containing low amounts of cobalt or no cobalt are being developed that are designed to serve the function of the high-cobalt alloys. These materials are currently in testing stages to show that their performance is sufficient for what is needed within the power plants. Some changes have already taken place, such as the replacement of pins and rollers in BWR control blades, which were previously of high-cobalt alloys and are now made of low-cobalt alloys. Such replacements offer significant opportunity for radiation field reduction in the future from ^{60}Co.

Surface Treatment. As both BWRs and PWRs are experiencing component replacements (recirculation pipes on the former and steam generators in the latter), the condition of the surfaces of these new components is also a consideration. Electropolishing has been shown to reduce the effective surface area up to a factor of five on pipe on steam generator surfaces. This is accomplished by trimming off the asperities present on the surfaces, thus creating a more uniform surface finish.

Decontamination solvents have been developed that are quite effective in removing the radioisotopes in the oxide layers that are present in previously operated nuclear power plants. These are used particularly when major maintenance and repair work is conducted on a piece of equipment that has very high radiation fields associated with it. Such decontamination can afford a utility an opportunity to make use of recently developed procedures, such as chemistry control or electropolishing, to reduce the subsequent radiation field buildups on the component.

SCC in Steam Turbine Materials

Floyd Gelhaus, Electric Power Research Institute

Stress-corrosion cracking is the fracture of a metal that results from the joint action of tensile stresses and a corrosive environment. Crack initiation and propagation are also dependent on metallurgical parameters (Ref 107). Cracking has occurred in both reheat and nonreheat turbines, in quenched-and-tempered 3.5NiCrMoV, and normalized-and-tempered 2.5NiCrMoV steels with a wide range of grain sizes. A typical intergranular crack is shown in Fig. 50. A single

compilation of laboratory and field data, in conjunction with an annotated bibliography of more than 200 references, was published in 1984 (Ref 108).

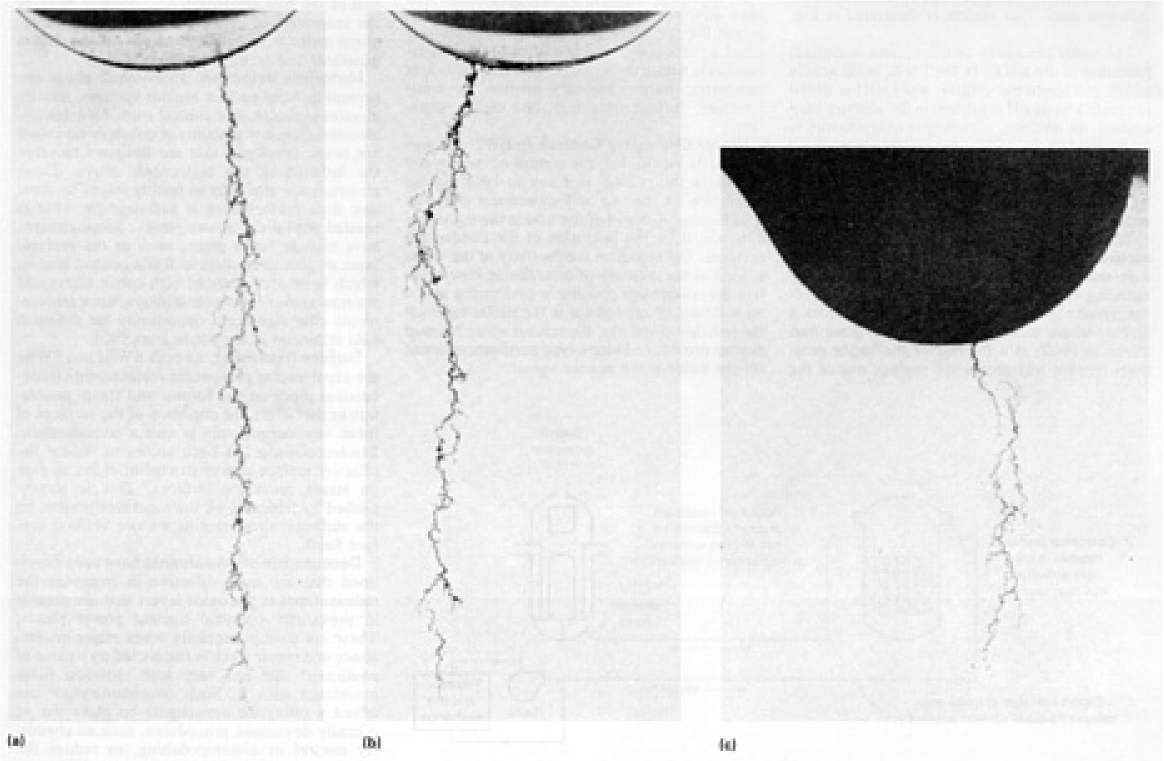

Fig. 50 Typical keyway intergranular stress-corrosion crack. Sections are orientated normal to the length of the keyway at different distances from the outlet face. (a) 28 mm (1.1 in.). (b) 10 mm (0.4 in.). (c) 75 mm (3 in.). Source: EPRI Report NP-3341

Parameters of Influence

Stress. Until the introduction of the 500 + Mg (550 ton) monoblock rotor by Japanese steel manufacturers in the late 1970s, the large low-pressure steam turbine rotors that are utilized in nuclear power plants were fabricated by one of two techniques. Brown Boveri Company in Switzerland pioneered the welded rotor, in which several large disks are joined at the low-stress outer diameter with a sequence of gas tungsten arc and shielded arc welding processes. Other manufacturers, including the General Electric Company (Fig. 51) and the Westinghouse Electric Company (Fig. 52), have used the technique of thermally shrinking disks onto a stepped-diameter shaft, keying each disk/shaft interface to prevent independent rotation (Fig. 53 and 54). In addition to creating a zone of high local stress, the shaft keyways are flow/no-flow locations that promote the capture of chemical species. The welded rotor has no keyways. Since the catastrophic rupture of a shrunk-on disk at the Hinkley Point A Nuclear Station in England in September 1969 (Ref 109, 110), considerable attention has been given to understanding disk cracking and this potential failure mode.

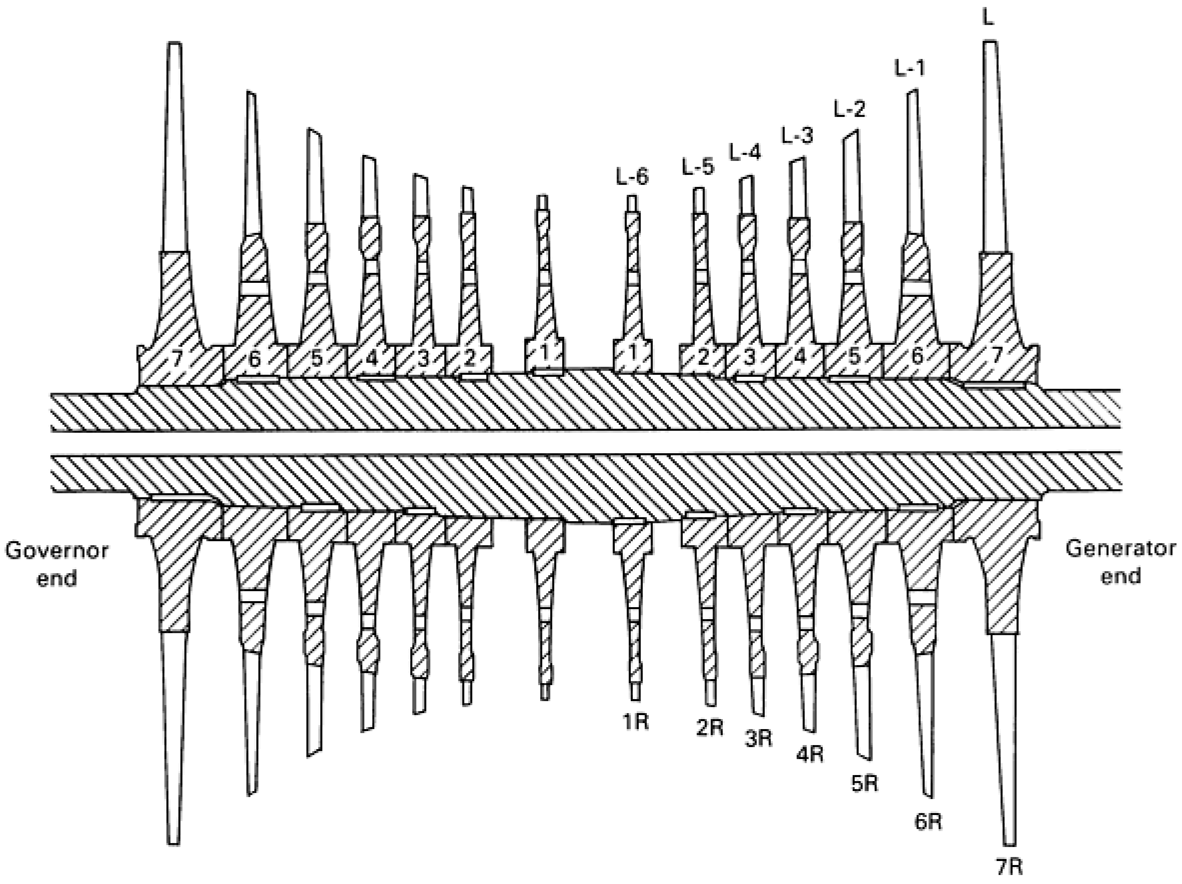

Fig. 51 Schematic of General Electric low-pressure turbine rotor. All disks are shrunk on, with one blade row per disk. Source: EPRI Report NP-2429-LD, Vol 6

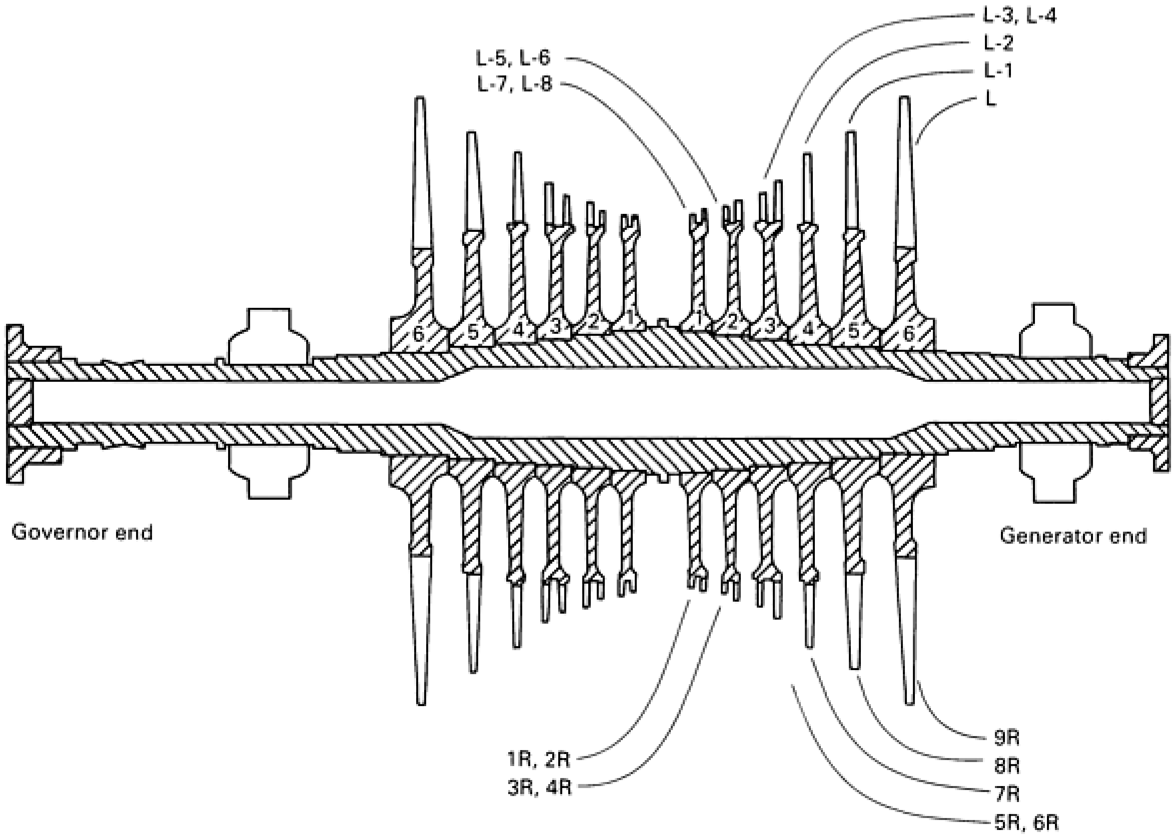

Fig. 52 Schematic of Westinghouse low-pressure turbine rotor. All disks are shrunk on, and the number of blade rows per disk is as indicated. Source: EPRI Report NP-2429-LD, Vol 6

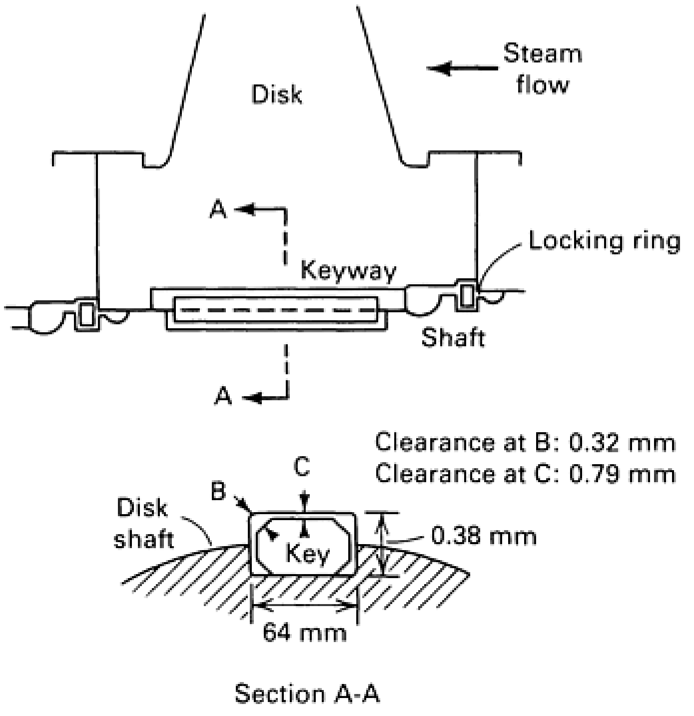

Fig. 53 Schematic of keyway design reportedly used by General Electric in shrunk-on disks of low-pressure turbine rotors. Source: EPRI Report NP-2429-LD, Vol 6

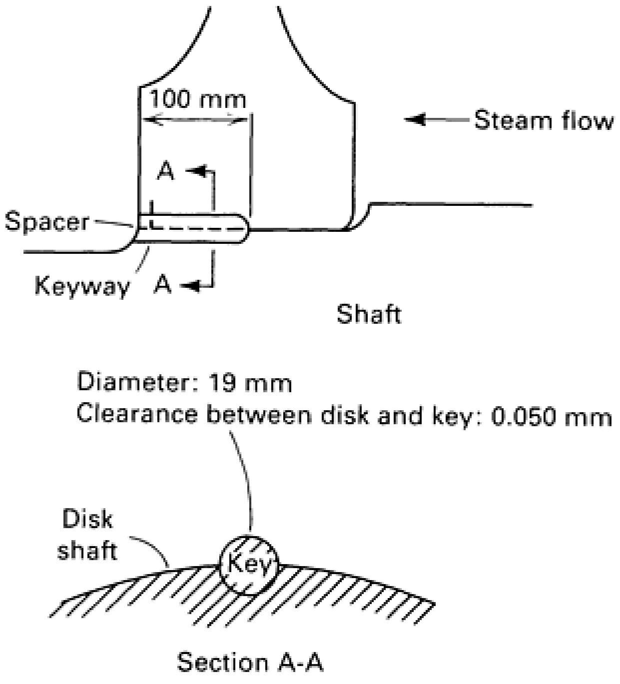

Fig. 54 Schematic of keyway design reportedly used by Westinghouse in shrunk-on disks of low-pressure turbine rotors. Source: EPRI Report NP-2429-LD, Vol 6

Cracking has occurred not only in keyways but also on the bore surfaces, hub faces, web faces, and in the rim attachment area of shrunk-on disks (Fig. 55). Also, cracks have been found on the web faces and in the rim blade-attachment area of the integral disks of monoblock rotors. Monoblock and welded rotor configurations eliminate the keyway as a crack-starter location, but cracks persist in the rim blade-attachment area (Fig. 56).

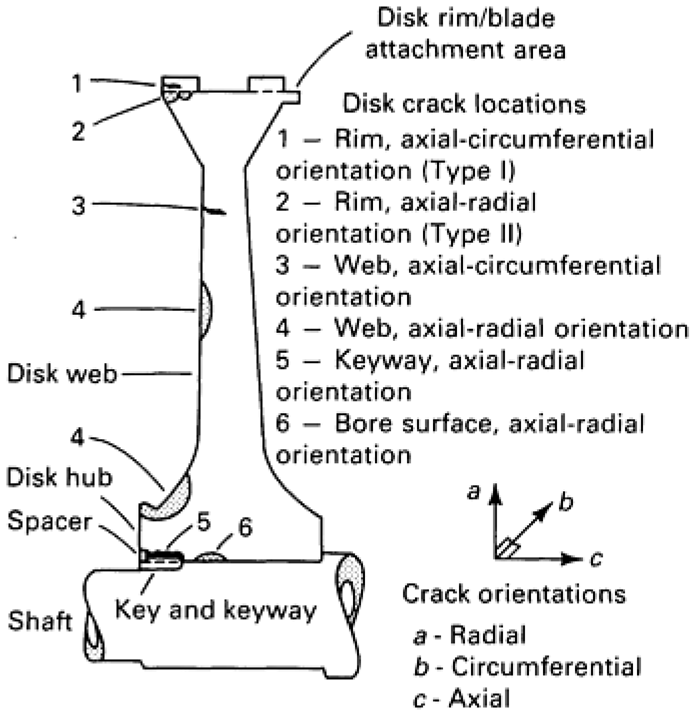

Fig. 55 Schematic showing typical locations and orientations of cracks in various U.S. low-pressure rotor disks. This illustration is of a shrunk-on disk with a semicircular keyway and an axial-entry fir-tree rim attachment

configuration. Disks of this type have experienced cracking at all of the locations illustrated except at the central web in the axial-radial orientation and on the web below the rim (location 3). Cracks at the latter two locations have been found in integral disks. Source: EPRI Report NP-2429-LD, Vol 1

Locations and orientations of rim attachment cracking experienced in various rotors are illustrated. (a) Axial-entry fir-tree. (b) Notch-entry dovetail. Source: EPRI Report NP-2429-LD, Vol 1

Material. Most modern U.S. turbine rotors use 3.5NiCrMoV steel, conforming to the requirements of ASTM A471 (Class 1 through 9). Yield strength variation with tempering temperature is shown in Fig. 57, and the A471 temperature boundary for all classes (>839 K, 565 °C, or 1050 °F) is specifically noted. Chemical compositions for A471 Class 6 and A470 Class 5 are shown in Table 8.

Table 8 Chemical specifications for representative steels used in modern U.S. low-pressure rotors with integral and shrunk-on disks

Element, wt%	ASTM A470 Class 5 steel for integral rotor disks	ASTM A471 Class 6 steel for shrunk-on rotor disks
Carbon (max)	0.28	0.28
Manganese	0.20-0.60	0.70 max
Phosphorus (max)	0.015	0.015
Sulfur (max)	0.018	0.015
Silicon (max)[(a)]	0.10	0.10
Nickel	3.25-4.00	2.00-4.00
Chromium	1.25-2.00	0.75-2.00
Molybdenum	0.25-0.60[(b)]	0.20-0.70
Vanadium	0.05-0.15	0.05 min

Source: EPRI Report NP-3634, Vol 2

(a) Modern U.S. turbine rotor disks are made from vacuum-deoxidized steels for which the silicon limit is 0.10%. For nonvacuum-deoxidized steels. A470, Class 5 allows a silicon range of 0.15-0.30%, and A471, Class 6 allows a silicon range of 0.15-0.35%.

(b) If desirable because of operating temperatures, a minimum molybdenum content of 0.40% may be specified by the purchaser.

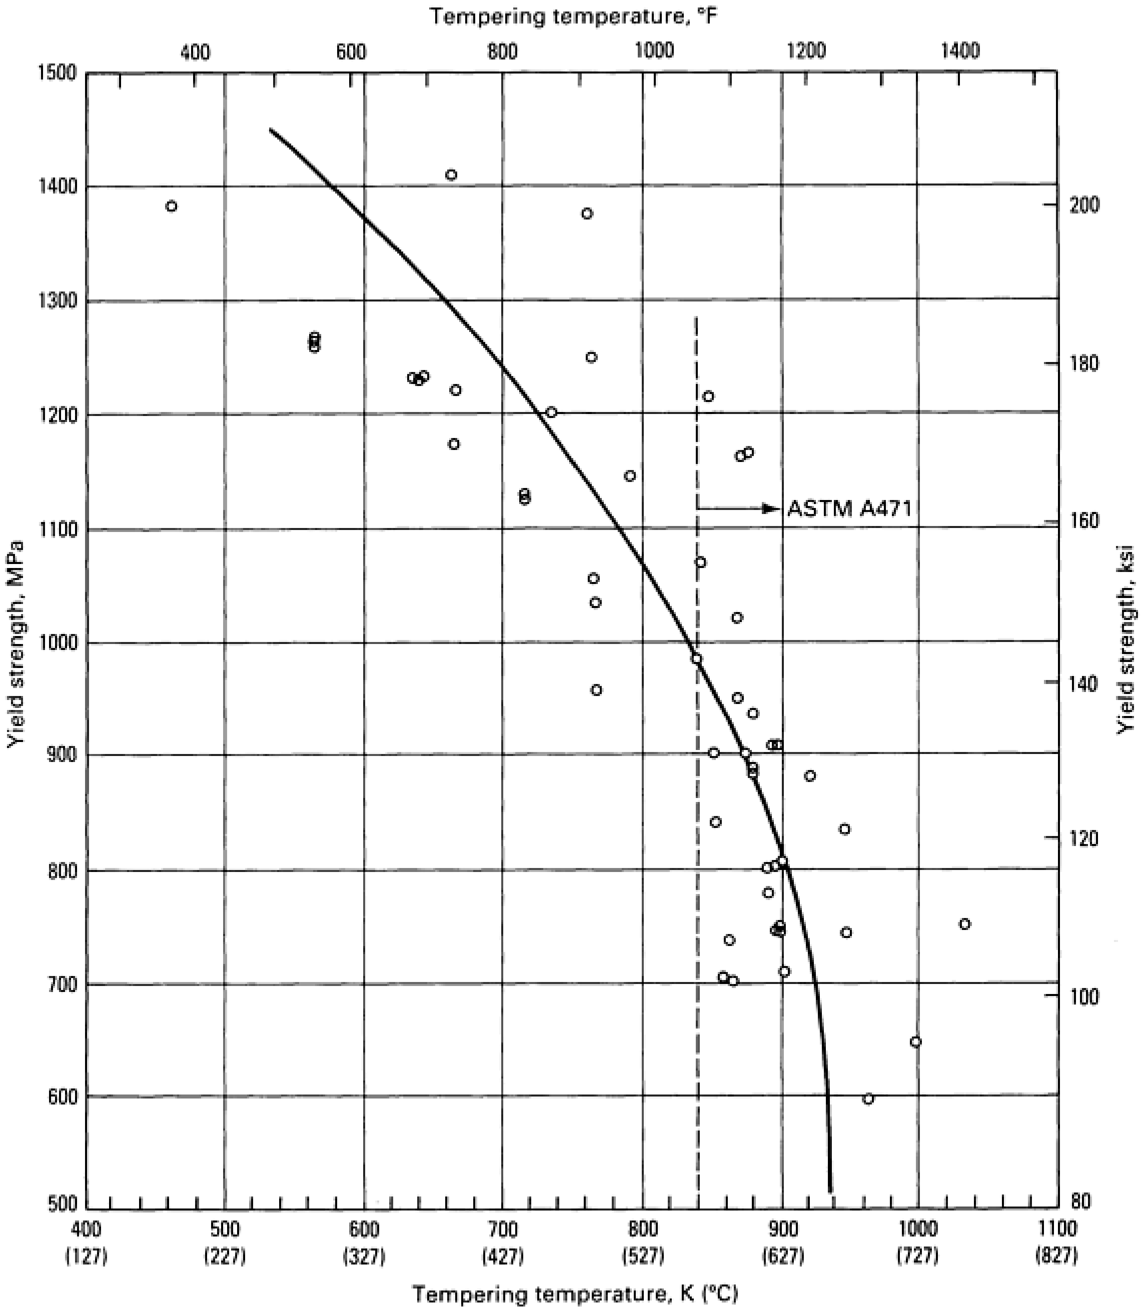

Fig. 57 Yield strength versus tempering temperature for low-alloy steels. Source: EPRI Report NP-4056

Early correlations of crack growth rate data revealed a dependence on yield strength and an inverse dependence on temperature. This equation is generally expressed as:

$$\ln \dot{a} = C_1 - \frac{C_2}{T} + C_3 s_y \quad \textbf{(Eq 14)}$$

where $\dot{a}$ is the crack growth rate. T is the disk operating temperature, s_y is the room-temperature yield strength, and C_1, C_2, and C_3 are fitting constants. A recent analysis identified two new key variables: composition and tempering temperature (Ref 111). The latter variable does not exhibit a strong effect for materials meeting A471 tempering temperature/yield

strength standards, and for these, the correlation with yield strength is sufficient. However, for NiCrMoV and other low-alloy steels, tempering temperature is a key variable, with a stronger but separate effect on crack growth rate as compared to yield strength.

Regarding composition, manganese was indicated by this analysis to be a strongly correlated variable, and Eq 14 was modified to include that effect by adding a C_4Mn term, using the weight percent of manganese. This manganese dependence should be interpreted as an unresolved manganese/nickel/vanadium effect, because nickel and vanadium were highly correlated with manganese. Sulfur concentration was also identified as a key variable, but no model containing a sulfur term was calibrated to the data. For the two-, three-, and four-variable model, Eq 14 is:

$$\ln \dot{a} = -8.8 - (4040/T) + 0.0231\, s_y \quad \textbf{(Eq 15a)}$$

$$\ln \dot{a} = -4.74 - (9270/T) + 0.3337\, s_y + 4.5\text{Mn} \quad \textbf{(Eq 15b)}$$

$$\ln \dot{a} = -4.74 - (9270/T) + 0.3337\, s_y + 4.53\text{Mn} \quad \textbf{(Eq 15c)}$$

$$\ln \dot{a} = -7.04 - (9270/T) + 0.0337\, s_y + 4.53\text{Mn} \quad \textbf{(Eq 15d)}$$

where $\dot{a}$ is given in inches per hour, *T* is in degrees Rankine, s_y is in kips per square inch, manganese (Mn) is in weight percent, and T_t, the tempering temperature, is in degrees Kelvin. Three of the Eq 15b constants were forced not to change when including the T_t term; Eq 15c permits a variety of low-alloy steels (single or multi-heat) to be analyzed on a common basis.

Laboratory experiments to determine the effect of the segregation of phosphorus to the grain boundaries have shown little effect of this impurity on SCC at high stress levels (Ref 112, 113). All specimens in both experiments failed in less than 500 h. When the test solution is neutral, segregated phosphorus has no effect on the resistance of an alloy to SCC. The response to a highly caustic solution (9 M NaOH) was, however, dependent on the applied potential, changing from a strong increase in the cracking susceptibility at -400 mV (Hg/HgO) to no effect at -800 mV (Hg/HgO).

Environment. Potential is a thermodynamic parameter that is a measure of the energy of a chemical reaction. It is a measure of the oxidizing power of a solution. For a corrosion reaction, potential is a measure of the energy necessary to cause a metal atom to be transferred from the metal lattice into solution as a metal ion. Both temperature and pH can either raise or lower the potential of a corrosion reaction, depending on the species involved and on other factors.

With no applied voltage, the rate of metal atom transfer would reach equilibrium, and those chemical processes would establish the free corrosion potential. To investigate the range of possible chemical reactions, a variable voltage is applied, and a polarization diagram is generated.

Figure 58(a) shows an anodic polarization diagram for a metal-solution combination that forms a protective corrosion layer (passivation film) over a range of potentials (E_{pr}). Figure 58(b) includes a second area of anodic activity ($E_{crit(2)}$), a phenomenon that can be associated with a redox reaction or with the dissolution of a second element, such as chromium, in low-alloy steels.

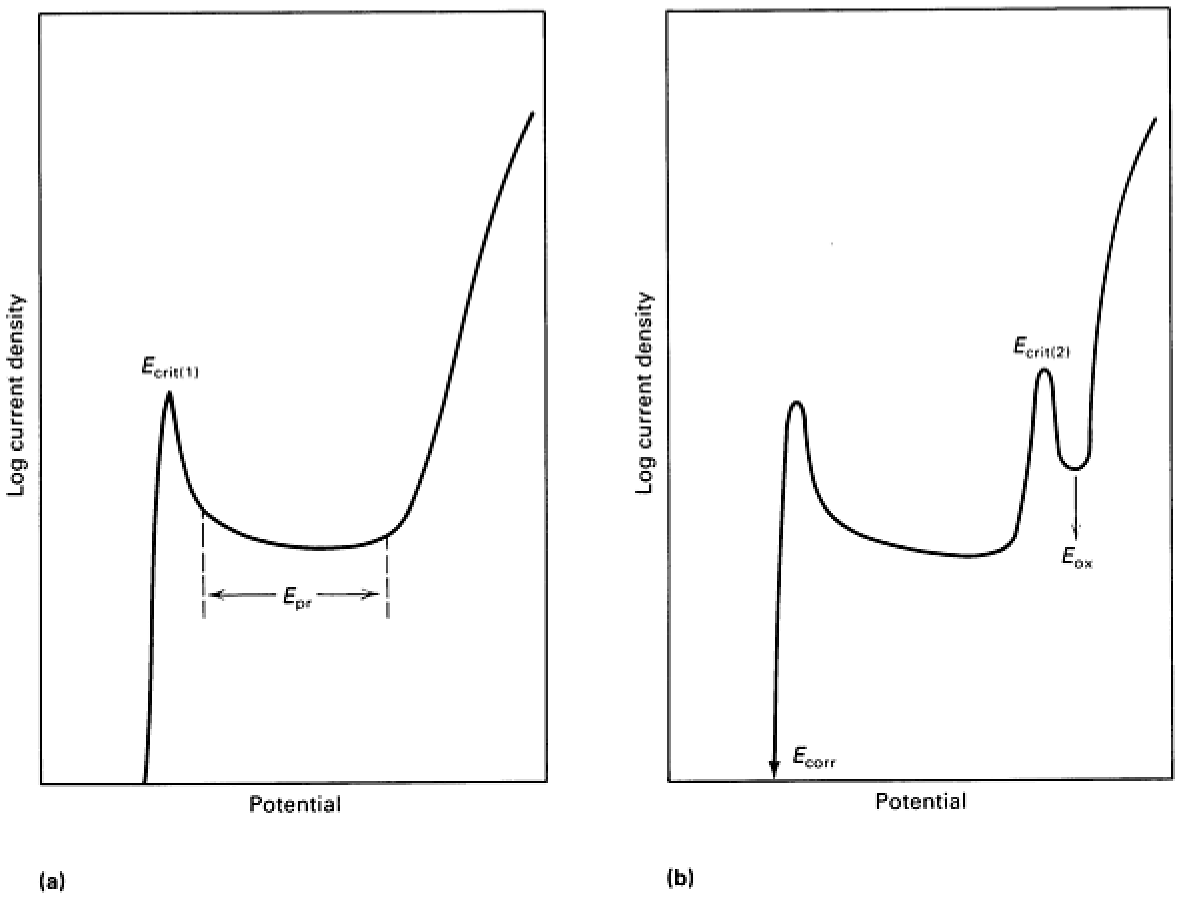

Fig. 58 Schematic of anodic polarization curves for (a) a metal that forms a protective layer and (b) an alloy that includes a second passivation peak where E_{corr} is the corrosion potential, E_{crit} is the critical potential of passivation, E_{ox} is the oxygen evolution potential, and E_{pr} is the passive potential range.

The importance of pH is shown by the curves in Fig. 59(a). The additional protection offered by neutral-to-higher pH in this example generally holds true for all the metals-environment combinations in steam turbines (type 403 stainless steel is used for turbine blades); therefore, the working fluid pH is held neutral for BWRs and between 8.9 and 9.6 for PWRs.

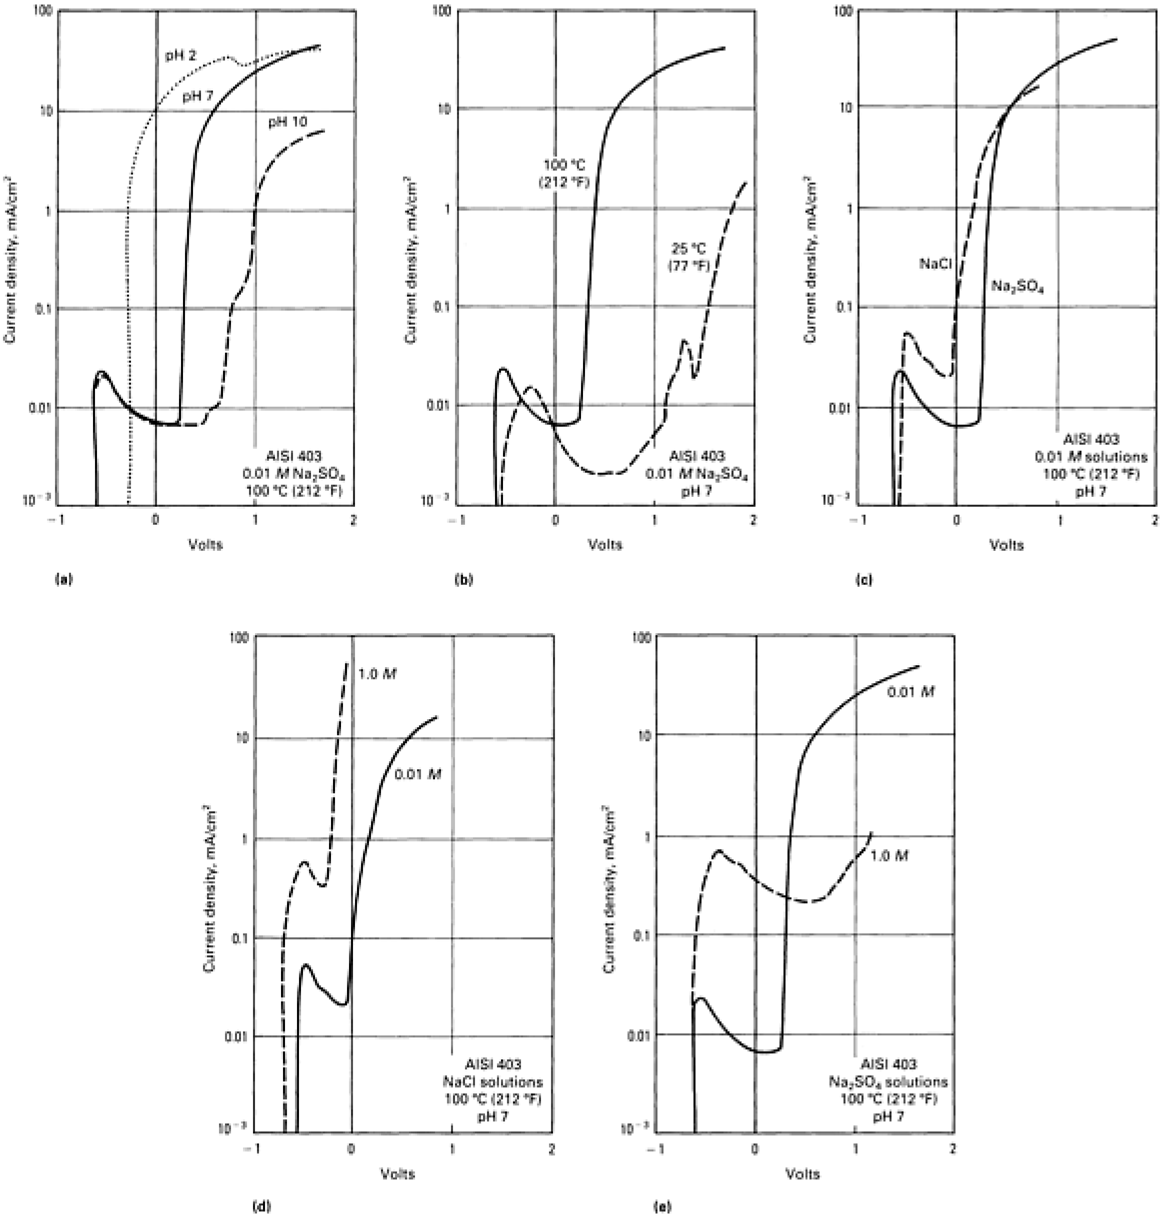

Fig. 59 Anodic polarization curves for type 403 stainless steel showing the effects of solution pH (a), temperature (b), different neutral pH solutions of the same molar concentration (c), sodium chloride (NaCl) solution concentration (d), and sodium sulfate (Na_2SO_4) solution concentration (e). In each of these figures, the current density is proportional to the corrosion rate.

Figure 59(b) shows the influence of temperature at the neutral pH 7. The corrosion potential becomes more negative with increasing temperature. The lower temperature allows the protective layer to remain intact over a much larger range of potential. It is important to note that, although type 403 stainless steel does suffer pitting (for example, at pH 10 in a solution of NaCl), the alloy tempered at 650 °C (1200 °F) is quite resistant to SCC.

The potential is most strongly influenced by the kind and concentration of species in solution, causing marked shifts in the corrosion rate (that is, the current density). Figure 59(c) shows how the polarization curve shifts with species kind, and Fig. 59(d) and 59(e) indicate the influence of concentration for the same species. The different behaviors exhibited by these latter curve sets are evidence of the complexity of the corrosion processes and point out that the behavior of an alloy in service is difficult to state in general terms, because the service environment is often complex and ill-defined. However, the general trends from laboratory tests help define what service conditions are required to get to observed response. For intergranular SCC, polarization curves for bulk alloys are helpful, but the real need is for data showing how grain-boundary compositions behave.

Laboratory Tests

Considerable data were obtained by U.K. experimenters following the failure at Hinkley Point, but most of this was generated using 3CrMo steel. Later work in the U.S. focused more on the 3.5NiCrMoV alloy, but much of these data were taking using strong caustic environment (35% NaOH). Table 9 summarizes the results of these earlier experiments. Analyses of these data show that several environments--for example, >1% NaOH, aerated/oxygenated water--produced higher crack growth rates than were estimated from the field data; models that are derived to help a utility predict the lifetime of turbine components (Eq 15a, 15b, 15c, and 15d) have to be based on laboratory data that approximate field conditions.

Table 9 Collation of crack growth rates from precracked wedge-opening load specimens

Steel and condition	Environment	Temperature		Yield strength(a)		Potential, mV	Stress intensity		Crack growth rate

In-Plant Conditions

The majority of U.S. PWR power plants control steam generator water pH using phosphates (Na_3PO_4) or all-volatile treatment, that is, control by ammonia (NH_3) or by amines such as morpholine (C_4H_9NO). The major advantage for phosphate treatment is its capacity to buffer against both acidic and basic upsets, a protection only weakly afforded by the amines. The volatile amines introduce no solids into the system, whereas the salts added in the phosphate method can accumulate and concentrate. No chemical additions are made to control feedwater pH in BWR power plants.

Oxygen levels in power plant feedwater are controlled by adding scavenging chemicals (hydrazine, N_2H_4) or by mechanical means. Only two U.S plants currently use a feedwater deaerator, with most using only air ejectors on the deaerating section of the condensers. In BWRs, the reactor water oxygen level can reach several parts per million during start-up. Chemical upsets can be initiated by a condenser tube failure, and the analyses of chemicals that can be introduced is shown in Table 10. Air in-leaking rates of 2800 L/min can be experienced with severe condenser leaks, while a rate one-tenth that levels is common. With 500 L/min in-leakage, the oxygen concentration in the condensate can increase to 30 ppm. Powder resin filters and deep bed demineralizers are two common full-flow condensate polishing systems used in U.S. plants. However, if not properly operated/regenerated, these systems can become sources of ionic impurities.

Table 10 Typical cooling water analyses

Table 11 shows typical power plant data, and such data are used to infer the concentration in the steam reaching the turbine systems. Because the solubility of salts in steam decreases as temperature and pressure are decreased, solubility limits are exceeded at some stage with the expansion of the steam in the turbine. The thermodynamic data required to predict the exact conditions under which various salts will deposit are not available. However, scrapings taken from turbine surfaces indicate that condensation to form concentrated solutions in the crevice areas (keyways, blade attachments) does occur and that SCC is a typical result. Field data on crack growth rate are comparable with lab data using deaerated water, steam, carbonated water, and 1% NaOH + 0.1% NaCl (Ref 53).

Data Analysis Results

Equation 15a, 15b, 15c, and 15d gives the relationship between crack growth rate and key material/environmental parameters. Those relationships were developed using both laboratory and field data. Failure rate analysis of the field data show that rim crack growth rates are higher than the rates for cracks located at the keyway but, for an equivalent number of operating hours, that the keyway is the preferential cracking site. Figure 60 shows these data; rim, face, and bore data are combined because they are similar, and the three-parameter Weibull fit does indicate that this incidence of cracking increases slightly more rapidly than incidences of keyway cracking. A comparison of the two U.S. manufacturers of turbines used in nuclear plants is shown in Fig. 61. Although the cumulative fractions of rotors experiencing keyway cracking is equivalent for 3- to 9-year-old turbine systems, the data show a more rapid increase in failure rate with plant age in General Electric turbines. Figure 62 results from adding data from NEI Parsons (United Kingdom) and from AEG (South Africa), and the two hypothetical points assume that a crack in the oldest known Brown Boveri & Co. Ltd. (Switzerland) and in the Kraftwerk Union (Germany) rotors was discovered in mid-1984. The predicted failure rates for Brown Boveri & Co. Ltd. and Kraftwerk Union are lower than the observed rates for the other manufacturers.

Life Prediction Methodology

The key decision facing the turbine owner who has some reason to believe that disk cracks exist is whether to run, repair, or replace. Nondestructive examination indications may give evidence of a crack, but even the best techniques leave a large uncertainty in crack size and sometimes also in crack orientation. Nonetheless, a decision has to be made regarding the growth of this flaw. Some obvious questions include:

- Is it safe to continue to run with the crack growing?
- Is repair necessary while a new disk is on order (a whole stage of blades is often removed, and a pressure drop plate inserted, and the turbine run at a much reduced output?
- Is immediate replacement called for because the suspected flaw is near critical size?

Life estimation calculations are made to provide insight for this complex decision. These predictions require input concerning the crack growth rate (which requires material and environmental information), the stress levels as a function of operational conditions (changing thermal and load boundary conditions) within the geometry containing the crack, applicable stress concentration factors, the initial flaw size, shape, and orientation, material fracture toughness, and stress intensity expressions.

Fortunately powerful numerical tools are available for these fracture mechanics life predictions (Ref 115) and can conveniently be used in conjunction with standard finite element temperature and stress distribution codes that calculate those conditions for the uncracked geometry. Simplifying assumptions/techniques are reasonable for most keyway cracking investigations. However, the blade attachment area requires a three-dimensional analysis. The nondestructive inspection techniques for the disk perimeter region are much less reliable than those for the bore the keyway. Also,

vibration can be present at levels sufficient to induce corrosion fatigue, introducing the need for a new set of material-environment data, most of which are not currently available. The step-by-step procedures for a life-time prediction analysis are given in Ref 114.

Solution Options

Remedies to eliminate and/or reduce SCC have been suggested and applied that focus on each of the three variables involved: stress, environment, and material. Both British and American manufacturers have offered designs that move the keyway from the disk/shaft interface to a lower-stress location along the common surface of adjacent disk faces (Fig. 63). Neither the new monoblock design nor the welded-rotor design has a keyway.

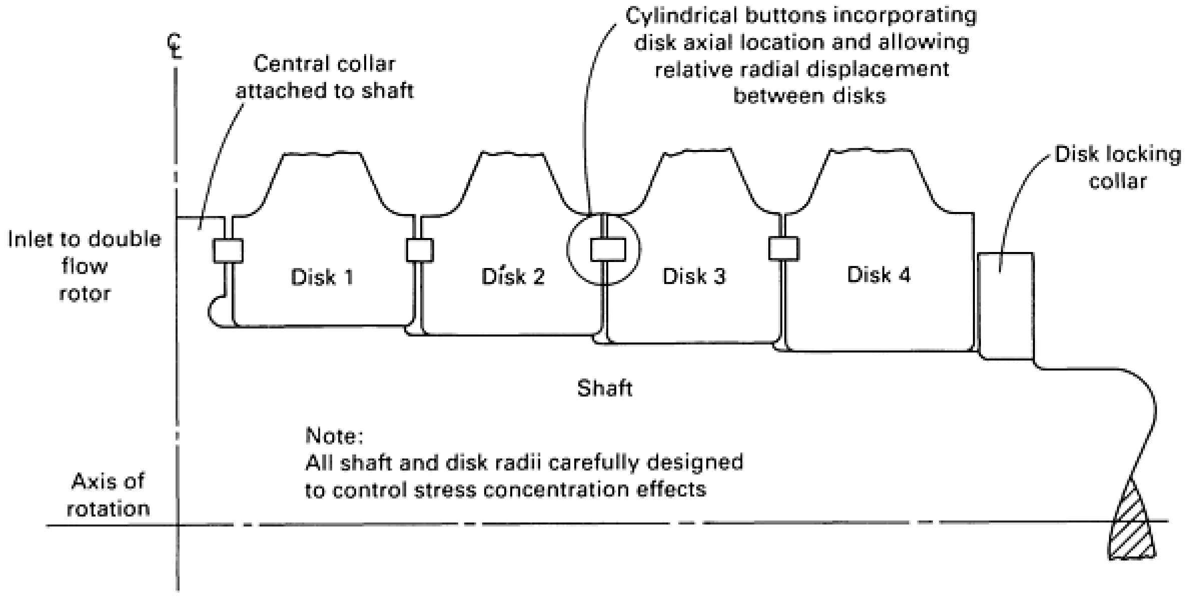

Fig. 63 Schematic of rehabilitated British rotor. Keyways have been moved from the shaft/disk interface to a lower-stress disk face position. Source: EPRI Report NP-2429, Vol 1

In producing the ingots required for the monoblock rotors, many significant metallurgical achievements have been demonstrated. Very low sulfur and phosphorus levels (for example, 30 ppm) are typical when using a combination of ladle refining and electric arc furnaces. Multiple heat treatments develop fine grain size after vacuum degassing has lowered both hydrogen (1 ppm) and oxygen levels (25 ppm). Although clean steel (Ref 116) SCC data are sparse, empirical data and analyses indicate better SCC resistance. This is particularly important, because blade attachments have not undergone a significant design change and remain as areas of SCC concern.

Significant advances have been made by U.S. plant operators toward better water chemistry control. Guidelines exist for both PWR and BWR configurations (Ref 117), and sophisticated online measuring instruments are available to track a wide variety of anions and cations. The magnitude of allowable condenser leak rates is now much lower, and considerable care is being given to the problem of resin/chemical carryover following regeneration of water cleanup systems. However, the rate of crack extension for the current generation of turbine materials is not 0 in even ultrapure water. Analyses of data and case histories have indicated that the elimination of keyways, lower attachment area stresses, and cleaner steels and environment have all contributed to the decrease observed in SCC events in steam turbines since 1985.

Effect of Nuclear Lubricants on Corrosion

Carl J. Czajkowski, Brookhaven National Laboratory

Lubricants are commonly used to prevent seizure/galling in threaded connections. They must allow easy disassembly of the connection and should aid in the control of the relationship between torque and clamping force.

Various failed components at nuclear power stations (turbine disks and bolts) have had the root cause of failure attributed to lubricant/coolant interactions in the reactor environment. The most commonly used lubricants for nuclear plant applications are solid-film lubricants. One of the primary reasons for using a solid-film lubricant versus an oil in power plant applications is the tendency for oil lubricants to dry out and oxidize at higher temperature; also, oils cannot withstand extreme pressures at low speeds and tend to permit seizing (Ref 118).

One additional use of solid-film lubricants is corrosion protection. This can be accomplished through the use of a baked-on lubricant coating applied to the component.

Lubricant-Related Failures

Turbine Disk Investigations. In-service failure of steam turbines at nuclear power stations not only cause the loss of hundreds of thousands of dollars a day to a utility due to extended shutdowns but may also cause damage to the safety systems of the plant. One instance of a catastrophic accident was the Yankee-Rowe failure. This unit first started commercial operation in June 1961. The failure occured during start-up of the unit, which had achieved 1800 rpm with 2% steam. The turbine disk, which was made of either ASTM A294 Class 3 or A471 Class 5 in the quenched-and-tempered condition, fractured and exploded into hundreds of pieces.

Examination of failed sections (Fig. 64) of the turbine disk disclosed numerous axial cracks running perpendicular to the circumferential direction of the hub. These thumbnail cracks (outlined in chalk in Fig. 64) were intergranular and had a tight, black adherent oxide associated with them. The bore of this turbine had been coated with a molybdenum disulfide (MoS_2) lubricant to facilitate disk assembly. This investigation concluded that the cause of the failure was a MoS_2/water/metal interaction resulting in intergranular SCC.

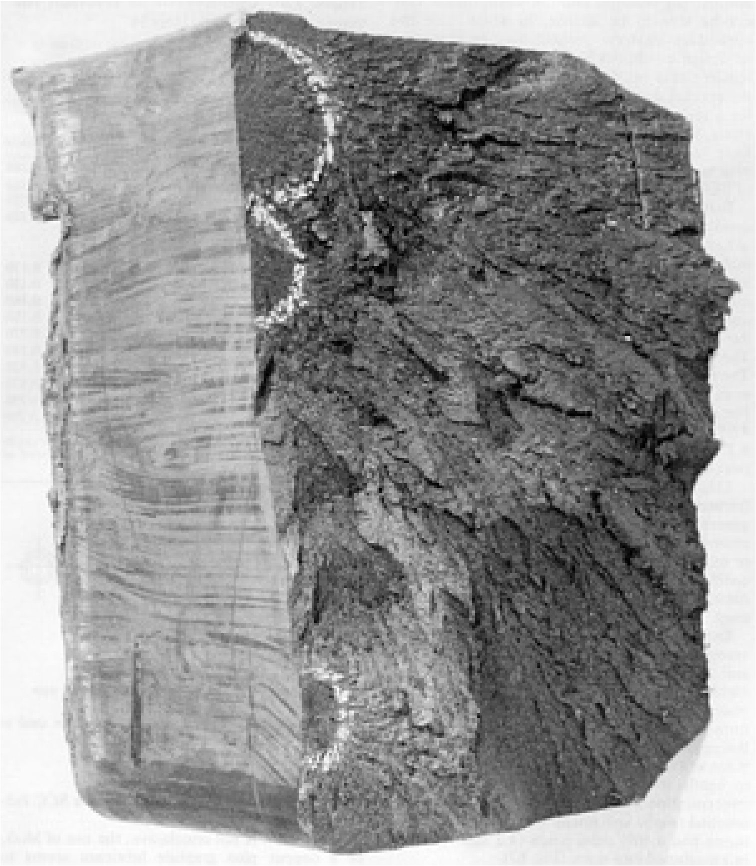

Fig. 64 Fractured section of the generator end disk from the Yankee-Rowe power plant. Thumbnail axial cracks are outlined in chalk.

A second instance of turbine disk cracking attributed to MoS_2 was keyway cracking of a turbine disk (Fig. 65) at the Cooper Nuclear Station (Ref 119). The cracking of this quenched and-tempered Fe-0.2C-0.4Mo-1.7Cr-3.5Ni steel was also predominantly intergranular with some evidence of pitting in the keyway area. Energy-dispersive spectroscopy (EDS) of the fracture surface and surrounding areas disclosed the presence of MoS_2 on the keyway surfaces of the disk. This investigation also attributed the intergranular SCC to a lubricant/moisture interaction. It was apparent from the two investigations that the potential for a stress-corrosion situation can result from the possible dissociation of MoS_2 in a moist environment.

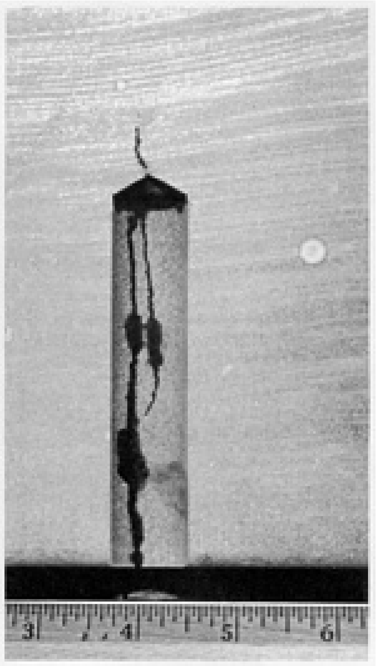

Fig. 65 Photograph of keyway crack after liquid penetrant examination (top view)

Bolting Investigations. In 1983, the NRC reported 44 distinct instances of bolting degradation at nuclear power stations between October 1964 through March 1982 (Ref 120). The materials investigated included plain carbon steels, alloy steels, and stainless steels. Nineteen of these were attributed to an SCC phenomenon, thirteen to boric acid wastage corrosion, three to fatigue, one to erosion-corrosion, and the remaining eight to material related causes. It was evident that the largest single cause of failure was SCC; the second most common cause of deterioration was corrosion of bolts adjacent to leaking gaskets.

Stress Corrosion of Steam Generator Manway Studs. Steam leaking through a gasket can react with the high-temperature lubricants used to assemble the bolted joint. This interaction occurred in at least two cases at PWRs. In both cases, failures of ASTM A540-B24 fasteners were attributed to a MoS_2/moisture reaction, which resulted in SCC (Ref 121, 122). The cracking was predominantly transgranular in nature with numerous secondary intergranular cracks.

Chemical Analysis of Various Lubricants

Eleven lubricants were evaluated at Brookhaven National Laboratory. These lubricants were types commonly used in construction and postoperational lubrication at nuclear power plants. The lubricants analyzed are listed in Table 12. Each of these lubricants was either sprayed or smeared onto carbon blocks and then placed into a scanning electron microscope and subjected to elemental EDS analysis. Energy dispersive spectroscopy will discern only elements with atomic numbers greater than 11 (sodium); therefore, certain light elements will not be detected. For detailed information on EDS, see the articles "Scanning Electron Microscopy" and "Electron Probe X-Ray Microanalysis" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.* The scans for most of the lubricants displayed the expected result with three notable exceptions.

Table 12 Various solid lubricants analyzed by Brookhaven National Laboratory with the use of EDS

Lubricant number	Type
1	Chemically pure MoS_2
2	Commercial MoS_2 spray
3	Commercial MoS_2 spray
4	Commercial MoS_2 spray
5	Graphite in isopropanol
6	Graphite in ammonia
7	Nickel + graphite lubricant
8	Copper + graphite lubricant
9	Antiseizing lubricant (copper-aluminum)
10	Nickel-base never-seizing lubricant
11	Never-seizing lubricant (copper-zinc-aluminum)

Note: The three commercially available MoS_2 sprays (lubricant numbers 2, 3, and 4) were obtained from three different manufacturers.

Figure 66(a) shows an EDS scan of a commercially available MoS_2 (lubricant 2) spray. The scan detected both antimony and titanium in addition to the molybdenum and sulfur. The titanium is sometimes used for coloring. The significance of the antimony addition is unknown. The EDS scan of lubricant 4, which is another commercial MoS_2 spray, is shown in Fig. 66(b). This scan showed only a sulfur peak with no molybdenum present. Lubricant 5, which is a graphite in isopropanol lubricant, was subjected to EDS, and the resultant scan is shown in Fig. 66(c). This lubricant showed a high sulfur peak with a trace of silicon also present. The presence of sulfur would not be normally anticipated in a graphite plus alcohol lubricant and might be detrimental to highly alloyed steels under certain conditions.

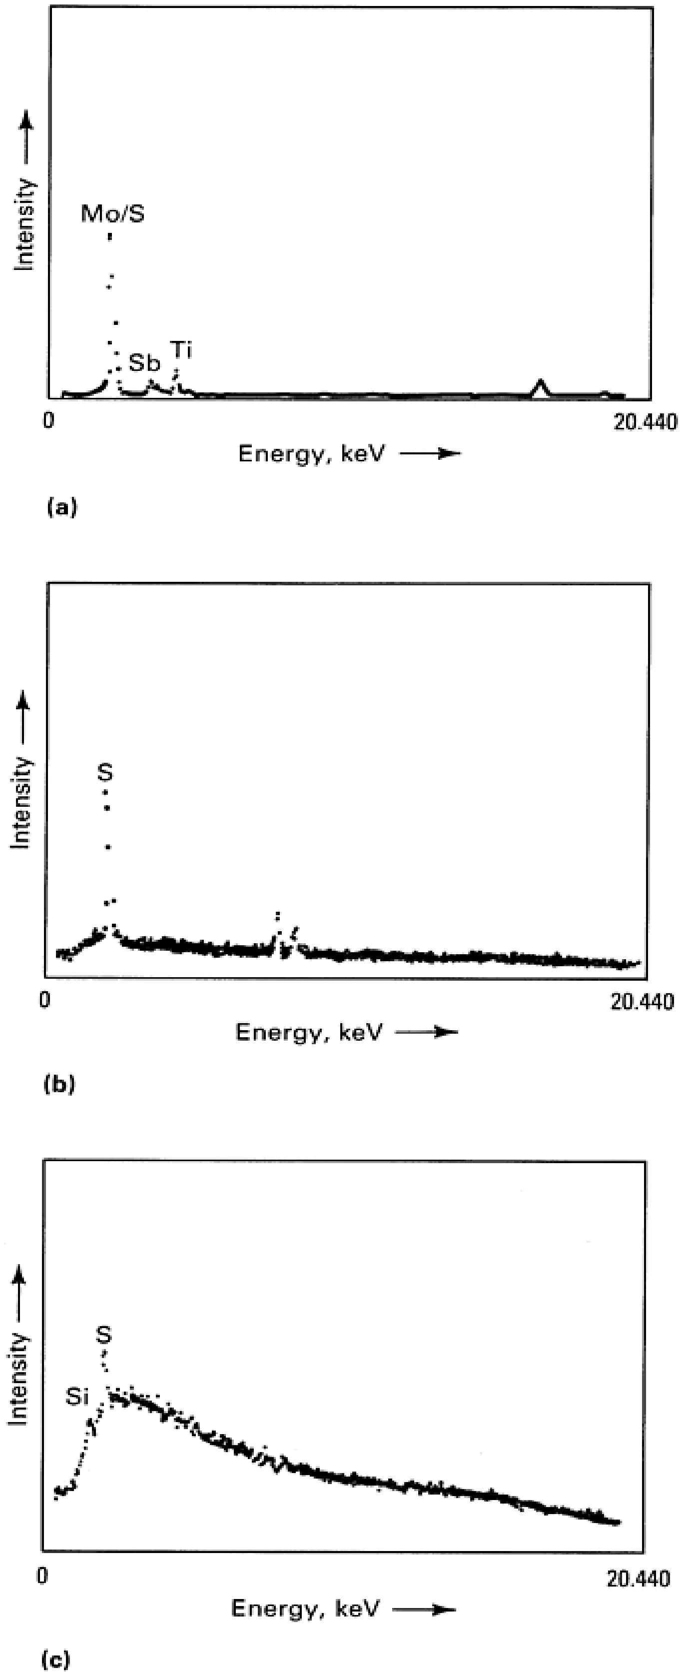

Fig. 66 EDS analysis of three solid lubricants. (a) Spectrum of Lubricant 2. (b) Spectrum of Lubricant 4. (c) Spectrum of Lubricant 5. Lubricant numbers are identified in Table 12.

In addition to the 11 lubricants discussed above, a baked-on bonded solid-film lubricant was also evaluated. This lubricant was not subjected to EDS analysis because of significant outgasing of the material when it is subjected to an electron beam. The reported chemical specifications of the manufacturer of this lubricant were as follows:

Constituent	Amount (max)
Fluoride	29 ppm
Chlorine	200 ppm
Sulfur	98 ppm
Lead	2 ppm
Mercury	1 ppm
Arsenic	0.05%
Zinc	1 ppm

Note: The carrier material for this lubricant is proprietary. Similar lubricants, however, use silicone-base carriers.

It can be clearly seen from the EDS scans shown in Fig. 66 that there is a significant variability in the chemical composition of allegedly similar lubricants. The appearance of possibly detrimental elements in lubricants 2 (antimony) and 5 (sulfur) and the total absence of molybdenum in lubricant 4 show that independent chemical analysis of lubricants before their use in a nuclear power plant is advisable.

Testing of Nuclear Lubricants

Steaming Tests on MoS_2. Prior work on turbine disks had indicated that in moist conditions MoS_2 could hydrolyze and form detrimental sulfides that could promote SCC failure in low-alloy steels (Ref 119). This work involved frictional tests in flowing nitrogen/water mixtures. Because rubbing forces are at work only during the torquing of a bolt and would not normally occur during its service life, some steaming tests were performed to determine if steam alone could interact with MoS_2 in order to form potentially detrimental compounds.

Three tests were performed to determine if a gaseous sulfide could be produced by steaming MoS_2. Distilled water was poured into an autoclave, after which a glass dish with chemically pure MoS_2 was suspended above the water; the autoclave head was tightened and the water heated to 100 °C (212 °F). The autoclave head was vented through a plastic tube with a metering valve into a test tube of water and then into a test tube of cadmium acetate ($Cd(C_2H_3O_2)_2$). The chemical reaction for this test is:

$$H_2S + Cd(C_2H_3O_2)_2 \rightarrow CdS \downarrow \text{(precipitate)}$$

After the experiment was completed, the amount of cadmium sulfide (CdS) produced was then weighed and calculated as sulfur in the water. All three tests showed that steaming MoS_2 will produce hydrogen sulfide (H_2S).

There has been a tremendous amount of controversy over the use of MoS_2 as a lubricant on nuclear power plant components. An investigation performed to explain the Hinkley Point A disaster found that MoS_2 reduces the crack initiation time of turbine steels by a factor of three in a steam environment (Ref 123). Other tests showed that the notched tensile strength of a disk steel can be reduced by a factor of 3.5 compared to a test in steam alone (Ref 119). Investigations have shown that MoS_2 accelerates the corrosive tendencies of metallic materials in moist environments (Ref 124, 125).

Early work showed that MoS_2 hydrolyzes in a moist environment to produce H_2S and that this hydrolytic reaction is reversible (Ref 126). A report for the Royal Aircraft Establishment (U.K.) cites accelerated corrosion of steel in contact with MoS_2 under conditions of high humidity (Ref 127). The products of this reaction were MoO_2 and sulfuric acid (H_2SO_4). Sulfuric acid is very detrimental to low-alloy steels. At least three other investigations have associated nuclear component failures with the use of MoS_2 (Ref 119, 128, 129).

Research conducted by AECL has shown that the following materials crack under BWR conditions when contaminated by MoS_2:

- Sensitized type 304 stainless
- Sensitized Inconel 600
- Inconel 718
- 17-4 PH in the H1025 and H1100 conditions
- PH 13-8 Mo
- Custom 455
- AM 355 SCT 1000

The AECL work is supported by a report that documents stress-corrosion tests on a number of materials with 12 different lubricants (Ref 130). One conclusion was that MoS_2 is the most aggressive lubricant. It readily cracked 17-4 PH (1100) and cold-worked type 304. After longer exposures, even annealed type 304 stainless steel cracked with this lubricant. Other studies have also shown that MoS_2 can produce H_2S under PWR conditions (Ref 131).

The chemical instability of MoS_2 in aqueous media has been addressed in an EPRI report (Ref 132). The report states that MoS_2 is not stable at pH values greater than 4.5. The stable compounds formed are $HMoO_4^-$ or MoO_4^{2-}, with aqueous H_2S, HS^-, or S^{2-} also formed. These compounds could easily promote a sulfide SCC phenomenon in critical bolting applications in which moisture is present with MoS_2.

Coefficient of Friction Testing. Stress-corrosion cracking requires the following three conditions to be present simultaneously: susceptible material, corrosive environment, and applied tensile stress. If any of the these conditions is missing, SCC will not occur. In the case of bolting, the material and the environment may not be able to be altered, in which case the applied tensile stress (preload) must be controlled (if design conditions allow) to keep the applied tensile stress below some critical level. Because the preload depends on the coefficient of friction for a given lubricant on a given surface or substrate, a factor of two to three (some lubricants have ranges given) in this frictional coefficient may put the applied stress into the critical range of SCC susceptibility.

Both static and kinetic coefficient of friction measurements were made at Brookhaven National Laboratory. Some of the lubricants were tested both wet (as sprayed or brushed) and dry (if the lubricants were of the air-drying type). The technique used for these measurements was the sled and bed technique. The tests performed are similar to those outlined in ASTM D 1894 (Ref 133). The results of these tests are given in Table 13. The results show that the coefficients of friction, even for similar types of lubricants, vary widely. For example, the static values for lubricants 1 to 4 (all MoS_2-base lubricants), range from 0.026 to 0.273, depending on manufacturer and condition (wet or dry).

Table 13 Coefficient of friction for various solid lubricants

The tests performed are similar to those outlined in ASTM D 1894 (Ref 133). Carbon steel blocks were used as the substrate materials.

Lubricant number[(a)] and condition[(b)]	Coefficient of friction	
	Static	**Kinetic**
1, dry	0.182	0.164
1, wetted with isopropanol	0.273	0.142
2, dry	0.266	0.223
2, wet	0.250	0.149
3, dry	0.223	. . .
3, wet	0.156	. . .
4, dry	0.026	0.150
4, wet	. . .	0.130
5, dry	0.130	0.160
5, wet	0.185	0.190
6, dry	0.351	0.170
6, wet	. . .	0.149
7, dry	0.055	0.126

7, wet	0.093	0.171
8, dry	0.042	0.296
9, wet	0.049	0.268

(a) Lubricant numbers are identified in Table 12.

(b) Dry condition, air-drying type lubricant; wet condition, as sprayed or brushed

This wide variation of measured coefficients of frictions for similar solid lubricants shows that generalizations of this value for same type (for example, MoS_2-base, graphite-base, copper-base, or nickel-base) should not be made and that the coefficient of friction should be determined (or obtained) for the specific lubricant and substrate used.

Environmental Notch Tensile Testing. To ascertain if bolting materials (specifically A193-B7 and A540-B24 Class 2) would have an environmental interaction with any of the lubricants and steam, constant extension rate tests were performed at 100 to 280 °C (212 and 535 °F). Because ordinary tensile tests on smooth specimens will not indicate whether a material is prone to brittle fracture in the presence of a stress concentration (similar to the threads on bolts), notched tensile specimens were used. The specimens had a 50% diam notch (3.2 mm, or 0.125 in.) machined into them (Fig. 67).

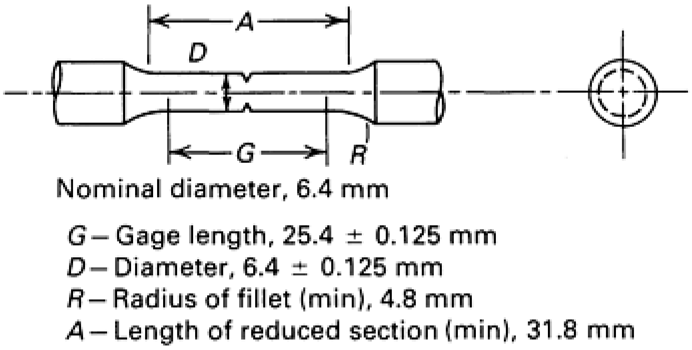

Fig. 67 Typical notched tensile specimen used in constant extension rate tests

The fracture face of each of the specimens was examined by scanning electron microscopy (SEM) after the constant extension rate test. Prior to examination by SEM, the specimens were electrolytically cleaned to remove the oxide film.

This investigation involved a total of 62 notched tensile specimens made from ASTM A193-B7 and A540-B24 Class 2 materials; 18 of these test specimens were coated with a bonded solid-film lubricant (Table 14).

Table 14 Results of notched tensile constant extension rate tests

Specimen number	Temperature		Test duration, h	Total extension		Extension rate, (s^{-1})	Tensile strength		Coating[c]

(a) Specimen made from quenched-and-tempered ASTM A540-B24 Class 2 nickel-chromium-molybdenum (modified 4340) steel.

(b) Specimen made from quenched-and-tempered ASTM A193-B7 chromium-molybdenum steel.

(c) Lubricant numbers are identified in Table 12.

All of the tests were conducted in a stainless steel autoclave. Approximately 1000 mL of demineralized water was added to the autoclave. The load was applied to the specimen when it was in the space above the water. The temperature of the solution was raised to test temperature--either 100 or 280 °C (212 or 535 °F)--through the use of resistance heating coils. After the required temperature was achieved and stabilized (approximately 30 min), the extension testing began in the steam environment. When the lubricant tests were conducted, the lubricants were either sprayed or brushed onto the notched area of the specimen. All specimens were tested at a strain rate of 5 to 9×10^{-7} s^{-1}. Fracture surfaces of two test

specimens are shown in Fig. 68. The notched constant extension rate tests of the bolting materials showed that both A540-B24 Class and A193-B7 materials are susceptible to a SCC failure in steam at 280 °C (535 °F).

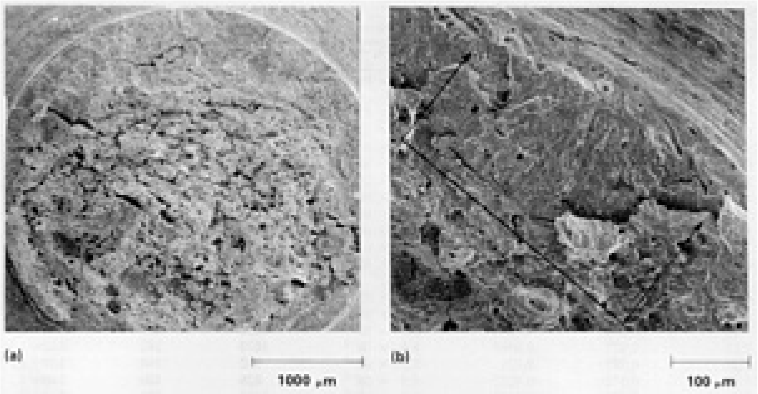

Fig. 68 Fracture surfaces of two failed notched tensile specimens. (a) Low-magnification SEM fractograph of the ductile + transgranular fracture face from specimen 42 in Table 14 (ASTM A193-B-7). (b) Higher-magnification SEM fractograph of the transgranular area seen on specimen 13 in Table 14 (ASTM A540-B24 Class 2)

Although it is not conclusive, the use of MoS_2 or a copper plus graphite lubricant seems to promote this susceptibility to SCC. The use of a solid bonded film lubricant does not significantly improved the bolting materials performance with either steam or MoS_2.

General Corrosion Adjacent to Leaking Gaskets and Corrosion Rate Testing. Pressurized water reactor gaskets around pumps have sometimes allowed seepage of small amounts of primary coolant. When this happens, the water flashes to steam, leaving behind a sludge or paste consisting of the dissolved boric acid (H_3BO_3) and LiOH from the primary coolant. This corrosive environment then attacks the bolt material. The most notable instance of this type of failure occurred at the Forth Calhoun Plant in May 1980, when certain bolts were degraded on reactor coolant pumps due to gasket leakage (Ref 121). The worst case of corrosion occurred when a bolt with an original diameter of 89 mm (3.5 in.) was reduced to a diameter of 28 mm (1.1 in.) by the H_3BO_3 over a period of approximately 7 years at about 150 to 200 °C (~300 to 400 °F).

Previously published data were used in the ensuing investigation on an AISI 4135 steel in H_3BO_3 and H_3BO_3 + KOH solutions at 20 and 60 °C (70 and 140 °F). In addition, data on A193-B7 and AISI 4130 material at higher temperatures were plotted to determine if extrapolations were valid (Ref 121). The temperature dependence of the corrosion rate is shown in Fig. 69. As the temperature increases to the boiling point of water, the corrosion rate increases at much faster rates. This increase continues until the boiling point is reached and then starts to diminish, probably because of the loss of water in solution. The decrease in corrosion rate continues through at least a temperature up to 178 °C (352 °F) in H_3BO_3 + LiOH. As higher temperatures are attained, water of hydration would also start to evaporate, which could lead to a deposit of lithium salt of metaboric acid ($LiBO_2$) ($LiBO_2$ has a melting point as high as 845 °C, or 1555 °F, in nonhydrated form). Corrosion products may have a similar stifling effect in the case of aqueous H_3BO_3 by itself, thus accounting for the drop in corrosion rate after H_2O is lost.

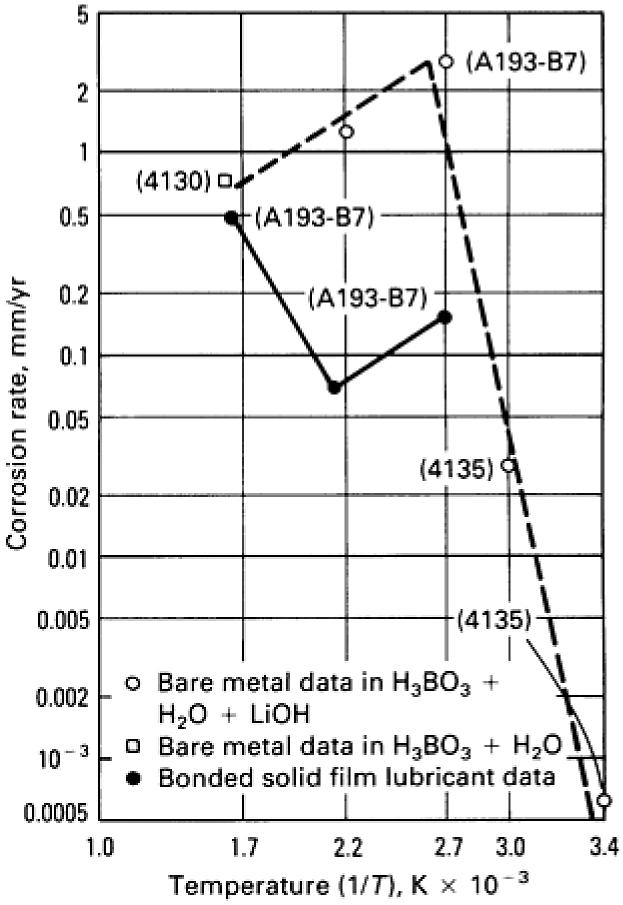

Fig. 69 Graph of the data from the corrosion rate versus temperature experiments for nonlubricated and lubricated specimens. All points represent the average of data collected.

Nine specimens coated with the bonded proprietary solid-film lubricant described earlier were subjected to the same tests as the bare metal specimens. Five specimens were tested at 100 °C (212 °F) (3 for 132.5 h and 2 for 77 h). Two specimens were also tested at 178 °C (352 °F) for 120 h, and two specimens at 315 °C (600 °F) for 130 h. The working solution used for the testing was 4000 ppm boron (as H_3BO_3) + H_2O + LiOH titrated to a pH of 7.3. The data generated from these tests are plotted on the graph of the original test data in Fig. 69.

These corrosion rate experiments, using previously coated solid bonded film lubricant specimens, show a marked decrease in metal loss at 100 and 178 °C (212 and 350 °F) compared to previously reported bare metal data. This lubricant protection disappears at 315 °C (600 °F), where the results on previously coated specimens differed little from results on bare metal specimens.

Observations on Copper Bearing Lubricants

The copper bearing lubricants have also been involved in at least one report as a crack initiator (Ref 130). The particular lubricant used (a copper plus graphite lubricant) produced cracks in 17-4 PH specimens. This result is complementary to the Brookhaven National Laboratory results, in which significantly lower notched tensile strength values were associated with the use of this lubricant. The effect of copper on low-alloy steels in as little as 1 ppm chloride solutions has been observed (Ref 134). In this case, the copper is speculated to have shifted the potential into the cracking range in a constant extension rate test at 268 °C (514 °F). This potential shift might well be applicable to the lubricants.

Erosion-Corrosion in Wet Steam Flow

Norris S. Hirota, Electric Power Research Institute

Erosion-corrosion is an accelerated form of corrosion caused by the relative motion between a corrosive medium and a metal surface. The erosion attack is directed at the protective layers and not on the metal itself. The metal corrosion is accelerated by the continuous erosive destruction of the protective layers. Wet steam erosion-corrosion of nuclear plant piping represents a potential industry-wide problem that can lead to costly outages and repairs as well as concerns for plant reliability and safety.

Carbon steel lines that carry wet steam, such as high-pressure turbine extraction and turbine exhaust piping in both PWRs and BWRs, are especially susceptible to erosion-corrosion. Pipe wall degradation rates as high as 1.0 to 1.5 mm/yr (40 to 60 mils/yr) have occurred and in some plants have resulted in pipe ruptures. Laboratory test results and extensive field test have indicated that erosion-corrosion in wet steam (two-phase) lines in similar to that which occurs in single-phase (water) lines. The appearance of damage is usually characterized by patterns of grooves, waves, rounded holes, and valleys in some consistent direction (Fig. 70). Regions of high water rates are those where liquid film was found (Ref 136). In wet steam lines constructed of carbon steel, the erosion-corrosion mechanism is complex and involves the electrochemical corrosion processes of oxidation and reduction, the convective mass transport of soluble compounds caused by the dissolution of the protective surface film, and the mechanical wear effects of abrasion, droplet impingement, and/or solid-particle erosion.

Fig. 70 Erosion-corrosion damage in wet steam piping. Source: Ref 135

Theory

Experimental work using both single- and two-phase flow, as well as extensive field testing and experiences in nuclear plants, strongly indicates that wet steam erosion-corrosion is similar to that which occurs in single-phase situations. Pipe regions of high wear are typically those where the metal surfaces contact liquid water only. However, prediction of actual erosion-corrosion rates in operating plants using single-phase test data and empirical equations has achieved only limited success.

There are a multitude of possible iron and iron-alloy corrosion processes. The following represents only one of the self-consistent set of reactions in single-phase situations. In oxygen-free water, iron, being thermodynamically unstable, dissolves to form Fe^{2+} ions with the formation of Fe(II)-hydroxide. Under static conditions, the fluid layer near the metal becomes saturated with this hydroxide, and the corrosion process essentially stops. However, with fluid flow, complete Fe(II)-hydroxide saturation of the fluid layer near the wall becomes less likely because of the mass transport between the boundary layer and the main flow field.

This set of reactions is written as:

$$Fe \rightarrow Fe^{2+} + 2e^- \qquad \textbf{(Eq 16a)}$$

$$2H_2O \rightarrow 2H^+ + 2OH^- \qquad \textbf{(Eq 16b)}$$

$$2H^+ + 2e^- \rightarrow H_2 \qquad \textbf{(Eq 16c)}$$

$$Fe + 2H_2O \rightarrow Fe(OH)_2 + H_2 \qquad \textbf{(Eq 16d)}$$

The Fe(II)-hydroxide can be converted into Fe_3O_4 by the Schikorr reaction (Ref 137):

$$3Fe(OH)_2 + Fe_3O_4 + 2H^+ + 2e^- + 2H_2O \qquad \textbf{(Eq 17a)}$$

$$2H^+ + 2e^- \rightarrow H_2 \qquad \textbf{(Eq 17b)}$$

$$3Fe(OH)_2 \rightarrow Fe_3O_4 + H_2 + 2H_2O \qquad \textbf{(Eq 17c)}$$

The reaction rate depends on temperature; at about 180 °C (355 °F), the Fe_3O_4 formation rate is high enough to protect against erosion corrosion. The oxidation reaction rate of steel and the dissolution rate of the oxide are equal. The dissolution is produced by the reduction of Fe_3O_4 by hydrogen. In oxygenated water, the overall reaction is:

$$2Fe + 2H_2O + O_2 \rightarrow 2Fe^{2+} + 4OH^- \rightarrow 2Fe(OH)_2 \qquad \textbf{(Eq 18)}$$

The Fe(II)-hydroxide, being unstable in oxygenated solutions, is oxidized to the ferric salt (Ref 138):

$$2Fe(OH)_2 + H_2O + \frac{1}{2}O_2 \rightarrow 2Fe(OH)_3 \qquad \textbf{(Eq 19)}$$

Magnetite can then be formed through (Ref 137):

$$2Fe(OH)_3 + Fe(OH)_2 \rightarrow Fe_3O_4 + 4H_2O \qquad \textbf{(Eq 20)}$$

The rate of erosion-corrosion varies according to:

$$\frac{dm}{dt} = k(C_s - C_b) \qquad \textbf{(Eq 21)}$$

where k is the mass transfer coefficient, C_s is the concentration of soluble iron at surface, C_b is the concentration of iron in flow, and dm/dt is the rate of metal loss.

The iron concentration corresponding to the equilibrium oxide solubility can be substituted for C_s. This oxide solubility varies with the potential of the oxide surface; at negative potentials where Fe_3O_4 is stable, the solubility increases as the potential becomes more negative. In addition, the potential depends on the corrosion rate; as the corrosion rate increases, the potential becomes more negative. The solubility of Fe_3O_4 has been shown to depend on the square of the mass transfer coefficient, k. Thus, the erosion-corrosion rate is dependent on the cube of the mass transfer coefficient (k^3). The mass transfer coefficient varies with the local hydrodynamic conditions.

Parameters of Influence

Moisture. The lack of erosion-corrosion damage in dry steam lines indicates the importance of moisture. In several PWR and BWR steam systems, moisture percentages can reach 15%, and under off-design conditions, even higher percentages occur. Although test data showing the effects of varying moisture levels on the rate of erosion-corrosion are not available, inspection reports from operating power plants indicate that piping systems carrying steam of high moisture content suffer higher rates of erosion-corrosion. These findings are consistent with Keller's equation, which will be discussed later (see Eq 22 and the corresponding discussion).

Material Composition. The most widely used material for U.S. nuclear plant wet steam piping is carbon steel, which has shown a susceptibility to erosion-corrosion. Under certain conditions of alloying (with elements such as chromium, copper, and molybdenum), erosion-corrosion resistance can be significantly improved (Table 15). However, in some current turbine exhaust piping, carbon steel with trace amounts of copper is used, but field experience indicates that this material is also susceptible to erosion-corrosion damage.

Table 15 Influence of chemical composition on wet steam erosion-corrosion test results

In comparison to ordinary carbon steel, erosion-corrosion rates can be reduced by three times with carbon-molybdenum steel and by more than ten times with chromium-molybdenum steels. Field experience showed that 1.25Cr-0.5Mo and 2.25Cr-1Mo steels are virtually immune to erosion-corrosion. Additional tests conducted under PWR conditions indicate that 12% Cr steels have excellent resistance, 2.25Cr-1Mo steel performed better than steel containing copper, and steel with less than 1% Cr did not have adequate resistance. Figure 71 shows material wear rates for 11 steels and 2 carbon steel specimens for three typical pH-oxygen combinations in 180-°C (355-°F) PWR water flowing at 20 m/s (65 ft/s).

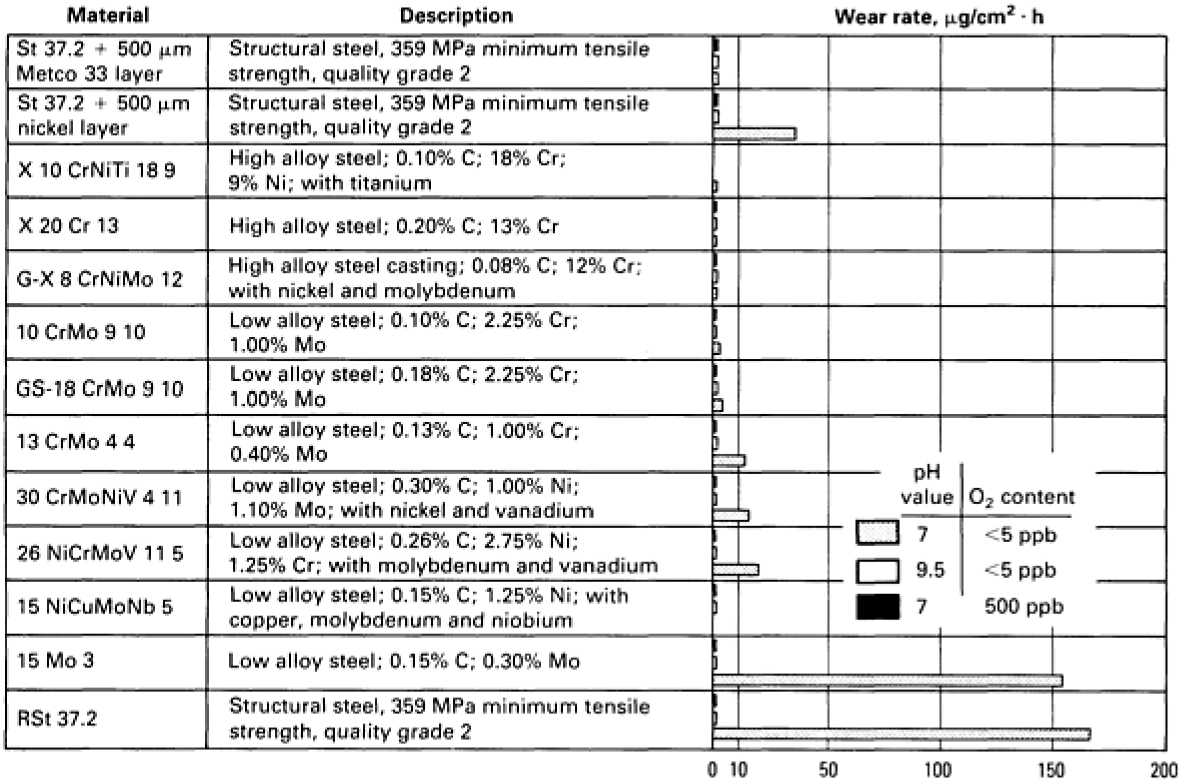

Fig. 71 Material wear due to erosion-corrosion of various metals. Pressure: 40 bar (4000 kPa, or 580 psi), Temperature: 180 °C (355 °F), Velocity: 20 m/s (65 ft/s). Source: Ref 137

pH. Water chemistry and pH play an important role in changing erosion-corrosion rates. Pressurized water reactor turbine piping has experienced erosion-corrosion damage when condensate pH falls below 9.3; similar damage in BWRs is experienced where pH is in the neutral range (7.0). Significant reduction in erosion-corrosion is achieved in PWRs when pH is maintained above 9.3, as shown in Fig. 72. In fact, the erosion-corrosion rate drops significantly at pH above 9.2, independent of the oxygen content.

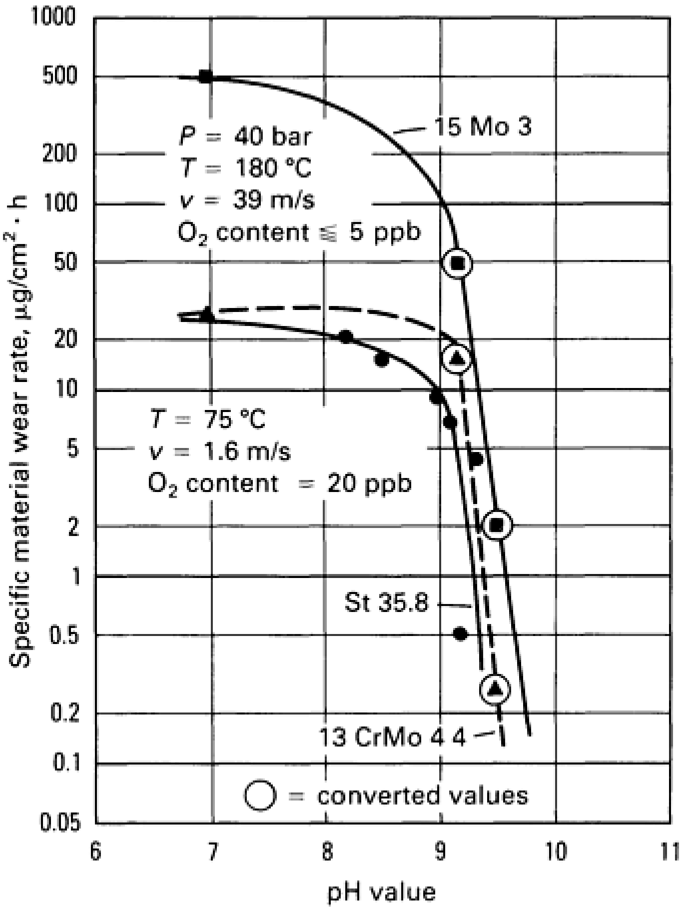

Fig. 72 Effect of pH value on material wear due to erosion-corrosion. *P*, pressure; *T*, temperature; *v*, velocity. For material composition, see Fig. 71. Source: Ref 137

Both NH_3 and C_4H_9NO have been used successfully to maintain pH above 9.3 Morpholine provides a better distribution ratio, which allows more of it to be retained in the water phase at high temperatures. The resultant higher pH helps prevent localized damage. Plants with all steel materials should maintain pH between 9.3 and 9.6. Plants with copper alloys, however, should maintain condensate/feedwater pH between 8.8 and 9.2 to avoid excessive copper pickup it ammonia is used to control pH. Condensate polishers, if used, also determine what optimum pH level to maintain, depending on the choice of operating mode, that is, hydrogen or ammonia cycle (Ref 135, 139).

Temperature. Erosion-corrosion rates are highly temperature dependent, as shown in Fig. 73. These curves represent single-phase flow laboratory test results and indicate a well-defined maximum erosion-corrosion rate that is a function of hydrodynamic conditions. At higher temperatures, the protective layer formation changes from the intermediate stage of the primary Fe(II)-hydroxide formation to the direct Fe_3O_4 formation. Under two-phase conditions in ammoniated water, the maximum erosion-corrosion rate occurs at approximately 180 °C (355 °F). At temperatures less than 180 °C (355 °F), lower erosion-corrosion rates are attributable to a slower rate of chemical reaction.

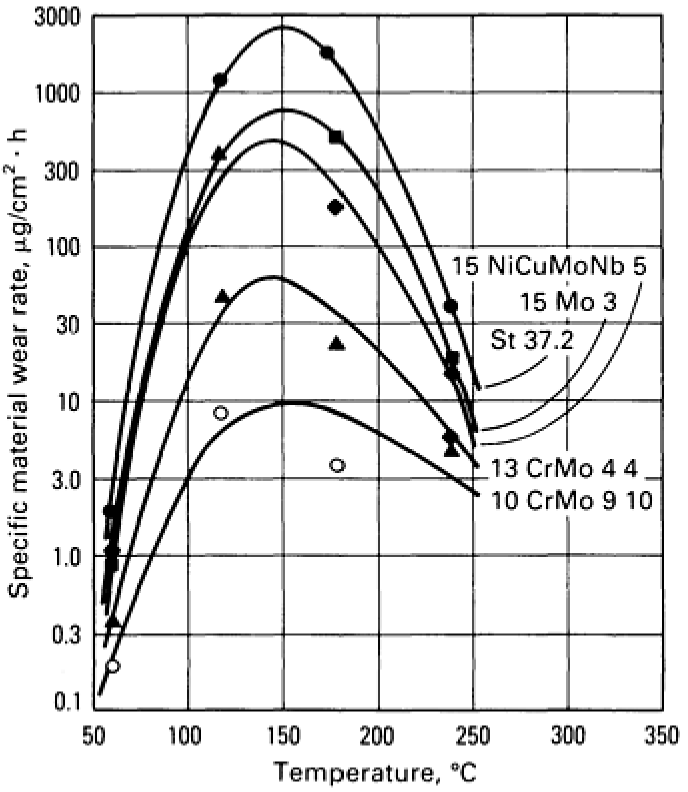

Fig. 73 Temperature effect on material wear due to erosion-corrosion. *P*: 40 bar, *v*: 35 m/s, pH: 7, O_2 content: <40 ppb, period of exposure: 200 h. See Fig. 71 for material composition. Source: Ref 137

Oxygen. Figures 74 and 75 illustrate the influence of oxygen on erosion-corrosion behavior. Under BWR conditions (neutral water), oxygen is beneficial (based on iron release data for carbon steel). The iron release rate may decrease by 100 times when raising the oxygen concentration from 1 to 200 ppb over the temperature range of 38 to 204 °C (100 to 3400 °F) in neutral water at 1.8 m/s (6 ft/s). This has been the experience in wet steam lines in BWR plants (Ref 135). Moreover, neutral water with low oxygen produced the maximum material wear. Consequently, some BWR plants maintain oxygen in the feedwater to the reactor above 15 to 20 ppb.

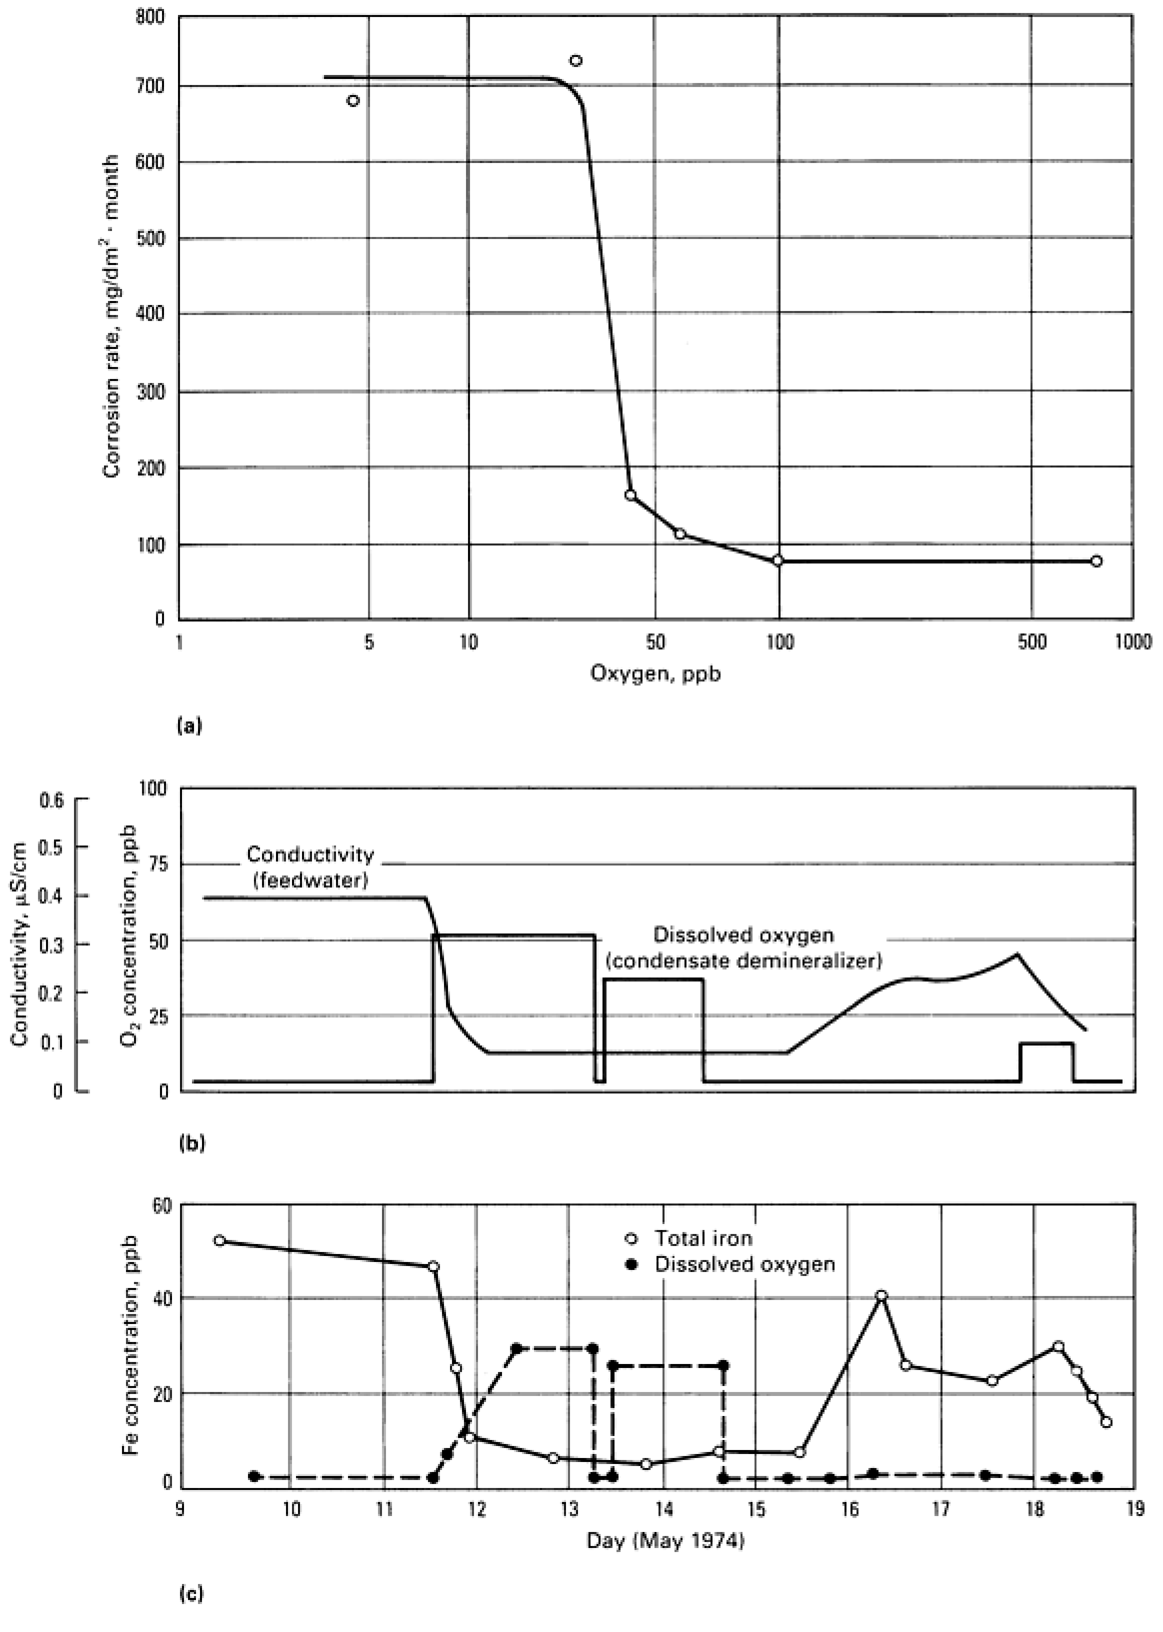

Fig. 75 Influence of oxygen on the corrosion behavior of carbon steel. (a) Effect of oxygen on the corrosion rate of carbon steel in neutral water at 100 °C (212 °F). (b) and (c) Time variation of total dissolved oxygen and total iron concentration in the feedwater with addition of oxygen gas to the feedwater system. The conductivity of the feedwater and dissolved oxygen concentration at the condensate demineralizer outlet are also shown. Source: Ref 135

Under PWR conditions, the use of oxygen as a conditioning agent has met with limited success. Care must be taken, because steam generator tube materials, such as Incoloy 800 and Inconel 60, are sensitive to oxygen, especially in crevices. More success has been achieved by raising the pH of steam condensates by replacing ammonia with less volatile amines (Ref 140, 141). Although oxygen feed is beneficial in single-phase flow, it may not be as effective in two-phase situations; a higher oxygen concentration is required to offset the unfavorable partition coefficient of oxygen between steam and water. Moreover, chloride and sulfate contamination, together with higher levels of oxygen, could cause rapid pitting.

Flow Path Geometry and Velocity. Poor flow path geometry can significantly accelerate the rate of erosion-corrosion attack. Typical examples of poor piping layout are shown in Fig. 76 and 77. In most of these cases, severe moisture impingement and very high velocities were involved. Areas of severe attack were located near or at system discontinuities, such as elbows, branch connections, and weld areas where backing rings were used. In the laboratory, tests indicated that the erosion-corrosion rate increased exponentially with velocity, as illustrated in Fig. 78. Although these curves were generated for neutral water, a similar tendency is noticed in PWR secondary circuits with pH levels of 9 using NH_3 and an oxygen content of less than 5 ppb. However, the absolute magnitudes of the specific material wear rates are significantly lower because of the higher pH.

Locations of Damage. Nuclear plant turbine piping and associated components are subjected to high-velocity steam of varying moisture content. Figures 79 and 80 show typical piping arrangements of affected systems. Some common piping systems that have suffered erosion-corrosion damage include high-pressure turbine exhaust piping, high-pressure turbine extraction piping, low-pressure turbine extraction piping, low-pressure turbine inlet piping (some plants), and miscellaneous wet steam lines (for example, auxiliary steam lines). Based on field experience, the following areas are the likely candidates for erosion-corrosion damage (Ref 135):

- Branch connections at the sides and bottoms of pipe runs are expected to contain a higher amount of

moisture and consequently have a higher erosion-corrosion rate than branch connections located on the tops of pipe run

- Where extraction steam piping is directed down into a feedwater heater with two inlet connections, the second connection will contain a higher moisture content and consequently have higher erosion-corrosion rate unless the piping design incorporates a method to remove the moisture (Fig. 77)
- Short distances between changes in direction and other discontinuities do not allow the turbulence to dissipate. These areas are expected to have higher rates of erosion-corrosion. Usually, a length equivalent to 10 diameters of straight pipe is required for flow to stabilize. In systems in which all fittings are not being inspected, one area that should be inspected is where two changes in direction are separated by the least distance
- Branch connections of 90° generally have a higher erosion-corrosion rate than bends and elbows do and should also be of higher priority for monitoring than lateral connections
- Elbows with turning vanes are expected to have significantly lower erosion-corrosion rates than those without. However, areas just downstream of turning vanes have a higher erosion-corrosion rate because of higher turbulence intensities
- Areas where repairs involve internal placement of weld metal are particularly susceptible to severe erosion-corrosion. Areas around the repairs should be inspected, especially the leading and trailing edges with respect to flow
- As the radii of directional changes are reduced, the rate of erosion-corrosion is expected to increase. Short-radius elbows are more susceptible to erosion-corrosion than long-radius elbows, and long-radius elbows are more susceptible than 5-diameter bends. The likelihood that bends are fabricated with wall thicknesses closer to minimum than elbows should also be a consideration

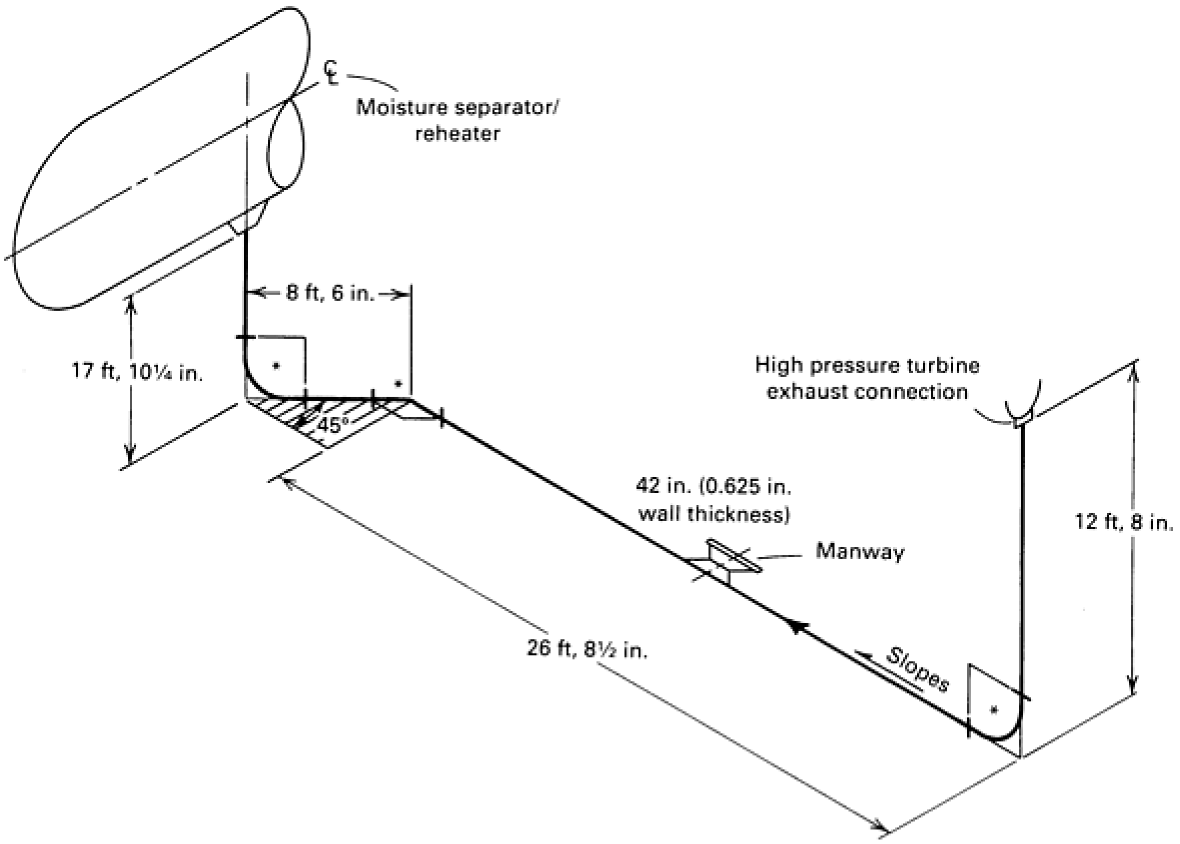

Fig. 79 Typical turbine exhaust piping arrangement. Turning vane elbows are marked with asterisks. Source: Ref 135

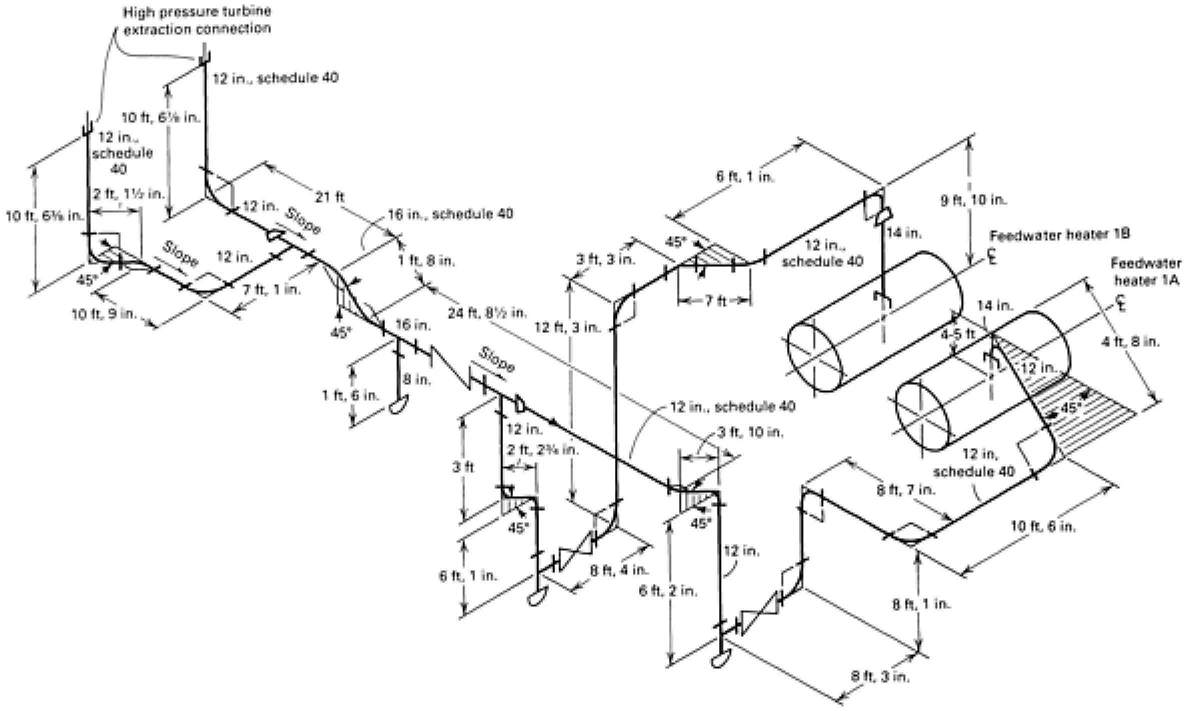

Fig. 80 Typical turbine extraction piping arrangement. Source: Ref 135

A form of erosion-corrosion called tiger-striping has been identified in a few plants (Ref 135). Tiger-striping is characterized by a striping of uniform degradation on the pipe inside diameter. The damaged areas are not limited to areas of flow discontinuities and have been documented in numerous straight pipe sections. Why only some systems are subject to this unusual phenomenon has not been determined. Although occurring less frequently than the more general form of erosion-corrosion, tiger-striping is no less severe from the standpoint of wall thickness degradation, and site inspection procedures should be able to detect its existence.

Inspection Program

Approach. Failure to detect and repair erosion-corrosion degradation can result in a disruptive event that would possibly injure plant personnel and cause extensive plant equipment damage requiring costly repairs and plant downtime (Fig. 81). An analysis program can provide a means of ranking systems based on their susceptibility to erosion-corrosion and identifying the components within those systems that are most likely to incur severe damage. This prioritization criteria can be used to limit the number of plant inspection sites, providing a cost-effective basis on which to estimate the severity of the problem with a high confidence level.

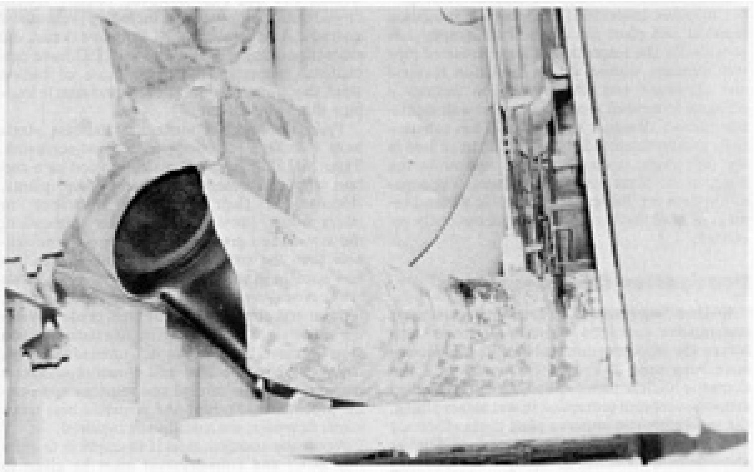

Fig. 81 Failure at high-pressure extraction piping elbow

An erosion-corrosion wear rate prediction model could serve as the basis for this methodology. By first calculating expected wear rates for potentially high erosion-corrosion susceptible areas and then determining the allowable wear for components in those areas, a wear period or remaining life can be established and used to identify high-priority inspection sites; a short wear period of remaining life identifies a high priority. The wear rate model provides only the first estimate of important inspection sites. There-after, the frequency and sites of future inspections should be based on the measured wear rates (Ref 135).

Keller's Equation. Keller proposed an empirical wear rate model in 1974 for power plant equipment. This model is based on velocity, temperature, configuration, and the amount of moisture. The model does not account for varying water chemistry (pH and oxygen). It was developed for two-phase flow conditions (temperatures between 50 and 150 °C, or 120 and 300 °F, and materials of low-carbon steel to 13% Cr steels) and for a wear rate range of 0.4 to 5 mm/yr (0.016 to 0.2 in./yr) (Ref 136).

The material loss prediction model can be used as the criterion for selecting and prioritizing components subjected to erosion-corrosion degradation for an inspection program. Keller's equation states:

$$s = f(T)\, f(x)\, c\, K_c - K_s \quad \textbf{(Eq 22)}$$

where s is the maximum local depth of material loss in mm/10,000 h; $f(T)$ is a dimensionless variable denoting the influence of temperature on erosion-corrosion damage ($f(T)$ versus T is shown in Fig. 82); $f(x)$ is a dimensionless variable denoting the influence of steam wetness on erosion-corrosion (for subcooled water, it has been suggested that this has a value of unity, but for two-phase mixtures, it has the form $f(x) = (1 - x)K_x$, where x is the steam quality, and $0 < K_x < 1.0$; a value of $K_x = 0.5$ is considered to be most appropriate); K_c is a variable accounting for the effect of local geometry on the fluid flow (Fig. 83); c is the fluid velocity (in meters per second); and K_s is a threshold value that the product of $f(T)$, $f(x)$, c, and K_c must exceed before erosion-corrosion is observed. A value of 1.0 mm/10,000 h (0.04 in./10,000 h) has been given by Keller.

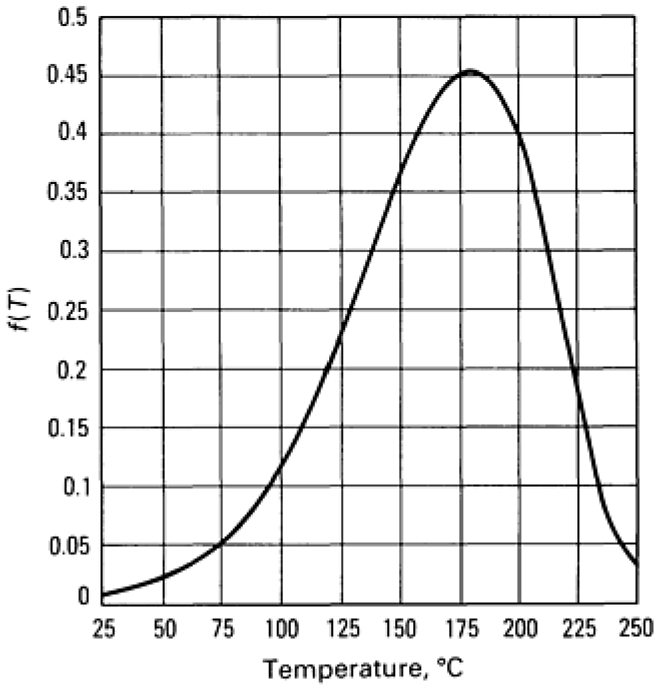

Fig. 82 Temperature influence function for Keller's equation (see Eq 22 in text for explanation). Source: Ref 135

Flow pattern				Reference velocity	K_c
Primary flow stagnation points		At pipes		Velocity of initial flow (upstream of stagnation obstacle)	1
		At blades			1
		At plates			1
		In pipe junctions			1
					0.8
Secondary flow stagnation points		$R_{mean}/D \cdot 0.5$	In elbow pipes	Flow velocity	0.7
		$R_{mean}/D \cdot 1.5$			0.4
		$R_{mean}/D \cdot 2.5$			0.3
		Behind pipe joints			0.2
Stagnation points due to vortex formation		Behind sharp edged admission pipes		Flow velocity	0.2
		At and behind barriers			0.2
No stagnation points		In straight pipes		Flow velocity	0.04
		In untight horizontal turbine joints		Velocity calculated from pressure drop	0.08
Complicated flow through turbine part		In turbine gland seal		Velocity calculated from pressure drop	0.08
		At and above turbine blades and at drainage collecting rings		Average circumferential blade velocity	0.3

Fig. 83 Flow path influence function for Keller's equation (see Eq 22). Source: Ref 135

Keller also developed a set of influence factors, K_c, that adjust the predicted rate of erosion-corrosion as a function of steam path configuration. The predicted wear rates for components with configurations other than straight pipe can be easily calculated using the *s* value determined previously for the straight pipe. Although the parameters of Keller's equation are, to a large extent, representative of and significant to the influences of erosion-corrosion, this method of calculating wear rates is not precise in predicting actual rates or material life. Instead, the intent of this model in establishing the inspection program is to identify high-probability erosion-corrosion areas. Once established, actual wear rate data from site inspections should be used (Ref 135).

Inspection Techniques. Inspection should be conducted visually where practical and supplemented by ultrasonic testing to establish an accurate wall thickness. This method can be used very easily for systems that have personnel access. Where direct visual inspection is not possible, remote visual techniques such as fiber optics or a remotely operated pipe crawler equipped with a video camera would be recommended. With manual ultrasonic testing techniques, it is

important that an inspection grid is established and that the grid size is not too large. Wall thickness measurements at the intersections of the grid and continuous scanning of the area bounded by the grid are required to identify areas of minimum wall thickness. Manual ultrasonic inspection, however, lacks the requisite degree of reproducibility. Automated ultrasonic inspection tool, usually computer enhanced, can produce a three-dimensional topographical representation of the pipe wall interior and can provide high reproducibility and improved records keeping.

Ultrasonic inspection requires pipe insulation removal and plant shutdown. Radiography can provide for the inspection of large areas of pipe wall interiors without costly insulation removal and ultrasonic test site preparation through a series of tangential shots of the pipe wall-insulation sectors. Because the pipe wall has substantially greater density than the insulation or fluid in the pipe does, contrast changes appear in the image at the inner and outer surfaces. The separation between these lines, which is a measurement of wall thickness, can be continuously recorded.

Prevention Considerations

In-Line Separators. In-line or preseparators can remove entrained moisture in steam as it leaves the high-pressure turbine. These devices have been used in French PWRs and in a few domestic nuclear plants. In addition to providing erosion-corrosion protection in wet steam piping, the separators can improve plant cycle efficiency through more effective moisture removal. Studies show definite economic advantages in retrofitting these devices in most domestic PWRs and BWRs (Ref 142). Typically, the in-line separators are placed in the turbine cross-around piping at the high-pressure turbine exhaust, where erosion-corrosion rates have been high.

Alternate Materials. Chromium-molybdenum steels have shown satisfactory service in power plant piping systems subjected to flashing liquids. In wet steam environments, 1.25 Cr-0.5Mo (P11 grade) and 2.25Cr-1Mo (P22 grade) alloy steels have shown good resistance to erosion-corrosion in both operating systems and laboratory tests (Ref 135). Of the two materials, P22 grade is more readily available in standard schedule pipe and fitting sizes and in plate for fabrication of the larger turbine exhaust piping. Grades P11 and P22, however, require special considerations for welding, including preheat and postweld heat treatment. At turbine exhaust and extraction temperatures. P11 and P22 have mechanical properties similar to those of carbon steel; therefore, thermal stresses and nozzle loadings should be similar.

Type 304 and 316 austenitic stainless steels have excellent resistant to erosion-corrosion. Type 304L has been successfully used as a carbon steel replacement in several power plants. Because of their improved resistance to intergranular stress corrosion after fabrication, the low-carbon grades are considered more reliable than the straight grades. Both low-carbon and straight grades of austenitic stainless steels are as readily available in standard schedule pipe, fittings, and plate as P22 alloy steel grades. Welding of austenitic stainless steels to existing carbon steel connections (that is, turbine casings, feedwater heater shells, and moisture separator reheater shells) is critical and requires appropriate procedures. Preheat and postweld heat treatment, however, are usually not required.

Austenitic stainless steel is susceptible to chloride SCC, and consideration must be given to using nonmetallic thermal insulation under wet conditions, because chloride and fluoride ions may leach onto the piping. Straight and low-carbon grades of austenitic steels will have the same dimensions and weight as the carbon steel piping. The thermal expansion coefficient, however, is about 1.4 times that of carbon steel. New piping analysis with possible layout changes and support modifications to control thermal stresses and nozzle loadings will be required (Ref 135).

Weld Repair and Cladding. Localized defects are good candidates for weld repair with the same filler metal as the base material or an alloy material more resistant to attack, such as 1.25Cr-0.5Mo. Experience in power plants, however, indicates that in many cases the areas adjacent to the weld repair were even more vigorously attacked, leaving the weld/clad itself almost untouched. Erosion-corrosion damage was typically apparent on both sides of the weld in the HAZ, which arises inherently during the welding process. An alternate method of repair, especially for small piping, is to overlay metal on the outside surface of the pipe. Cladding extremely large areas, although possible, is not considered feasible because of the extremely high cost (Ref 135).

Corrosion of Containment Materials for Radioactive-Waste Isolation

J.W. Braithwaite, Sandia National Laboratories

The safe disposal of radioactive waste requires that the waste be isolated from the environment until radioactive decay has reduced its toxicity to innocuous levels. Many different types of radioactive waste are produced during commercial and defense nuclear fuel cycles. However, one type of waste, denoted high-level waste (HLW), contains the highest concentration of radiotoxic and heat-generating species. Because of this factor, the most stringent standards for disposing of radioactive wastes are being placed worldwide on HLW, and the majority of the radioactive waste management effort is being directed toward the HLW problem.

All of the countries currently studying the options for disposing of HLW have selected deep geologic formations to be the primary barrier for accomplishing this isolation. However, for conservatism, engineered components will also be used. The principal engineered component in this multibarrier approach is called the waste package and includes the waste itself, possibly a stabilizing matrix for the waste (together termed the wasteform), and a metallic container that encloses the wasteform.

The waste container may be a single vessel, but because of the many requirements being placed on the waste package, it will probably consist of two or more concentric vessels, each having a specific function. For example, the container that directly holds the wasteform may be designed to facilitate safe waste handling and emplacement operations. This container may be overpacked with a corrosion-resistant outer layer. Additional vessels may also be present to attenuate radiation and/or resist external loads following emplacement. This section will specifically address the long-term corrosion behavior of HLW container materials. The information presented is also applicable to the selection of materials for shorter-term components (for example, to allow waste retrieval) and for use in the disposal of other, less toxic radioactive wastes.

Two basic types of HLW exist that will require disposal. The majority of the HLW in the United States will simply be spent nuclear fuel from commercial power reactors (Ref 143). Assemblies of spent fuel will either be placed intact into a container or first consolidated and then loaded into a container. The second type of waste results from the reprocessing of either defense-related or commercial spent fuel. Both sources of this reprocessed waste will be stabilized in a matrix material, probably a borosilicate glass, and then cast into a canister.

The programs of all the nations involved with HLW isolation recognize the advantages of having the container remain intact for the relatively long period of 300 to 1000 years. The major heat-producing species in HLW are two isotopes of cesium and strontium, both with 30-year half-lives. A 300- to 1000-year lifetime container allows the concentration of these two fission products, and thus the thermal output of the waste, to be reduced by a factor of at least 1000 before any dissolution and/or release of radioactivity can begin. The lower temperature of the waste is beneficial because dissolution of both wasteforms is thermally activated (Ref 144, 145). Also, after this time period, the radiotoxicity of the remaining fission products is less than that for a long-lived isotope of americium and less than four times that for the entire inventory at extended time periods (>10,000 years) (Ref 146, 147). Finally, a 300+ year container could assist any short-term waste retrieval operations, should that option need to be exercised.

In the U.S., the Nuclear Regulatory Commission (NRC) requires that the waste be reliably contained for a period of 300 to 1000 years (Ref 148). Other countries have adopted this requirement at least as a goal in their programs. The ultimate application for the container would be for it to function as an absolute barrier for the entire time that significant radiotoxicity is present. Canada and Sweden are investigating this possibility by determining the potential for containing the waste for periods of at least 100,000 years (Ref 147, 149).

Because the container must function both as a transportation vessel and as a corrosion barrier, almost all of the materials being considered for its construction are metallic. Given the environments and the candidate metals, the forms of corrosion that are applicable to waste containers include:

- General, or uniform, corrosion
- Localized attack (crevice, pitting, and intergranular attack)
- Stress-corrosion cracking

- Hydrogen-assisted cracking

The extremely long lifetime requirement being placed on the container forces the designer to consider only materials that have very predictable and reliable behavior. The rates of the latter three mechanisms are all sufficiently high or unpredictable that any design specifying a material that would fail by these types of nonuniform attack would be impractical. Thus, the challenge is to identify materials that will undergo only general corrosion in a given disposal environment. Materials that are acceptable in one environment may not be usable in another (for example, crystalline rock versus bedded salt).

Two basic approaches have evolved for potentially satisfying the lifetime requirement being placed on the waste container: use of a corrosion-resistant material or use of a corrosion-allowance material. For a reasonably designed container to survive for 300 to 1000 years, its corrosion rate must be relatively small. As will be shown, a number of materials have been identified with corrosion rates that are practically nil (micrometers or less per year). Very little corrosion allowance is required in the design of the waste package constructed with these "corrosion-resistant" materials. These metals usually owe their durability to very adherent oxide films, and as such, the major difficulty in their characterization is to demonstrate that the other, more insidious corrosion mechanisms will not be active during the long containment time. Examples of corrosion-resistant materials are titanium alloys, nickel-base alloys, and, in some applications, possibly stainless steels.

The alternate approach is to use "corrosion-allowance" materials that, in general, have more predictable corrosion characteristics. Although these materials have much higher general corrosion rates, their susceptibility to nonuniform corrosion is usually very limited due, in part, to a lack of protective oxide containing product layers. The corrosion rate of these active materials is often controlled by the rate of the cathodic process (oxygen reduction and/or hydrogen ion discharge). As will be shown later, the ground-water flow rates (oxidant supply) are very limited, and their pH is usually near neutral. Given these types of conditions, the general corrosion rate may be relatively low and can be measured reliably. Thus, an allowance for the material wastage can be incorporated into the design. Examples of these types of materials include mild steel, cast iron, and copper.

Given the above considerations, the materials characterization programs have two primary objectives:

- To quantify the general corrosion rate
- To demonstrate that no accelerated attack will occur. This requirement can be satisfied either by showing that the material is not susceptible to these forms of attack or that their time to initiation (the incubation period) is longer than the required lifetime of the container (for example, sensitization of stainless steel)

The impact of these two objectives on the corrosion programs will be evident in the discussion of "Corrosion Results From Site-Specific Studies" provided later in this section.

In addition to corrosion characteristics, cost and mechanical properties must also be considered in the selection of container materials. The mechanical properties can be very important when satisfying waste package requirements related to waste-handling and retrieval operations, but this subject is not relevant in this section. Container cost can be a factor. Unit material costs for the corrosion-allowance materials tend to be much lower than those for corrosion-resistant alloys; however, because wall thicknesses must be greater, this cost difference is reduced. Overall fabrication costs are very design dependent, and cannot be generalized. To compare costs properly for different container options, total disposal cost should be considered because the use of a corrosion-resistant material may allow a simple, lightweight design to be used with substantially fewer components, less fabrication, less emplacement-hole mining, and smaller handling equipment.

The remainder of the background information needed to evaluate properly the results of ongoing and completed corrosion testing is given in the next two parts of this section. The first, "Considerations for Waste Isolation." describes the unique problems associated with characterizing waste container behavior, and the second, "Environment," summarizes the expected container environments.

Considerations for Waste Isolation

The requirement that a waste container survive intact for periods of several hundred years in elevated-temperature irradiated geologic environments has created a difficult problem for materials and design engineers to solve. The unique aspect of this problem is associated with making very reliable predictions about the corrosion behavior or container materials for these extended periods of time. Many of the alloy systems being considered have been in existence for less than 100 years. Thus, a data base concerning long-term behavior is practically nonexistent. Because most countries, including the United States, do not plan to have their first repository operational until the late 1990s, sufficient time (10 to 15 years) exists to allow most of the needed long-term simulations and accelerated testing to be completed. In the U.S., an additional 50 years is available for testing before the repository is actually sealed (the "retrieval period"). Certainly, the important corrosion processes should be identifiable within these time frames.

The general problems associated with interpreting results from long-term and accelerated testing have been addressed by many investigators (Ref 150, 151, 152). For example, K. Nuttall discusses many of the considerations that should be given to identifying long-term failure processes and noted that unless the effect of a particular failure mechanism is large, it is difficult to characterize by using short-term (Ref 152). The real concern is that these unknown changes may lead to delayed, catastrophic stress-assisted failures (for example, SCC, hydrogen cracking, hydriding). The materials engineer should remember, however, that a proper waste package design will minimize container stress and thus greatly decrease the potential for these types of stress-related corrosion processes. A detailed methodology for predicting long-term behavior using accelerated testing is proposed in Ref 153.

The specific problems associated with predicting material behavior over extended time periods relate to identifying potential changes in both the environment and the metallurgical characteristics of the alloy. To understand these types of problems better, some examples are given below.

The important environmental parameters affecting corrosion include container temperature, groundwater chemistry, groundwater flow rate, hydrostatic and lithostatic pressure (influences water phase and container stress), and radiation flux. The predicted history for these parameters must be quantified before accurate and reliable assessments of the performance of the container can be made. The difficulty in easily predicting the effect of these environments on corrosion was demonstrated by some results from initial site studies performed in Canada. The groundwater in the crystalline-rock disposal environment in the Canadian shield was expected to be benign (no halide ion, neutral pH, low ion strength) (Ref 147). During a research-drilling program, however, groundwater containing 5.6 g/L of chloride ion was encountered. The existence of isolated pockets of saline groundwater in the deep rock formations supports the need for careful site characterization studies.

Metallurgical changes could be important because of their effect on the structures and properties of passive films, time to inducement of delayed mechanical failure, and time to sensitization of the microstructure. Again, the state of stress in the container could be a major factor that determines whether these metallurgically induced changes will actually lead to a failure. These potential effects are recognized and are being addressed by many investigators (Ref 151, 152, 154, 155).

Theoretically, radiation can affect the corrosion behavior of the container by affecting both the container environment and its metallurgical properties. However, the general conclusion reached by most investigators is that the types and dose rates of radiation emitted from decaying wastes are not sufficient to degrade the properties of either the container material or its passivating oxide layer and that the important effect of radiation is the change produced in the external environment due to groundwater radiolysis (Ref 152, 156). The effect of radiation on the environment is covered in the latter part of the next discussion. However, radiation has been shown to produce small changes in the properties of some metals that could lead eventually to increased corrosion rates (Ref 157). Such potential effects of radiation should be identified during long-term testing.

Environment

Numerous deep-geologic formations are being considered by the various countries as the media for isolating radioactive waste with the characteristics of many of these formations being quite similar. To aid in these discussions, this similarity allows the formations to be grouped into the following three categories:

- Crystalline rock (igneous and metamorphic)
- Salt deposits (bedded and domed)

- Sedimentary deposits (clay and seabed sediments)

The properties of the geologic formation are very important because of their influence on many of the factors that determine the corrosion behavior of container materials. These factors include the groundwater chemistry, the groundwater flow rate, the hydrostatic pressure, the lithostatic pressure, the phase of the water contacting the container (liquid and/or vapor), the temperature of the container, and the types and concentrations of radiolysis products. The container temperature and radiation output are influenced by the design and loading of the waste package (size, thermal output, radiation output), the rate and density of waste package emplacement, and the thermal properties of the formation.

A brief summary of the types of environments being used in the selection of waste container materials follows. Because radiation could have an important and potentially unique impact on the environment of the container through the production of radiolysis products, this discussion of environment is separated into two parts: general characteristics and radiation effects.

General Characteristics

Temperature. Because heat is a significant by-product of HLW decay, the temperature of all waste containers will initially increase and then decrease as the activity of the waste decays. The predicted temperature history for 3-kW waste packages emplaced in a consolidated volcanic ash (tuff) formation in the U.S. is shown in Fig. 84. Typical maximum container temperatures for a number of other repository locations are given in Table 16. Although these maximum temperatures are quite different, the general shape of the temperature curve shown in Fig. 84 should be similar for the other repositories. The variability in maximum temperature is due primarily to design philosophy. The temperature at a given location can be lowered by longer waste aging before emplacement, lower package loading, and lower overall repository loading. The lower temperatures will, in general, enhance the performance of the entire waste package and decrease the impact of emplacing waste on the geologic formation itself. However, a penalty is incurred to reduce temperatures because higher handling and emplacement costs, along with a larger usable area, are also required.

Water Chemistry. A summary of the expected composition of the groundwaters associated with several of the candidate formations is given in Table 17. The E_h, or oxidizing potential, of the groundwater in most cases will be determined by the presence of radiolysis products (see the discussion of "Radiation Effects" in this article). However, if radiation shielding is used in the package, conditions can range from slightly oxidizing (unsaturated tuff) to slightly reducing (basalt, granite, sub-seabed). The groundwaters associated with the crystalline-rock formations should all be relatively benign to most materials because of their low ionic strengths, near neutral pH, and low concentrations of halide ions. The corrosivity of these waters could be increased if significant groundwater vaporization occurs during the early times following emplacement when high container temperatures exist. Any brine contacting the container in the salt repositories will be quite corrosive because of the high concentration of halides and the potential for low pH due to magnesium salt hydrolysis (Ref 154). The situation is similar for the chloride-containing seabed environment. The corrosivity of ground-waters in a clay environment should fall between that of seawater and the crystalline-rock waters.

Water Availability. Because water movement is the primary mechanism for transporting radioactive species away from the package, an important criterion for selecting geologic formations is a lack of available water. The candidate formations have a low permeability and/or a small quantity of flowing water, resulting in a very low flow rate of groundwater past the waste containers. For crystalline-rock formations, groundwater will flow, because of hydraulic gradients, to the package either through the rock matrix or fractures and fissures. The water flow rate through the granite formation in Sweden and the tuff formation in the U.S. has been estimated to be of the order of 0.1 L/m^2/yr (Ref 149, 158).

Brine can be transported in the relatively dry (0.05 to 2% H_2O) salt formations by thermally induced migration of brine inclusions. This process has been estimated to transport only 8 L of brine to the package in the first 1000 years (Ref 151). Additionally, more significant quantities of brine could contact the package as a result of accidental flooding. Sub-seabed sediments will be saturated with essentially stagnant seawater (water velocity: <1 mm/yr, or 0.04 in./yr). Containers placed in clay will be exposed to humid air contaminated with volatile compounds released from the clay during heating or possibly to water due to intrusion from overlying aquifers.

Water Phase. Almost all of the repository sites being considered are located below the water table. During construction and water emplacement, these repositories will be dewatered and become dry. Immediately following closure, the container will be exposed to hot, relatively dry conditions, thus promoting oxidation. As water slowly resaturates the formation, inundated conditions may be produced and the hydrostatic pressure may allow liquid water to be present on the container at temperatures above 100 °C (212 °F). For repositories located in fractured, unsaturated rock, liquid water above 100 °C (212 °F) should never exist. For reference, the International Atomic Energy Agency qualitatively described many of the general features of the candidate sites that are relevant to this issue (Ref 169).

Radiation Effects

The dose rate of gamma radiation at the surface of the container will be determined by the concentration of the various radioactive isotopes within the package (a function of age, type, length of time the fuel is in the reactor) and the attenuation provided by the container. Currently, the U.S. plans to accept the most active waste fordisposal (5 years out of reactor). This waste will produce maximum dose rates at the container surface of 10^3 to 10^5 rads/h (Ref 159). Most of the corrosion testing conducted in the presence of radiation uses these maximum dose rate levels.

Many researchers have addressed the effect of radiation on the environment of the waste container. The information available on this subject has been collected and analyzed as of 1981 (Ref 157). Based on this information, some general conclusions can be made, as follows. First, only gamma radiation from the HLW can affect the environment, because the other forms of radiation will not penetrate the container. The gamma radiation will cause radiolysis products to be formed in the groundwater or vapor environment around the container. Second, the net effect of the radiolysis products will be to make the environment more oxidizing. In general, the higher the solute concentration in the groundwater, the higher the concentration of radiolysis products. Lastly, the major radiolysis products associated with the three rock types can be summarized:

I Crystalline rock
Groundwater: H, OH, e^-_{aq}, H_2, H_2O_2, HO_2, O_2^-
Vapor: CO, O_3, HNO_3, NH_3, NO_x
II Salt deposits
Brine: species from Category I plus oxychlorides, oxybromides, Cl_2^-, Cl_2, Br_2, O_2
Vapor: species from Category I plus HCl, HBr
III Sedimentary deposits
Subseabed: Same as Category I with the addition of the chloride containing species from Category II
Clay: Based on groundwater chemistry, radiolysis products for clay should also be close to those for the hard-rock formations.

Radiolysis of the low ionic strength groundwaters associated with crystalline rock is very similar to that for pure water, with the stable species being molecular hydrogen (H_2) and hydrogen peroxide (H_2O_2). A detailed investigation of brine radiolysis and some semi-quantitative predictions of product yield are discussed in Ref 170 and 171.

Recently, a study was conducted to determine the effect prior irradiation of rock salt may have on the chemistry of the brine that may contact the container (Ref 172). It was concluded that the pH and total base of a saline solution made from irradiated rock salt can be significantly different from a solution made from nonirradiated salt. Either alkaline or acidic brine can result, depending on the shielding of the waste container and the quantity of brine present during the irradiation period.

Because metals corrode by oxidation, radiolysis may adversely affect corrosion rates. The strong oxidants produced in brines should make salt the most aggressive of the geologic media being considered. However, the presence of strongly adherent oxide films on certain metals can significantly reduce the impact of radiolysis products. For two localized corrosion mechanisms applicable to austenitic stainless steel (crevice and stress cracking), radiolysis has even been shown to have a beneficial effect by repairing localized defects in the oxide layer and thus reducing their susceptibility to these forms of corrosion (Ref 156, 157).

Simulating the effect of radiolysis products on the groundwater chemistry is a difficult task because most of the available information on radiolysis products is not quantitative and because many of the radiolysis products themselves, especially the free radicals, have very short lifetimes. For this reason, the corrosion tests completed to date that have included radiolysis products have been done under irradiated conditions. These tests require specialized facilities and procedures, factors that have dramatically limited the number of corrosion studies that include radiation effects. Attempts to produce simulated environments are continuing with limited success to date. For example, some of the electrochemical characteristics of type 316 stainless steel in low ionic strength solutions have been reproduced by simply adding H_2O_2 to the solution (Ref 173).

Corrosion Results From Site-Specific Studies

The first comprehensive programs undertaken to identify acceptable container materials started by selecting several classes of potentially suitable alloys and evaluating their performance in the laboratory and/or the field. In general, relatively simple corrosion tests were used, often under overtest conditions. This initial selection of candidate alloys was based on such criteria as corrosion behavior (general rate and susceptibility to localized/stress-assisted attack), material costs, and material availability (Ref 161). Based on the results of these screening tests, a few very promising materials were identified that are now being subjected to detailed characterization studies, the eventual objective of which is to qualify definitively a material for constructing licensable waste containers. Currently, none of the programs has completed the detailed-study phase. A list of the major candidate alloys, along with their nominal compositions, is given in Table 18.

This discussion will present corrosion results from both the screening tests and the detailed studies. These results are grouped by the three categories of rock types defined in the previous section. Because of space limitation, a comprehensive review is not possible and only selected information is given, the majority of which addresses general corrosion. However, a significant portion of the actual investigations is or was concerned with characterizing nonuniform corrosion behavior. The detailed results are available in the References. Two factors should be remembered when considering this information. First, proper container design could eliminate most tensile stresses, thus reducing the potential for stress-assisted types of failures, such as SCC, hydriding, and hydrogen-assisted cracking. Second, one testing parameter that was highly variable and is noted with all the results is the duration of the exposure. The short length of many tests should preclude the use of the associated results in any extrapolations of corrosion rates or behavior to long time periods.

For an excellent general reference, an in-depth review of this subject through 1981 was performed by the Brookhaven National Laboratory (Ref 156). Also, the Pacific Northwest Laboratory compiled all of the relevant results of corrosion testing in the U.S. up to 1983 (Ref 174). Following this section, the author's overall observations and conclusions based on this site-specific information are presented.

Crystalline Rock

Several countries are currently investigating the suitability of isolating high-level waste in a crystalline (metamorphic or igneous) rock formation. Formations included in this list are granite (Sweden and Europe), granitelike (Canada), basalt (U.S.), and tuff (U.S.). Because some of the characteristics for each type of formation are different, results will be presented separately below.

Granite. In the well-developed Swedish program, the emphasis on the selection of materials and ultimate design of the container was driven by a Swedish law that required the identification of demonstrably safe disposal methods (Ref 149, 165, 175). Container fabrication and handling costs were not considered to be important factors. Two metallic containers resulted from their assessment, both self-shielded to eliminate potential radiation effects. The first container, for reprocessed waste, consists of a 100-mm (4-in.) thick lead lining surrounded by a 6-mm (0.25-in.) thick unalloyed titanium canister. The second container, for spent fuel, is a 200-mm (8-in.) thick copper canister. Without radiation, the expected environment within the granite repository is slightly reducing. The general corrosion rate of the titanium was measured to be less than 0.25 μm/yr (0.01 mil/yr), and the susceptibility to localized attack judged to be very small. Although the risk of delayed failure due to hydrogen/stress effects was also believed to be small, such a failure mode could not be fully excluded. Furthermore, lead could cause solid-metal embrittlement of the titanium. Because of the potential hydrogen effects, their conservative approach is to not depend on the titanium, but to rely solely on the lead component for corrosion protection.

The maximum corrosion rate of both the lead and the copper canister under these conditions will be constrained by the rate of oxidant transport to the surface of the canister. The potential rate of oxidant (oxygen and sulfide) supply was determined assuming expected water flow rates (see the discussion on "Environment" in this article). Penetration rates were then calculated as follows. If all the attack is concentrated into one hemispherical pit in the lead, the liner would perforate in 4500 years. For the copper canister, even if pits 25 times deeper than the average penetration occurred, only 60 mm (2.4 in.) of the copper would be penetrated after a million years. Their conservative conclusions were that the titanium/lead container should last for thousands of years and the copper container for hundreds of thousands of years.

In Europe, emphasis has been placed on studying corrosion-resistant alloys (nickel-chromium base and Ti-Gr7), along with several low-alloy steels (Ref 164, 176). The general corrosion rate of the resistant alloys is usually less than 1 μm/yr (0.04 mil/yr). Under certain possible conditions, the corrosion behavior of the Ti-Gr7 alloy has been shown to be superior to that of Hastelloy C-4. In irradiated granitic solutions, Hastelloy C-4 was found to be susceptible to pitting. In high-

temperature solutions, Hastelloy C-4 was susceptible to both crevice corrosion and SCC. The titanium alloy showed no susceptibility to these forms of attack.

Corrosion rates measured for the carbon steels ranged from 3 to 55 μm/yr (0.12 to 2.2 mils/yr), with one study showing that the rate reaches a maximum around 80 °C (175 °F) (Ref 177). It was concluded in Ref 178 that (1) the conditions that would lead to localized corrosion of carbon steels are quite specific and unlikely to be present in typical granitic groundwaters and (2) that hydrogen embrittlement and hydrogen blistering of low-alloys steels is possible in granitic environments with a high rate of hydrogen production. However, the first conclusion was qualified by the observation that localized corrosion should still be studied because the possibility exists that conditions in the future could produce the correct combination of passivating ions (for example, bicarbonate) and aggressive ions (chloride) to cause localized corrosion. If the hydrogen effects are found to be viable processes, then radiation shielding may be required.

The Canadian container program along with some recent results are described in Ref 147, 152, and 179. The alloy families being considered include austenitic stainless steels, copper, nickel-base superalloys, and titanium alloys. Results have shown that the susceptibility of Ti-Gr2 to crevice corrosion at temperatures above 100 °C (212 °F) may be inhibited by the presence of gamma radiation and that two nickel-chromium alloys, Hastelloy C-276 and Inconel 625, should not undergo localized corrosion at temperatures below 100 °C (212 °F) even in 20% NaCl solutions.

Basalt. The early screening studies performed with aerated basalt groundwater showed that low-alloy steels and irons could be viable container materials (Ref 180). The majority of the subsequent activity has focused on cast irons, steels, and titanium-base alloys, with a new comprehensive study devoted to copper-base alloys just beginning. The titanium alloys were selected as a potential alternative because of their excellent performance in more aggressive brine solutions. The corrosion-allowance materials (iron, steel, copper) are being studied because, without radiation, the basalt groundwater should be slightly reducing (similar to the Swedish granite environment). Thus, for shielded packages, the performance of these materials could be very good.

The evaluation program has consisted of three major testing elements: general corrosion, irradiation corrosion, and environmental cracking. Some results from the first two elements are shown in Table 19 and Fig. 85 and 86. Oxidizing conditions increase the corrosion rate over anoxic conditions by a factor of 9 to 10 (Table 19). It has been estimated (Ref 163) that irradiation enhances general corrosion by a factor of two to three for all the alloys being studied (Fig. 85 and 86). However, the maximum steady-state corrosion rate observed was only 11 μm/yr (0.43 mil/yr) under temperature and irradiation conditions that are conservatively severe. Based on these and other results, it has been concluded that cast iron or cast steel appear to be suitable materials for long-term barriers in basalt. If effective radiation shielding is used, a corrosion allowance of approximately 12 mm (0.47 in.) would be required. In the presence of radiation, an allowance of 25 mm (1 in.) might be adequate.

Table 19 General corrosion rates of carbon steels under various conditions in basalt groundwater

Test duration: 2 weeks

AISI designation	Average corrosion rate, μm/yr (mils/yr)		
	Deoxygenated (<0.1 ppm O_2)		**Oxygenated (~8 ppm O_2)**
	150 °C (300 °F)	**250 °C (480 °F)**	**150 °C (300 °F)**
1006	13 (0.51)	12 (0.47)	118 (4.64)
1020	13 (0.51)	12 (0.47)	101 (3.97)
1025	11 (0.43)	13 (0.51)	105 (4.13)

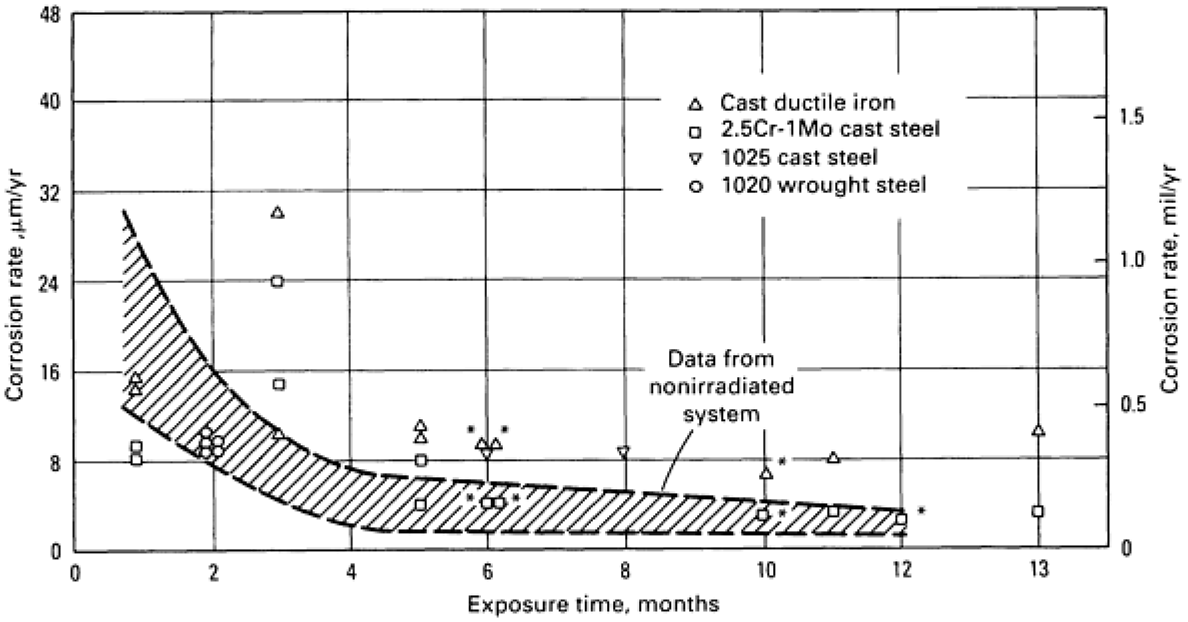

Fig. 86 General corrosion rate of cast ferrous alloys in synthetic basalt groundwater at 250 °C (480 °F) and a gamma irradiation rate of 3 × 10^5 rad/h. Source: Ref 163

Corrosion rates for Ti-Gr2 and Ti-Gr12 in both oxygenated and irradiated basalt environments are very low--less than 2 μm/yr (0.08 mil/yr) (Ref 151, 182). Additionally, the titanium alloys have not been shown to be susceptible to any form of environmentally enhanced cracking (Ref 163). The long-term corrosion rates of many copper-base alloys are also

sufficiently low, <20 μm/yr (0.78 mil/yr), at 200 °C (390 °F) that their use now appears feasible. More detailed copper evaluations are being conducted (Ref 183).

Tuff. The potential location of a waste repository in tuff is unique among all the sites because it is located in the unsaturated zone. This factor, along with the fractured character of the tuff, should preclude the possibility of the waste container becoming inundated at temperatures above 100 °C (212 °F), but could also keep any groundwater at the repository horizon aerated. Three test environments are applicable: hot, "dry" air with controlled humidity (below saturation) at temperatures from 95 to 300 °C (205 to 570 °F); moist air with humidity at or near saturation; and inundated conditions (Ref 158). Inundated conditions represent an overtest, but may exit temporarily if unexpected episodic intrusions of water occur. The latter two environments were used in the material screening studies.

Because the groundwater composition is relatively benign (Table 17) and the temperatures associated with groundwater contact are low, several ferrous-base alloys were selected for the initial screening study. Results from testing with and without radiation are given in Tables 20 and 21, respectively. The general corrosion rates of the stainless steel alloys are all very low (<1 μm/yr, or 0.04 mil/yr). No susceptibility to localized attack or SCC was noted for the stainless steels in these screening tests.

For the low-alloy steels, the corrosion rates are much higher, and localized attack was observed on all the samples. The best nonstainless material tested was the 9Cr-1Mo alloy steel, but this material stress corrosion cracked during testing. Radiation did not significantly affect the corrosion behavior of any metal studied with the exception of the 9Cr-1Mo steel. This alloy showed some evidence of pitting attack that was not observed without radiation. A few years later, more detailed corrosion testing of the low-alloy ferrous materials was completed, with one of the objectives being to quantify the localized corrosion rates (Ref 184). Results are shown in Table 22. Although the general corrosion rates are quite different from those reported in Table 20, the importance of pitting and crevice corrosion for most of the alloys is evident.

The screening tests resulted in the selection of type 304L stainless steel as the reference material. Because it was recognized that a material with better resistance to localized attack and SCC may be required, several alternate stainless-type alloys are also being subjected to the detailed-testing phase (Ref 158). These alternate alloys include type 316L, type 321, and Incoloy 825, each offering the potential for some improvement in performance over type 304L, but each being more costly. Many of the detailed studies have been completed, and many are ongoing or planned. Subjects already addressed include the effect of stress on the behavior of type 304L (Ref 185), the potential for low-temperature sensitization of type 304L (Ref 155), and the investigation of corrosion processes in irradiated environments (Ref 173, 186). Activity is continuing on the identification and experimental detection of the critical sensitization parameters. In addition, a metallurgical examination was completed of a type 304L container from a spent-fuel field test in a similar environment with the result that after almost 3 years of exposure no observable cracking or general corrosion was identifiable (Ref 187).

Recently, the list of alternative materials being studied in detail was expanded to include several copper-base alloys: oxygen-free copper, aluminum bronze, and cupro-nickel (Ref 186, 188). These additions were made because of the recognized difficulty in reliably characterizing passive, metallurgically complex alloys such as type 304L. The initial feasibility study for these copper-base alloys has been completed, and detailed studies, including testing in irradiated environments, are ongoing. Corrosion rates measured after 6-month exposures for the copper alloys under nonirradiated conditions at 100 °C (212 °F) were all less than 3 μm/yr (0.12 mil/yr).

Salt Deposits

Waste isolated in bedded and domed salt deposits is being considered by the U.S. and several European countries, most notably West Germany. The first studies to screen potential materials were associated with Project Salt Vault and involved both laboratory and field testing in a bedded salt formation in Kansas. These tests were conducted in relatively dry salt (up to 2% H_2O). Some of the laboratory results are given in Table 23. The conclusion from this testing was that austenitic stainless steels are resistant to corrosion as long as the salt remains dry. However, the field tests confirmed that containers may not remain dry because SCC occurred in many of the stainless steel containers instruments (Ref 189).

A large amount of corrosion data has been collected in the geothermal energy programs. This information is qualitatively relevant to waste isolation in salt because of the similarity in temperature and solution compositions. The missing environmental parameter is radiation. The majority of this source of information is summarized in Ref 174.

The results of the initial, comprehensive screening program using severe, high-temperature, inundated conditions were reported in Ref 161. These "overtest" conditions were used to allow the best performing materials to be identified. A partial list of the corrosion results from this study is given in Table 24. As shown, the majority of the 20 materials tested had fairly low general corrosion rates, and only a few experienced localized attack (pitting or crevice corrosion). The effect of radiation was found to increase with increases in the solute concentration in the water and the gamma dose rate. This study also showed that the magnesium-containing brines are the most corrosive of the various brines being investigated. This characteristic is probably due to magnesium salts that hydrolyze as the temperature of the brine is increased. The hydrolysis, in turn, significantly lowers brine pH. For consistency, all of the corrosion results given in this discussion were taken from testing that used magnesium-containing brines. Based on corrosion behavior, material cost, and material availability, several promising alloys were identified, with Ti-Gr12 being selected as the primary candidate.

(b) Pitting corrosion.

During the same time period, a complementary screening study was being performed at the Pacific Northwest Laboratory (Ref 180). In this activity, some of the above tests were repeated (see bracketed values in Table 24), and a few more low-cost iron-base alloys evaluated. The available information on the corrosion of iron and steel has been compiled and is given in Fig. 87. A conclusion reached by the U.S. group investigating commercial HLW disposal (Salt Repository Project) was that some of the relatively inexpensive iron-base alloys may be usable in the high-temperature salt environment.

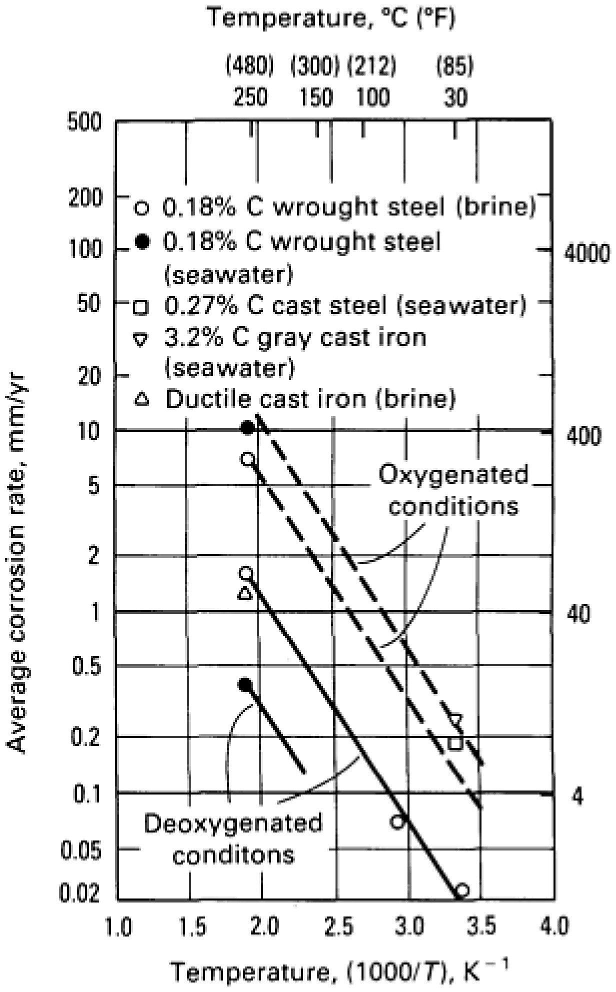

Fig. 87 The effect of temperature on the general corrosion rate of cast iron and steel in chloride solutions. Test duration: 2 to 8 weeks. Source: Ref 174

A few years later in West Germany, a more in-depth long-term screening study was performed. In this study, localized corrosion, along with the effects of gamma irradiation and brine chemistry, was quantitatively evaluated. Some of the results are given in Table 25. As can be seen, the effect of gamma irradiation is very significant for most of the alloys. These tests concluded that Ti-Gr7 has excellent corrosion resistance, even in the presence of gamma irradiation. The general corrosion rate should be less than 1 μm/yr (0.04 mil/yr) with no susceptibility to localized or stress-assisted attack. The only other alloys that are viewed as viable candidates are Hastelloy C-4 and the unalloyed steels. However, for these latter materials, radiation shielding must be included because of the deleterious effects of radiolysis products.

Most of the detailed characterization studies completed to date have been done in the U.S. These studies have focused on corrosion-resistant titanium alloys and inexpensive corrosion-allowance iron-base alloys. Sandia National Laboratories has been the dominant investigator of titanium behavior (Ref 154). General corrosion rates for titanium alloys are shown in Tables 26 and 27. The majority of the titanium studies have been directed at determining the susceptibility to nonuniform types of behavior, including localized corrosion, SCC, and hydrogen embrittlement. Other factors being considered are the effects of radiation, composition, microstructure, and processing history. The Sandia studies have shown that a container made from Ti-Gr12 should not fail by general corrosion during the initial 1000-year period with total penetration less than 1 mm (40 mils). Although a significant amount of research has been performed without identifying any susceptibility, the unresolved concerns are with SCC and hydrogen embrittlement. The results of other investigations addressing delayed failure in titanium alloys are given in Ref 190 and 191.

The Pacific Northwest Laboratory has been the prime investigator or iron-base alloy corrosion (Ref 166, 180, 192, 193). The effects of water content, time, and irradiation on the corrosion rate of several of the candidate alloys are shown in Fig. 88, 89, and 90. The important conclusions reached from these studies included the following:

- In the absence of radiation, the corrosion rate of low-alloy ferrous materials is sufficiently low even under inundated conditions that 25 mm (1 in.) of material allowance would be adequate for a 1000-year time period. However, at a dose rate of 10^5 rads/h, the corrosion rate increases by a factor of six. If the container is thick enough (approximately 80 to 100 mm, or 3 to 4 in.) to reduce radiation levels to 10^3 rads/h, then only a small enhancement in rate would be expected
- The corrosion rates of a variety of low-alloy ferrous materials are all similar
- Some evidence was found that cast steel undergoes a limited amount of environmental embrittlement. However, no susceptibility to SCC was found
- A preliminary corrosion rate model was developed that includes the effects of temperature, brine flow rate, brine volume, container area, and radiation dose rate. Also, a less detailed corrosion model has been developed for a wider range of materials than is reported in Ref 194

Sedimentary Deposits

Two types of sedimentary deposits are being evaluated as potential hosts for a waste repository: sub-seabed sediments (U.S. and Europe) and clay formations (Europe). In general, the corrosion research portion of the programs investigating these deposits is not developed to the same level as that given in the previous discussions on "Salt Deposits" and "Crystalline Rock" in this section. Only the screening phase to select viable candidate materials has been completed.

Sub-Seabed Sediments. The U.S. program has been conducted at Sandia National Laboratories in parallel with the salt investigations reported above. The corrosion behavior of candidate alloys in heated seawater and sediments was shown in Tables 24 and 26. Because seawater is a diluted brine, the conclusions presented in the previous discussion on "Salt Deposits" for both the screening study and the detailed analyses of titanium and iron-base alloy corrosion are largely applicable. Supporting the detailed Sandia findings are the results discussed in Ref 15. This study investigated the corrosion behavior of Ti-Gr2 in hot (100 to 130 °C, or 212 to 265 °F) Baltic seawater and found no evidence of pitting corrosion and a general corrosion rate typically less than 0.1 μm/yr (0.004 mil/yr). Finally, some archeological data exist that show metals can survive for very long time periods (greater than 1000 years) in deep seawater environments (Ref 195, 196). For example, a 10- to 20-mm (0.4- to 0.8-in.) thick copper container could provide 1000 years of containment. These data must be used only as indicators of performance because heat and radiation were not present during these extended exposures.

Similar to their materials selection for the salt formations, the Europeans have chosen titanium alloys and low-alloy steels as their prime candidate materials (Ref 162). Some results from this European activity are shown in Fig. 91 and 92. For comparison, the corrosion rates given in Fig. 92 for steel in deaerated seawater may be 1000 times higher if the seawater is aerated. In the heated seabed environment, Ti-Gr2, Ti-Gr7, and Ti-Gr12 should have excellent resistance to general attack (maximum rate of 12 μm/yr, or 0.47 mil/yr). All the titanium alloys may crevice corrode if the temperatures are too high (130 °C, or 265 °F, for Ti-Gr2; 170 °C, or 340 °F, for Ti-Gr7), but should not be susceptible to SCC. For the low-alloy steels under expected deaerated conditions, the corrosion rates will be small (8 μm/yr at 90 °C, or 0.31 mil/yr at 195 °F). However, if oxygen and/or radiolysis products are present or if the temperature exceeds about 150 °C (300 °F), then the rates may appreciably increase. For a steel container to be acceptable, a radiation shield may have to be included as part of the waste package.

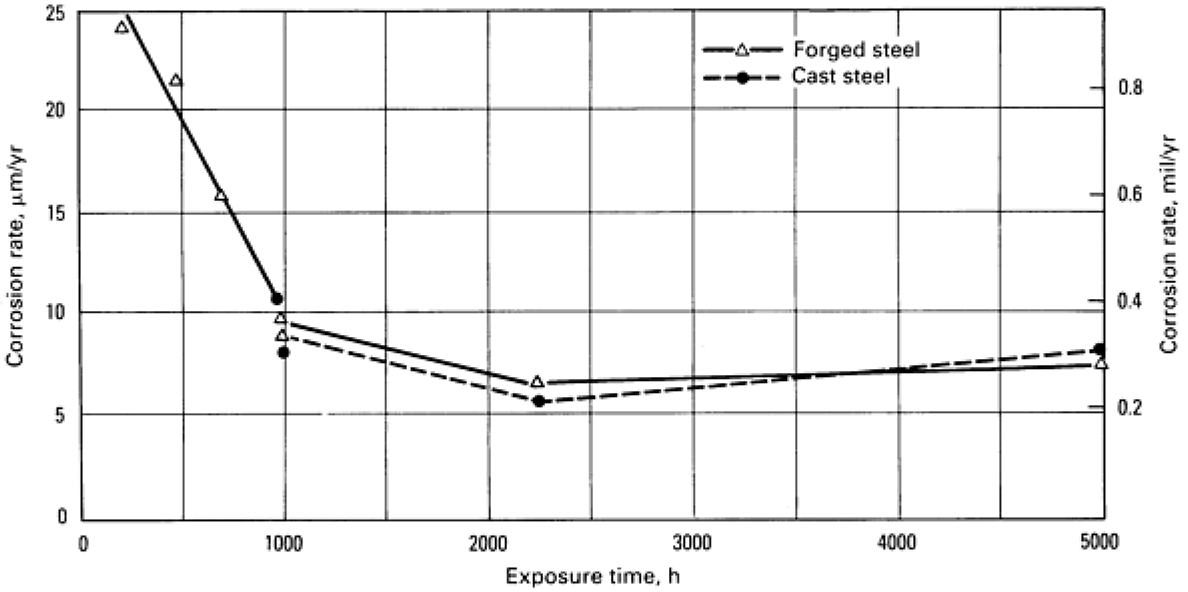

Fig. 92 Effect of time on the general corrosion rate of low-alloy steels in deaerated seawater at 90 °C (195 °F). Source: Ref 162

Clay Formations. The initial screening of materials for use in a clay formation was reported in Ref 168. The study identified sulfur and sulfur compounds as the corrosive agents released from heated clay that could ultimately contact the container. Carbon steel and chromized steel performed poorly in these environments. The general corrosion rates of the stainless steels, nickel-base alloys, and titanium alloys were all relatively low. The only materials that were not susceptible to localized attack were the titanium alloys and Hastelloy C-4. A more detailed screening study of metal behavior in clay was recently completed (Ref 164). Some of the results from this latter study are shown in Tables 28 and 29. The corrosion rates of the preferred resistant materials, Ti-Gr7 and Hastelloy C-4, are less than 1 μm/yr (0.04 mil/yr) under all experimental conditions. The corrosion rate of the carbon steel reference material depends on the temperature and the oxygen content of the aqueous phase and is thus highly variable, ranging from 2 to 300 μm/yr (0.08 to 11.8 mils/yr). Corrosion tests that include the effect of radiation have not been performed.

General Observations

Based on information presented and referenced in the discussion on "Corrosion Results From Site-Specific Studies" in this section, several common elements were observed that are, in general, applicable to the identification of container materials. These include:

- Most of the waste management programs have included low-alloy steels/irons and titanium-base alloys in their list of prime candidate container materials. The most notable exception to this general selection is Sweden, with a proposed very thick copper container for spent fuel. The nonuniform corrosion behavior of metallurgically complex alloys, such as the stainless steels and the nickel-base superalloys, is recognized to be very difficult to characterize reliably. This factor is limiting the acceptability of these types of alloys
- The corrosion rates of irons and steels may be low enough to allow thick containers to be usable in many environments. Titanium alloys have very low general corrosion rates (<1 μm/yr, or 0.04 mil/yr) and only one identified potential problem: hydrogen-assisted failure. However, with proper container design, a favorable stress state should exist that would eliminate concern for this and any other stress-assisted type of nonuniform failure
- The presence of gamma radiation has been shown to have an important, mainly detrimental, effect on the corrosion processes, especially for corrosion-allowance materials. To alleviate this potential problem, many designs will have to be self-shielded if corrosion-allowance materials are to be used
- The corrosivity of the geologic environments being studied decreases in the order salt > sub-seabed > clay > crystalline rock
- Theoretically, the corrosion characteristics of the candidate materials together with the total disposal costs (container, packaging, mining, emplacement) can be used to determine if the container should be constructed from a corrosion-resistant (for example, titanium) or a corrosion-allowance (for example, steel) material. This determination cannot currently be made primarily because the characterization process has not been completed and the exact requirements that must be satisfied to license a material for this application have not been specified. In this latter area, for example, what constitutes a failure? What failure frequency is acceptable? The author's personal speculation is that if a corrosion-resistant material can be satisfactorily qualified, then it will probably be cost effective to use in the corrosive environments (for example, bedded salt). Alternately, a relatively benign environment (such as basalt) could justifiably use a corrosion-allowance material. As such, the selection of the most cost-effective material will be possible only after more licensing details become available in each country.

Corrosion of Fossil Fuel Power Systems

R.I. Jaffee, Electric Power Research Institute

THE ELECTRIC POWER INDUSTRY uses three types of fossil-fired plants. The most common plant is the pulverized coal-fired steam power plant, which may be used either as a baseload plant (where the plant runs continuously at capacity except for scheduled outages for maintenance) or for intermediate loads between the steady baseload and higher loads needed daily. Gas turbines are used for peak loads that occur for an hour or two each day. Combined cycles using both gas and steam turbines are generally intended for baseload sustaining intermediate-load service.

The fuels used in fossil-fired plants are natural gas, petroleum, and coal. Natural gas is generally extremely pure and does not constitute a corrosion threat, unless firing is substoichiometric for reducing NO_x emissions. Petroleum fuels can be corrosive to boilers if they contain vanadium and alkali metals; these produce liquid vanadium oxides or alkali sulfates, both of which are highly corrosive to metals in the combustion chamber or hot-gas passages. Coal can contain such impurities as sulfur, chlorides, and alkali metals, which are extremely corrosive. Many coals are virtually unusable except under deaerated service conditions.

Steam Power Plants

Figure 1 shows an illustration of a fossil-fired steam power plant. Three fluid flow loops circulate through the system: fuel-air, water-steam, and condenser cooling. In the fuel-air loop, the fossil fuel is burned in air, transfers its heat to a series of heat exchangers, is cleaned of particulate matter, is scrubbed of sulfur oxides, and exits through the stack. In the water-steam loop, clean feedwater is converted into superheated steam in a boiler, which expands through a series of turbines, converting its heat into mechanical energy, and is condensed, conditioned, pumped, and heated as feedwater. In the condenser-cooling loop, cold water is passed through the condenser and can be recirculated if a cooling tower is used or an be exhausted back to the source of the cooling water. Each fluid loop possesses its unique corrosion problems.

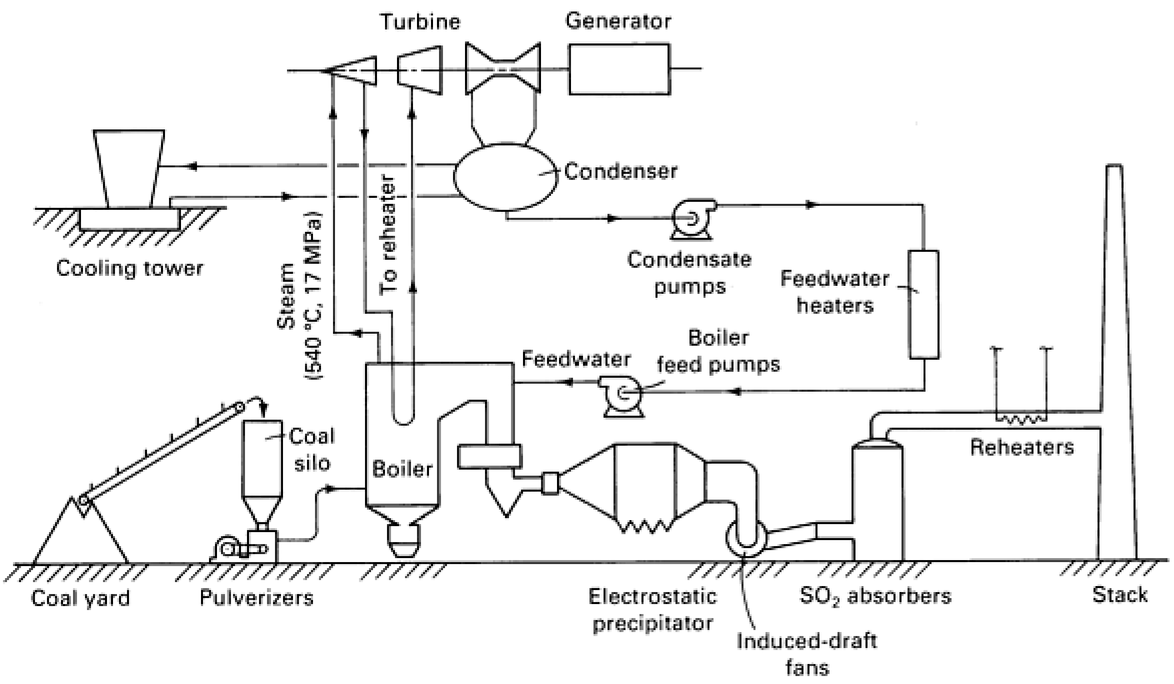

Fig. 1 Schematic of a coal-fired power plant

The fossil fuel is burned in a very large chamber constructed of water walls consisting of vertical or spiral steel tubes about 60 mm (2.4 in.) in diameter that are welded together in a web about 20 mm (0.8 in.) wide. The feedwater ascends

the water walls and is heated by the combusted fuel. In subcritical boilers, the generated steam is separated from the water such that the water is returned to the bottom of the water wall through downcomers, but the saturated steam is superheated in tubular heat exchangers suspended in the gas stream. In supercritical boilers, the pressure is above the critical point, and the liquid becomes superheated vapor without undergoing a phase change. The feedwater is conditioned to be slightly alkaline, but the fluid in the boiler may become acidic or caustic, depending on the presence of corrosion deposits and flow interruptions. Under acidic conditions, the steel boiler tubes may be hydrogen embrittled; under caustic conditions, the tubes may be caustic gouged. In supercritical boilers, overheating and excessive internal scaling in water walls may occur if boiling undergoes departure from nucleate boiling conditions at the region near the critical pressure.

The superheaters and reheaters are subject to steam oxidation on their inner surfaces and to hot corrosion on their outer surfaces. Steam oxidation results from attack by superheated steam, which acts similarly to oxygen at the same temperatures. For low-alloy steels, steam oxidation is of concern above 540 °C (100 °F). This is about the temperature at which creep strengths limit low-alloy steels, and it becomes necessary to use alloys with higher chromium contents for higher allowable stress and for better steam oxidation resistance.

Fire-side corrosion in superheaters and reheaters is a typical problem. In coal-fired boilers, it exhibits a maximum rate at 700 to 750 °C (1290 to 1380 °F), where the corrodent is liquid, and decreases to a minimum at higher temperatures, where the corrodent does not condense. The liquid ash is generally an alkali sulfate or a complex alkali iron trisulfate. At higher temperature, corrosion is predominantly the oxidation of uncooled parts, such as hangers.

Another types of boiler, the fluidized-bed boiler, was once thought to be free of fire-side corrosion because it operated under dry conditions at about 850 °C (1500 °F). The coal is burned in a fluidized bed composed of limestone or dolomite. The calcium sulfate ($CaSO_4$) product of desulfurization is in equilibrium with the calcium oxide (CaO) absorbant. At low oxygen potentials, such as those that occur in the condensed bed itself, the sulfur potential may rise high enough to sulfidize many otherwise very corrosion-resistant alloys.

Following the coal-air loop in a conventional power plant further, the flue gas passes through heat exchangers for preheating combustion air. It is important to maintain the flue and gas temperature above its dew point in order to avoid the deposition of sulfuric acid (H_2SO_4). After passage through the precipitator while above its dew point, the flue gas is scrubbed of its sulfur dioxide (SO_2) content in a flue gas desulfurization scrubber. There are many points of corrosion concern in the scrubber, but the most serious areas are the inlet duct, where the SO_2-laden gas is hottest and a wet/dry interface exists, and the outlet duct, where the scrubbed gas, still containing sulfur trioxide (SO_3), begins to condense on the walls of the duct.

Once the steam has been compressed and superheated, it leaves the boiler through heavy-wall pipes and enters the high-pressure turbine. There it expands and returns to the boiler for reheating before entering the intermediate-pressure turbine for a second expansion. After one or two expansions and reheatings, the steam enters the low-pressure turbine.

As long as the steam is dry, there is little corrosion in the high- or intermediate-pressure turbines except when condensation of solid sodium hydroxide (NaOH) occurs. However, when expansion of the steam in the low-pressure turbine reaches the point of initial condensation (at the so-called Wilson Line), high-concentration chloride and sulfate salt solutions may deposit if the steam is contaminated. The distribution of salts between steam vapor and steam condensate is such that the condensate may be 10^6 times more concentrated than the vapor. Thus, the premissible impurity levels in the feedwater are measured in parts per billion in order to protect the low-pressure turbine at the Wilson Line, which generally occurs at the next to the last (L - 1, or last minus one) row of turbine blades. The Wilson Line shifts to a highest temperature point in the low-pressure turbine at reduced load such that in load-cycling plants there is alternate wetting and drying of the salt deposit as the load increases and decreases during cyclic operation. This is a serious condition for corrosion of blades and disks in the L - 1 row.

The salt solution is often acidic as a result of evaporation of ammonia (NH_3) from the water-conditioning process. During shutdowns, oxygen and carbon dioxide (CO_2) may dissolve in the acidic salt, aggravating the corrosive condition at the L - 1 row of a low-pressure turbine. The commonly used 12% Cr turbine blade alloy becomes pitted under these conditions and may lose up to 90% of its fatigue strength. Corrective measures include using blades designed to be strong enough to operate with pitted surfaces, cleaning and maintaining the steam to avoid corrosive salt deposition, using more corrosion-resistant low-pressure turbine blade materials (such as titanium alloys), or protecting 12% Cr steel blades with corrosion-resistant coatings.

Corrosion problems may occur in the condenser-cooling loop, especially if the cooling water is sulfide-contaminated seawater or brackish water acting on copper-base tubes or tubesheets. Also, pitting or crevice corrosion may occur under deposits or barnacles or between tubes and tubesheets. However, the primary concern with condensers is leakage of seawater or contaminated cooling water into the water-steam loop, which operates below atmospheric pressure; this leakage would result in drastic corrosion effects on boiler and turbine components.

Gas Turbines

In a gas turbine, inlet air is compressed in a compressor, reacted with fuel in a combustion chamber, and directed at stationary airfoil vanes and through rotor blades or buckets constituting the turbine stage. Thus, the entire fuel and air input passes through the gas turbine without an intermediate heat exchanger. Any corrosive impurities present in either fuel or air will affect the high-temperature components, primarily the combustor, nozzle diaphragm, and turbine. The principal threats are oxidation and hot corrosion. These have been largely met by using alloys of increased chromium content, particularly Ni20Cr and Co-30Cr alloys. However, as the turbine inlet temperature increased to achieve higher thermal efficiency, it became necessary to strengthen the alloys, which resulted in lower chromium contents and greater vulnerability to oxidation and hot corrosion. The use of bypass air cooling of the hot-section parts essentially reduced the metal temperature to a point at which the high-temperature strength was sufficient, while the gas temperature increased progressively. The high-temperature high-velocity gas stream causes evaporation of volatile chromium trioxide (CrO_3) from otherwise protective chromic oxide (Cr_2O_3) scales. The alloys subjected to the highest turbine temperatures are protected by coatings containing over 5% Al, which from protective aluminum oxide (Al_2O_3) scales.

If the fuel or inlet air contains alkali metals, sulfur, or vanadium as impurities, hot corrosion may occur. This is combated by limiting these impurities in the fuel. Additives such as magnesium oxide (MgO) also help. Air filtration is used for reduce ingestion of airborn impurities. Vanes and blades are washed periodically to remove accumulated salts. The coatings that form Al_2O_3 protective scales are sometimes improved by platinum metal additions or sublayers. Also, coatings with small additions of yttrium promote adherence of all Al_2O_3 scale, which otherwise might spall off.

Combined Cycle Plants

In a combined cycle power plant, the gas turbine is used as a high-temperature topping cycle whose exhaust gas enters a waste heat boiler, which raises steam to operate the steam turbine and generator. To a large extent, corrosion problems in the combined cycle are simply the sum of the corrosion problems in the gas turbine and the steam boiler and turbine. Control of impurities in the inlet air and fuels is essential. Corrosion from the use of gasified coal, which may have caused severe problems in the gas turbine and steam generator, has largely been eliminated by scrubbing the gasified coal in a water-quenching operation. There are severe corrosion problems in the radiant cooler used to generate process steam from the raw gasified coal, which contains hydrogen sulfide (H_2S) and other corrosive agents before the scrubbing operation. These problems can be handled by limiting the temperature of the radiant cooler to be commensurate with the heat-exchanger material used, which is generally coated or clad steel.

Corrosion of Condensers

Barry C. Syrett, Electric Power Research Institute; Roland L. Coit, Consultant

---

A steam surface condenser is a shell and tube heat exchanger that is positioned immediately downstream of the low-pressure steam turbine. Heat is transferred from steam on the outside of the condenser tubes (the shell side or steam side) to water on the inside (the tube side or water side). A schematic of a typical electric power plant condenser is shown in Fig. 2.

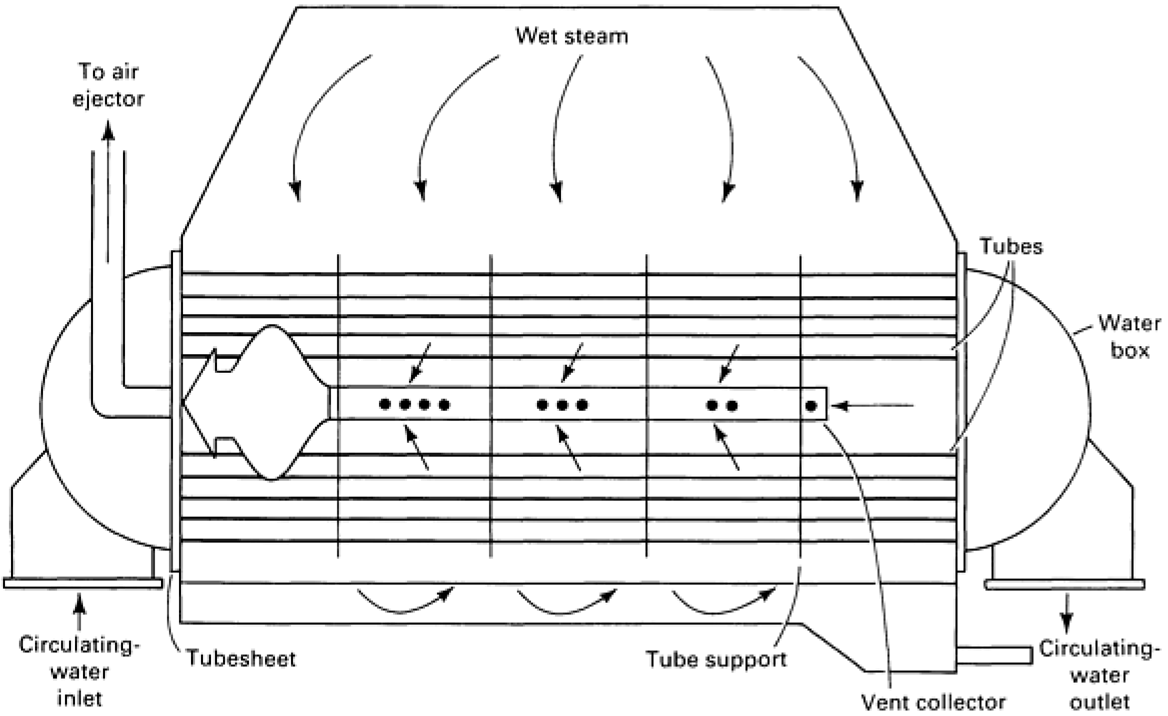

Fig. 2 Schematic of a typical condenser in an electric power plant

The condenser is a particularly critical component in a power plant because its failure can affect many other components in the steam-water cycle. The root cause of many of the corrosion problems in fossil fuel boilers, nuclear steam generators, low-pressure steam turbines, and feedwater heaters has been traced to condensers that have leaked and allowed contamination of the steam condensate with raw cooling water and air. Most tube leaks are caused by corrosion, but some failures are purely mechanical, such as those caused by steam impingement (erosion), tube-to-tubesheet joint leaks, mechanical ruptures from foreign object impact, and tube vibration resulting in fretting wear and fatigue. Purely mechanical failures will not be discussed further.

Corrosion mechanisms that have led to failure or serious problems in power plant condenser are summarized in Table 1. Table 1 reflects known service problems to date, rather than susceptibilities that might be inferred solely from laboratory tests; each form of failure occurs only under specific environmental and metallurgical conditions. Information on tubesheet materials requires special explanation. Because tubesheets are very thick (>25 mm, or 1 in.), corrosion rates can be 15 to 50 times higher than in condenser tubes and still be considered acceptable in most cases. Furthermore, even if corrosion is a serious problem in a tubesheet, inspections are usually scheduled frequently enough, and the tubesheet is thick enough, that suitable repair can made or corrosion protection procedures can be instituted along before the tubesheet is penetrated. Thus, although Table 1 indicates that copper alloy tubesheets have suffered significant (often severe) galvanic corrosion under certain conditions, leakage of cooling water through the tubesheet from the water side to the steam side has rarely occurred. Each of the corrosion mechanisms responsible for failures in condensers will be reviewed below. Some of the methods of preventing these failures will also be summarized.

Table 1 Corrosion mechanisms that have caused problems in power plant condensers under certain conditions

Alloy	Corrosion mechanism						
	Erosion-corrosion	**Sulfide attack**	**Dealloying**	**Crevice corrosion/ pitting**	**Galvanic corrosion**	**Environmental cracking**	**Condensate corrosion**
Copper alloys							
Muntz metal (tubesheets)	N	(W)	(W)	N	W	N	N
Aluminum bronze (tubesheets)	N	(W)	N	N	(W)	N	N
Aluminum bronze	W	W	(W)	(W)[(a)]	(W)	(S)	(S)
90Cu-10Ni	W	W	(W)	(W)[(a)]	(W?)	N	(S)
70Cu-30Ni	W	W	N	(W)[(a)]	(W?)	N	(S)
Aluminum brass	W	W	(W)	W[(a)]	W	W/S	S
Admiralty brass	W	W	(W)	W[(a)]	W	W/S	S
Stainless steels							
AISI type 304	N	N	N	W	N[(b)]	N	N
AL6X	N	N	N	(W)	N[(b)]	N	N
AL29-4C	N	N	N	N	N[(b)]	(W)	N
Sea-Cure	N	N	N	(W)[(c)]	N[(b)]	(W)	N
Titanium alloys							
Commercial-purity titanium	N	N	N	N	N[(b)]	(N)	N

W, water-side problem; S, steam-side problem; N, not a problem; ( ), slight sensitivity to problem; ?, problems have occurred in similar alloys.

(a) Perhaps a problem only when sulfide is present.

(b) Can induce galvanic-corrosion of adjacent copper alloys, iron, and carbon steels when used in seawater or other highly conductive waters.

(c) A problem in heats containing only 25.5% Cr and 3% Mo

Erosion-Corrosion

Erosion-corrosion is a relatively common waterside phenomenon that is a problem only in copper alloy condenser tubes. It occurs in areas where the turbulence intensity at the metal surface is high enough to cause mechanical or electrochemical disruption of the protective oxide film. In these turbulent regions, pitlike features develop. Turbulence increases with increasing velocity and is greatly influenced by geometry. For example, turbulence intensity is much higher at tube inlets than it is several feet down the tubes; this results in the phenomenon of inlet-end erosion-corrosion. Tube inserts have been used to circumvent this problem. A tube insert is a tightly fitting internal sleeve, typically 150 to 300 mm (6 to 12 in.) long, made from a material resistant to erosion-corrosion that shields the susceptible tube ends. However, unless there is a smooth transition between the end of the insert and the tube, the insert can itself create turbulent conditions and promote erosion-corrosion further down the tube (Fig. 3). Recent experiments have demonstrated that inlet-end erosion-corrosion can also be prevented by installing a cathodic protection system in the water box region.

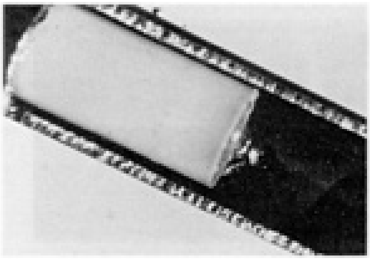

Fig. 3 Erosion-corrosion occurring immediately downstream of a nylon insert in an aluminum brass condenser tube cooled by seawater

Erosion-corrosion may also occur when marine life or debris in a tube creates a partial blockage, resulting in locally high velocities through the restricted opening. In these cases, the best solution is to keep the tubes clean, using one or more of the following methods:

- Install or improve intake screens
- Install on-line sponge ball cleaning
- Periodically reverse flow (backwash)
- Manually clean with brushes, balls, scrapers, and so on (off line)
- Prevent biofouling by chlorination or thermal shock

Alternatively, some copper alloys benefit from periodic dosing of the water with ferrous ions (Fe^{2+}), which are usually added as ferrous sulfate ($FeSO_4$) solution. The Fe^{2+} ions deposit as a protective lepidocrocite [FeO(OH)] layer on the copper alloy surface.

Sulfide Attack

This form of attack affects only copper alloys and occurs when the cooling water, most often brackish water or seawater, is polluted with sulfides, polysulfides, or elemental sulfur. As little as 10 mg/m^3 (10 ppb) of sulfide in the cooling water can have a detrimental effect, and concentrations far greater than this are often measured in polluted harbors and estuaries. Sulfide attack manifests itself in many ways. It can greatly increase general corrosion rates, and it can induce or accelerate dealloying, pitting, erosion-corrosion, intergranular attack, and galvanic corrosion. Penetration rates in polluted waters can be extraordinarily high, sometimes as high as 20 mm/yr (80 mils/yr). No copper alloy is resistant to sulfide attack, and the relative performance of copper alloys in polluted or brackish waters seems to depend on the precise environmental conditions.

If the incoming water contains sulfide and there is no obvious method of eliminating the source, the most successful method of reducing or preventing the problem is to dose the water periodically or continuously with $FeSO_4$or some other source of Fe^{2+} ions. However, sulfide attack can also occur in condensers cooled with nominally unpolluted water if marine organisms trapped within the condenser during downtime are allowed to die and putrefy to produce sulfides. This can probably be prevented, or at least reduced, by turning on the pumps for an hour or two each day to flush out the condenser with fresh seawater. In addition, sulfate-reducing bacteria can produce sulfides under debris and deposits where the oxygen content is low. Thus, the risk of sulfide attack is greatly reduced if the copper alloy tubes are regularly cleaned.

Dealloying

Another water-side problem in brass-tubed condensers is dealloying. Dezincification is an example of dealloying that has been observed in utility condensers. In dezincification, zinc is selectively removed from brass alloys to leave a copper-rich surface layer.

Dealloying is rarely the cause of condenser tube failure, but when it does occur, it is normally restricted to localized areas, such as beneath deposits or at hot spots. This results in plug-type dealloying. Clearly, maintaining clean tubes will reduce the incidence of this type of failure. A much less localized from of dealloying, termed layer-type dealloying, is rare in tubes, but has occasionally occurred in brass tubesheets, particularly in conjunction with galvanic corrosion in induce by titanium or stainless steel condenser tubes. Under such circumstances, a cathodic protection system installed in the water box will control both galvanic-corrosion and dealloying.

Crevice Corrosion and Pitting

Some stainless steels and cooper alloys are susceptible to water-side pitting and crevice corrosion. Brass and austenitic stainless steel condenser tubes, in particular, are known to have failed by pitting and crevice corrosion. There is limited evidence that copper alloys have adequate resistance to these forms of corrosion if the cooling water is completely free of sulfide. Certainly, susceptibility seems to be greatly increased when sulfide is present.

Pitting and crevice corrosion of stainless steels are more dependent on the chloride content of the cooling water than on the sulfide content, although laboratory data have demonstrated that the detrimental effects of chloride are accentuated in

the presence of sulfide. Some alloys, such as AISI type 304 and 316 stainless steels, which generally perform well in freshwaters or slightly brackish waters, suffer rapid pitting and crevice corrosion in seawater (Fig. 4). The newer, more highly alloyed stainless steels, including AL6X (UNS NO8366), AL29-4C (Fe-29Cr-4Mo-0.35Si-0.02C-0.02N-0.24Ti), and Sea-Cure (Fe-27.5Cr-3.4Mo-1.7Ni-0.4Mn-0.4Si-0.02C-0.5Ti+Nb), generally perform well even in seawater. However, a few failures have been reported for AL6X and for some of the early heats of Sea-Cure.

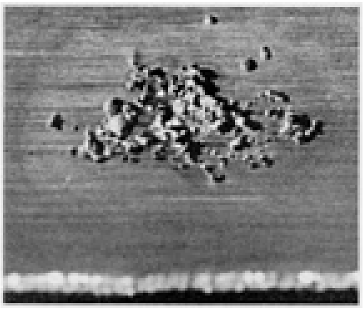

Fig. 4 Example of pitting in AISI type 316 stainless steel in seawater service

Again, tube cleanliness is a critical issue because debris and deposits promote the formation of concentration cells (the precursor to crevice corrosion) and because they favor the production of sulfides. The tube-cleaning techniques summarized earlier in this section are therefore equally useful in preventing crevice corrosion and pitting in copper alloys and stainless steels.

Galvanic Corrosion

Galvanic corrosion is not a problem is poorly conducting waters, such as those normally found on the steam side of condensers. However, it can be a water-side problem in condensers cooled with seawater or with medium- or high-conductivity fresh and brackish waters.

In seawater, tube materials, such as copper-nickel alloys, stainless steels, and titanium, are more noble than tubesheet materials, such as Muntz metal and aluminum bronze. Consequently, the tubesheet may suffer galvanic attack when fitted with these more noble tubes (Fig. 5). Laboratory tests have demonstrated that the rate of galvanic corrosion of a Muntz metal tubesheet fitted with titanium or stainless steel tubes can exceed 5 mm/yr (200 mils/yr) in seawater. Similarly, if stainless steel inserts are installed in copper alloy tubes to prevent inlet-end erosion-corrosion, rapid galvanic corrosion can be promoted in the tube close to the insert/tube interface.

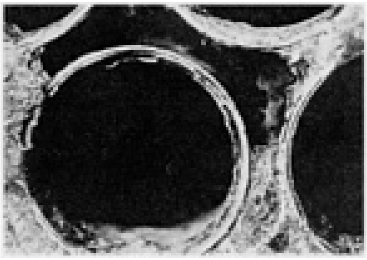

Fig. 5 Galvanic corrosion of a Muntz metal tubesheet, fitted with AL6X stainless steel tubes, after 1 year of service

Other galvanic couples can exist in a condenser, but in each case, the recommended method of alleviating the problem is to install a cathodic protection system in the water box. Cathodic protection current requirements can be reduced by coating the tubesheet and water box with a nonconducting material.

Environmental Cracking

Stress-corrosion cracking (SCC) and hydrogen embrittlement cracking are forms of environmental cracking that can affect condensers. Hydrogen embrittlement cracking was identified as a problem on the water side of ferritic stainless steel tubes in a couple of condensers fitted with cathodic protection systems. It is believed that hydrogen was generated on the surface of the tubes by the passage of too high a cathodic protection current and that this hydrogen promoted slow crack growth and failures at the ends of the tubes. The tube ends were particularly susceptible to hydrogen embrittlement cracking because roller expansion during fabrication introduced higher-than-normal residual stresses in these zones.

Entry of hydrogen into cathodically protected titanium tubes is also possible if too high a cathodic protection current is delivered. In such cases, the absorbed hydrogen can react with the metal to form a brittle titanium hydride phase which could conceivably crack and lead to premature failure. However, so far no titanium condenser tube failures have been reported. One electric utility that grossly overprotected the waterbox region of a titanium-tubed condenser discovered that the ends of the tubes were severely hydrided, but even here the affected tubes did not leak.

Apart from the rather unusual failures in ferritic stainless steels, environmental cracking is a problem only in copper alloys, specifically the brasses. Here, SCC (not hydrogen embrittlement cracking) is the mechanism of failure. Most SCC failures initiate on the steam side of the tubes, and all occur when the steam condensate contains high concentrations of NH_3 and oxygen. The NH_3 is derived from the chemicals added for boiler feedwater chemistry control, and oxygen originates from air that leaks into the system through imperfectly maintained turbine glands, expansion joints, valve packing glands, and so on. The NH_3 and oxygen concentrations are particularly high in the air removal section, and it is here that SCC occurs most frequently.

Steam-side SCC can be controlled by ensuring that the condensate on the tubes has a low oxygen concentration. The maintenance of an airtight system requires continuing attention to all seals, glands, and joints that are subjected to internal pressures less than atmospheric during start-up, normal operation, or shutdown. Helium tracer and similar techniques allow leaks to be detected with moderate ease.

Water-side SCC of brasses has occurred less frequently than steam-side attack, and in most cases, the species responsible for the failure were not positively identified. However, NH_3 and its derivatives (nitrates and nitrites) are often suspected of promoting SCC. Possible sources of these species are farm fertilizers (runoff) and decaying organisms in polluted water. Water-side failures frequently initiate beneath surface deposits, probably because the deleterious species can concentrate beneath the deposit to levels that favor SCC. Thus, once again, tube cleanliness is important, and cleaning techniques can be used to minimize water-side SCC.

No matter which side of the tube is susceptible to environmental cracking, the incidence of cracking can be controlled by reducing or eliminating residual tensile stresses. Roller expansion of the tubes during installation will always introduce some residual stresses, but care should be taken to avoid expansion beyond the back of the tubesheet, and event that can lead to particularly high residual stresses. In addition, fully stress-relieved tubes should be used, and during installation, they should not be bent or mechanically abused.

Condensate Corrosion

Copper alloy condenser tubes, particularly brass condenser tubes, are susceptible to condensate corrosion in steam condensate that contains high concentrations of HN_3 and oxygen. Consequently, condensate corrosion, like SCC, is most prevalent in the air removal section. Condensate corrosion, also known as NH_3 attack, is a form of corrosion that is localized not by microstructural features in the metal but by the localization of the corrosive environment (Fig. 6). For example, the slight tilt routinely given to condenser tubes may promote flow of some of the steam condensate toward one side of a tube support plate. There, the flow from a large number of tubes can collect and run down the plate surface. Such localized flow can create deep circumferential grooves, termed condensate grooving, in the tubes immediately next to the support plate (Fig. 6b) if the condensate contains high levels of HN_3 and oxygen. Condensate corrosion can be controlled by reducing the oxygen concentration in the condensate, as discussed previously for steam-side SCC, or by selecting more resistant alloys, such as copper-nickel alloys, or completely resistant alloys, such as stainless steels and titanium.

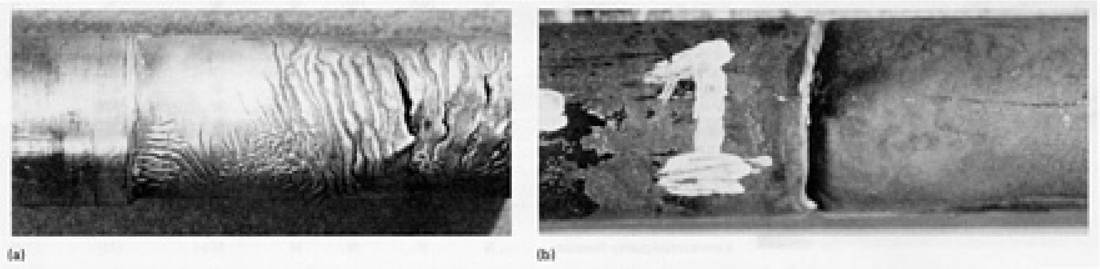

Fig. 6 Examples of NH_3 attack on admiralty brass. (a) The unattacked tube end (left) was protected by the tubesheet. (b) Condensate grooving that occurred at one side of a support plate

Corrosion Prevention

Many corrosion modes operating in condensers can be prevented if only two maintenance procedures are followed. First, if air is eliminated from the steam, condensate corrosion and SCC of copper alloy tubes can be prevented. Second, if condenser tubes are kept clean and free of deposits, debris, and biofouling on the water side, sulfide attack, dealloying, erosion-corrosion, crevice corrosion, pitting, and SCC can be prevented or minimized.

Corrosion of Deaerators and Feedwater Heaters

Robert J. Bell, Heat Exchanger Systems, Inc.

Deaerators (direct contact deaerating feedwater heaters are used in fossil and a few nuclear power plants primarily to remove dissolved gases (mostly oxygen and nitrogen) from condensate/feedwater and to raise the condensate temperature by exchange with extraction steam by mechanical deaeration. Another function is to provide deaerator storage capacity and proper suction conditions for the boiler feed pump. Closed feedwater heaters (Fig. 7) are used in power plants to increase the overall cycle efficiency of the plant by delivering to the boiler or steam generator water at higher temperatures, thereby reducing the heat required to produce steam. This is accomplished by heating the feedwater (condensate) using extraction steam from the turbine.

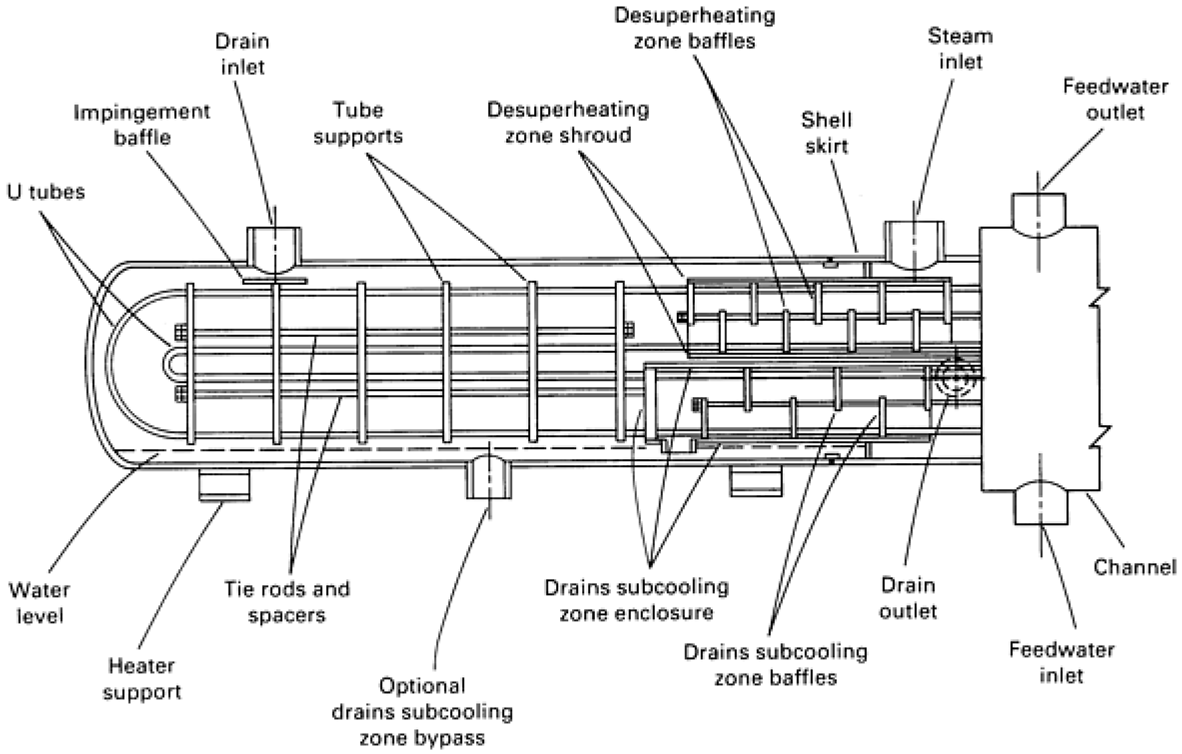

Fig. 7 Schematic of a 3-zone feedwater heater. Zones: desuperheating, condensing, and subcooling

Deaerators and feedwater heaters are susceptible to various forms of corrosion. This section will discuss corrosion in these applications as well as the measures that can be taken to minimize it.

Closed Feedwater Heaters

Corrosion problems in closed feedwater heaters are usually manifested as tube failures. Although tube failures may be a symptom of another problem, such as a baffle failure, the predominant causes of tube failures are destructive vibration, impingement erosion, cavitation-type erosion, and corrosion. Corrosion is a lesser cause than the others. The tube alloys most frequently used in closed feedwater heaters and their associated corrosion concerns are summarized in Table 2 and will be described in the rest of this section.

Table 2 Tube alloys used in closed feedwater heaters and associated corrosion mechanisms

Alloy	Corrosion mechanism and alloy susceptibility[(a)]							
	SCC	**Exfoliation**	**Erosion-corrosion**	**Crevice corrosion**	**Pitting**	**Condensate corrosion**	**General corrosion**	**Snake skin**
Admiralty brass	S	I	I	I	I	S	S	I
90Cu-10Ni	I	I	I	I	I	I	S	I
80Cu-20Ni	M	S	I	I	I	S	S	I
70Cu-30Ni	M	S	I	I	I	I	S	S
Carbon steel	I	I	S	I	I	I	S	S
Austenitic stainless steels	S	I	I	S	S	I	I	I
Ferritic stainless steels (for example, AISI type 439)	S[(b)]	I	I	I	I	I	I	I
Monel 400	M	I	I	I	I	I	I	S

(a) S, susceptible; I, immune; M, marginally susceptible in the annealed state and susceptible in the drawn stress-relieved state.

(b) AISI type 439 stainless steel has greater immunity than AISI type 304; AISI type 446 is virtually immune.

Stress-corrosion cracking occurs when an alloy under a tensile stress (applied and/or residual from manufacture or welding) is exposed to a specific corrosive environment. The chloride ion (Cl^-) induced SCC of austenitic stainless steels, for example, AISI type 304, in power plant systems is well documented. Failures due to SCC in feedwater heaters have not been significant in number, and gross deviation from normal feed-water chemistry is the universal cause. The potential for concentration of corrosively aggressive chlorides occurs mainly on the shell side in the desuperheating zone in the event of a small leak. This factor, combined with controlled feedwater conductivity, pH, and dissolved oxygen content, possibly explains why there have been few reported failures of stainless steel tubes due to SCC.

The copper alloys are susceptible to NH_3-induced SCC. When many plants switched to all-volatile water treatment (a source of NH_3), the incidence of SCC in copper alloys correspondingly increased. The failures typically occur in poorly vented areas where oxygen and NH_3, can concentrate. Stress-corrosion cracking can be minimized by reducing the residual stresses in the material, for example, by stress relieving tube U-bends. Because of the susceptibility of copper alloys to other corrosion mechanisms and because of the overall need to reduce copper within the system, the application of the copper alloys has been greatly diminished.

There have been a few reported failures in Monel 400 tubes, primarily at the U-bend because of SCC. Such failures can be prevented by limiting residual stress.

Exfoliation is a form of corrosion in which the corrosive penetration runs primarily on a plane that is parallel to the tube surface (Fig. 8). Generally, attack is along boundaries of grains that are elongated in the drawing direction. The expensive force of insoluble corrosion products tends to force these grains apart. The outside surfaces of exfoliated tubes exhibit heavy scaling with a leafy appearance; hence the term exfoliation. Both 70Cu-30Ni and 80Cu-20Ni alloys are susceptible to this form of attack; the degree of susceptibility increases with nickel content.

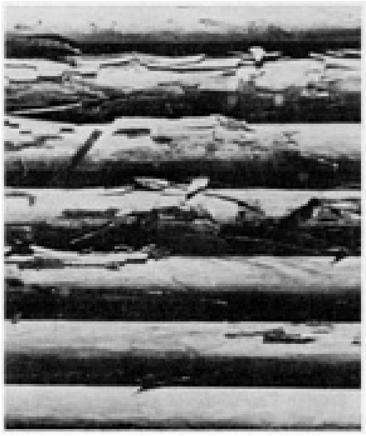

Fig. 8 Exfoliation of tubes in a closed feedwater heater

In the power generation industry, exfoliation was first encountered in units that were converted from baseload operation to peaking/cycling service (Ref 1). The peaking/cycling service results in greater and more frequent exposure to oxygen. This problem is reduced by steam or nitrogen blanketing when the unit is out of service.

Erosion-Corrosion. Many closed feedwater heater tubes are protected from accelerated corrosion by the formation of a corrosion product film, which in turn acts as a diffusion barrier that can limit the net diffusion rate of the corrodent (for example, dissolved oxygen) to the underlying base metal, By limiting the net diffusion rate of corrodent through the film, the corrosion rate is also limited. Turbulence at tube entrances can produce excessive shear forces on the protective corrosion product film; these forces reduce the section thickness of the film and consequently accelerate corrodent flux and the corrosion process. This process is erosion-corrosion.

Although other tube alloys used in closed feedwater heaters are theoretically susceptible to erosion-corrosion, only carbon steels have exhibited widespread failures (Fig. 9). The primary causes are excessive water velocities, either by design or by abnormal operation of the feedwater heaters, and channel geometries that cause local zones of turbulence at the tubesheet. Low feedwater pH, for example, less than 8.8, accelerates this mechanism because of the impact of pH on the carbon steel corrosion product film.

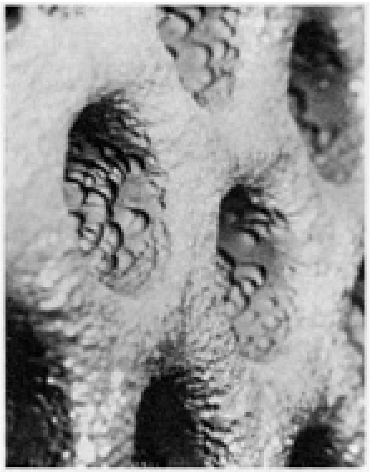

Fig. 9 Erosion-corrosion of carbon steel tubes in a closed feedwater heater. Courtesy of the Electric Power Research Institute

Erosion-corrosion is also predominant at temperatures between 150 and 230 °C (300 and 450 °F). At these temperatures, the protective corrosion product film is soft and comparatively friable (Ref 2).

Pitting of feedwater heater tubes is generally limited to austenitic stainless steel alloys and carbon steels, Pitting of austenitic stainless steel alloys is caused by the contamination of feedwater by chlorides. Pitting typically occurs when chlorides are concentrated under deposits, within crevices, and through evaporation, for example, in the desuperheating zone. The few reported incidents of chloride-induced pitting in austenitic stainless steel (type 304) are generally associated with excessive seawater intrusion permitted by condenser tube leaks (Ref 2). There are no reported similar occurrences with ferritic stainless steels, such as AISI type 439.

Failure to control feedwater oxygen content properly (<7 ppb) has resulted in a few reported incidents of pitting in carbon steel tubing (Ref 3). One incident of carbon steel tube pitting was also attributed to excessive saltwater intrusion due to operating with a condenser tube leak (Ref 2).

General corrosion occurs in all closed feedwater heater tube alloys. Corrosion rate, however, varies substantially among the typical feedwater heater tube alloys. Passive materials, such as the austenitic and ferritic stainless steels, demonstrate negligible uniform corrosion rates and are therefore considered essentially immune to this form of corrosive attack. In general, susceptibility to general corrosion decreases as alloy selection changes from carbon steel to brasses, copper-nickels, Monel 400, and stainless steels (immune). The nature of the corrosion product film is the primary controlling variable.

In terms of the corrosion product film, two characteristics are important; the corrodent flux through it and the uniformity of diffusion resistance at all points. General corrosion typically occurs where diffusion resistance is essentially the same at all points.

The variables affecting general corrosion, and therefore the corrosion product film, are pH, temperature, fluid velocity, and concentration of corrodent. The magnitude of influence exerted by each variable significantly increases or diminishes as a function of the exposed tube material.

Two very critical parameters are introduced into the general corrosion reaction when cycling service begins. First, greater amounts of oxygen and CO_2 are present during low loads and during outages. Because the corrosion rate of carbon steel is directly proportional to corrodent concentration, greater corrosion is likely with cycling service. Second, cycling service creates thermal expansion-contraction problems that arise from the difference in the thermal expansion coefficients of the carbon steel tube and its corrosion product film. Therefore, cycling service leads to fracturing of the protective corrosion product film. The metal directly beneath these fracture sites has little, if any, remaining film to provide a protective diffusion barrier. It follows, then, that fossil plant cycling can accelerate the corrosion of carbon steel tubes.

Snake skin are a result of the redeposition of copper corrosion products on Monel 400 or 70Cu-30Ni high-pressure feedwater heater tubes. The deposition results in a thin flaky film that shrinks and subsequently sheds from the tubes when dried. The film appearance is similar to a skin shed by a snake (Fig. 10). It can cause a significant reduction in heat transfer. Low-pressure closed feedwater heaters employing admiralty brass tubes are usually the source of the copper.

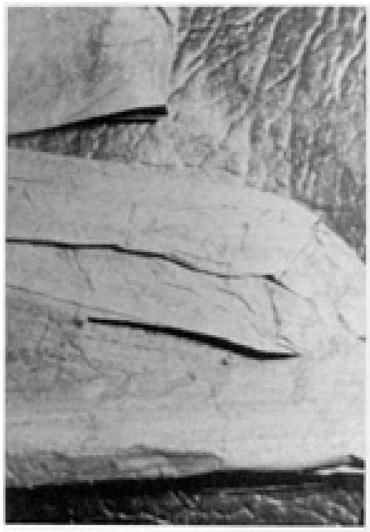

Fig. 10 Snake skin formed by the redeposition of copper corrosion products on copper alloy reheater tubes. Courtesy of the Electric Power Research Institute

Deaerators

Deaerators are subject to general corrosion, erosion-corrosion, SCC, and corrosion fatigue. The corrodent for the latter mechanism is dissolved oxygen--even at concentrations of 7 ppb or less. This corrosion process usually begins as oxygen-induced pits, which in turn act as stress risers, that ultimately promote the initiation of (typically) transgranular cracks. This process requires low-frequency stress cycles that produce greater contact time between the metal and corrodent.

Corrosion of Steam / Water-side Boilers

R.B. Dooley, Electric Power Research Institute

The cost to electric utilities from corrosion and deposition on steam- and water-side boilers is high--approximately $3.5 billion per year. One-half of the outages forced by plant failures have also been estimated to be attributable in some way to water-side corrosion. Contaminant deposition in most cases reduces equipment efficiency and induces corrosion by a variety of mechanisms and is implicated in a variety of boiler tube failure mechanisms that are most common in water walls and economizers.

Water side deposits often begin as accumulations of corrosion products transported to the boiler from other parts of the system. The corrosion product deposit is porous, in contrast to the protective magnetite (Fe_3O_4) film. This porous deposit serves as a trap for corrosive impurities, such as caustic, chlorides, and acid sulfates.

Boiler tube failures initiating in steam-containing tubing have also almost exclusively been the result of entrainment of contaminants within the steam. Chlorides, sulfates, and caustic are the most common contaminants. However, the growth of Fe_3O_4 on the inside tube surface can also be a secondary contributor to tube failure. If its growth rate is excessive, this will act as a thermal barrier and cause the tube wall temperature to rise, sometimes above the point at which excessive creep damage will result in an over-heating failure.

Water Walls and Economizers

These components are usually manufactured of plain carbon steel (ASTM A210, ASME SA-192); in a few exceptions, the tubes are a low-chromium ferritic material (ASME SA-213, grade T-11). In most cases, the tube metal temperatures are less than 400 °C (750 °C) for subcritical boilers.

Normal Protective Fe_3O_4 Growth. It has been pointed out many times that the only thing that protects a boiler is a thin film of Fe_3O_4 on the water-side tube surface. The ability to use inexpensive carbon or low-alloy steels in contact with water at high temperatures and pressures is due to the reaction between iron and oxygen-free, neutral, or slightly alkaline water:

$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 4H_2 \qquad \textbf{(Eq 1)}$$

by which a film of Fe_3O_4 is formed on the water-side surface of the tube; the kinetics of the reaction are parabolic, and the protective oxide consists of two layers described as the inner and outer. In practice, the outer layer is seldom formed, because as the iron diffuses outward the Fe_3O_4 formed at the outer interface usually becomes entrained in the boiler water flow and then deposits, together with feedwater corrosion products in another region of the boiler, which may be of higher heat flux.

The growth of Fe_3O_4 in economizer tubing occurs in a similar fashion to that in the water wall. However, a common observation is that the water-side surfaces are more uneven and contain more pits than those in the water walls.

Breakdown of the Normal Protection Mechanism. The corrosion resistance of water wall/economizer tubing depends on keeping the protective Fe_3O_4 in place, on the pH level of the water, and on the amount of contaminants. Figure 11 shows the effect of pH on the rate of corrosion of steel by water. Magnetite is unstable and soluble at pH values below 5 and above 12.

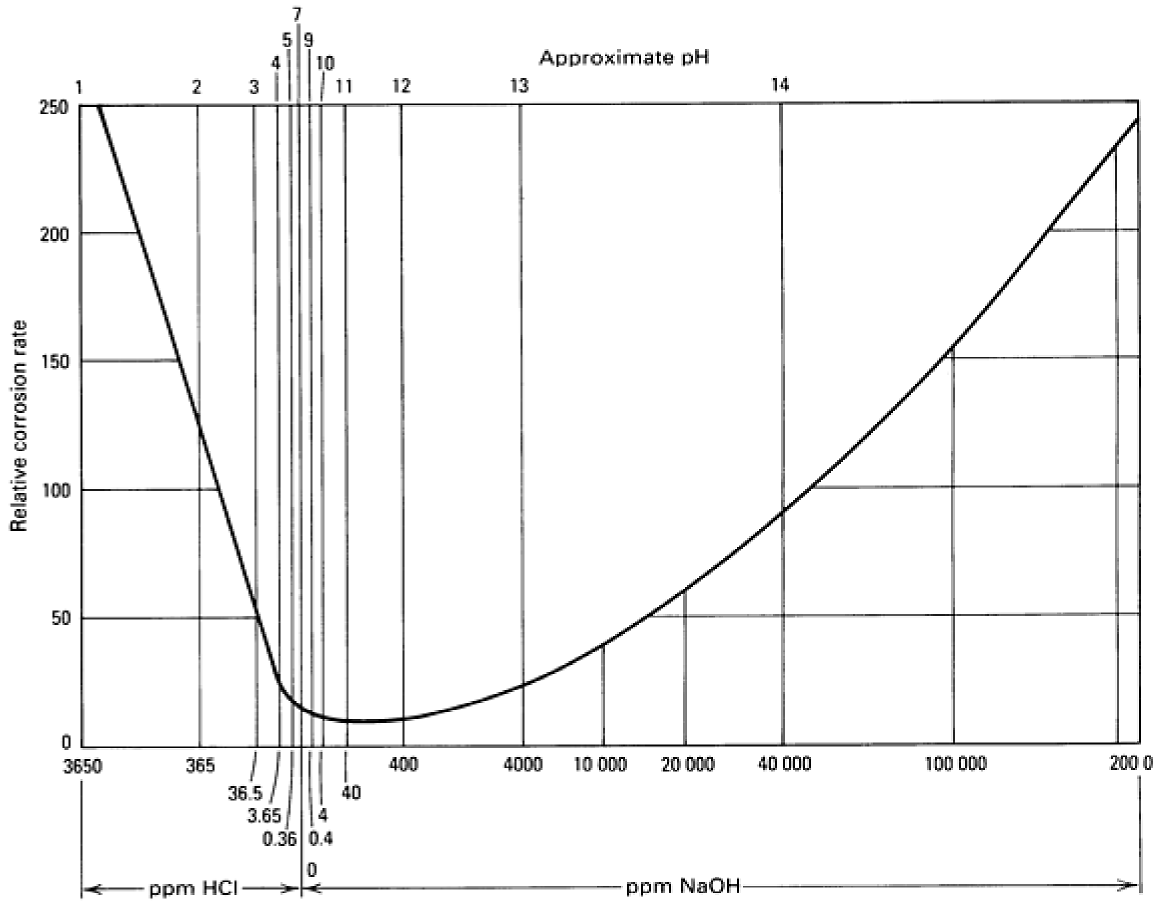

Fig. 11 Effect of pH on the corrosion rate of steel in water at 310 °C (590 °F). Upsets in water chemistry that increase or decrease the pH of boiler water or of wall deposits can result in corrosion of the water wall tubes.

Source: Ref 4

The significant categories of water-side corrosion failure mechanisms are caustic corrosion, hydrogen damage, and pitting (localized corrosion). A significant factor in these mechanisms is the amount of corrosion product deposited on the wall tube. Caustic corrosion and hydrogen damage result from the breakdown of the protective Fe_3O_4 layer by the concentration of corrosive chemicals within a wall deposit. As indicated below, different failure mechanisms will be experienced, depending on the contaminants present.

Caustic corrosion is sometimes referred to as caustic attack, caustic gouging, or ductile gouging. Caustic corrosion develops from the deposition of feedwater corrosion products in which NaOH can concentrate to high pH levels. At high pH levels, the protective Fe_3O_4 layer of the tube steel becomes soluble, and rapid corrosion occurs (Fig. 11).

Caustic corrosion is caused by the selective deposition of corrosion products and NaOH at locations at high heat flux. As porous deposits accumulate in high heat input areas, NaOH concentrates through a process known as wick boiling. The caustic levels can concentrate from less than 100 ppm NaOH in the bulk water to over 200,000 ppm adjacent to the tube surface. The electrochemical nature of the attack is shown in Fig. 12. The hydroxide ions (OH^-) are concentrated within the deposit layer so that the hydrogen ion (H^+) concentration is highest in the boiler water.

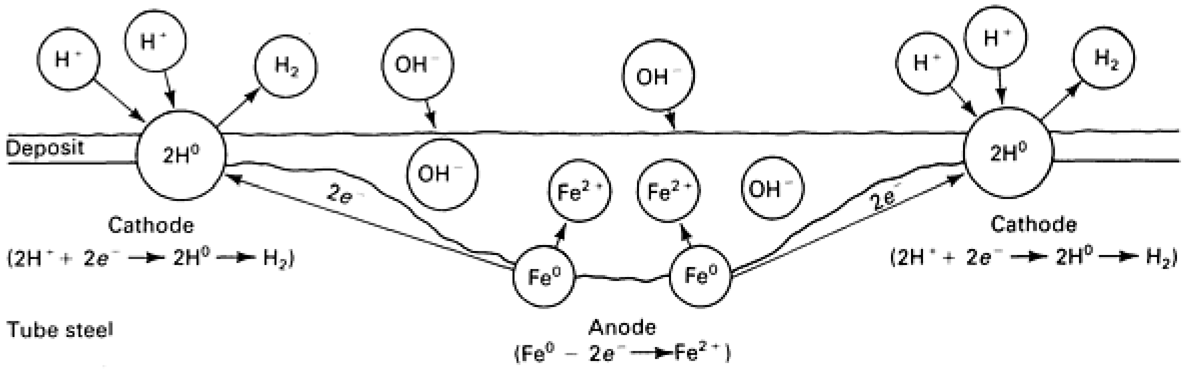

Fig. 12 Schematic of the mechanism of caustic corrosion. A caustic upset in boiler water conditions can result in concentration of OH^- ions in the deposit and generation of hydrogen gas into the boiler water. Source: Ref 5

The susceptibility of high-pressure boilers to such corrosion damage may be reduced by minimizing the entry of deposit-forming materials and by performing periodic removal of the water-side deposits by chemical cleaning. Rigorous monitoring and control of the water chemistry is necessary to prevent high caustic levels.

Hydrogen damage develops from the generation of hydrogen during rapid corrosion of the internal surface of the tube. The atomic hydrogen migrates through the tube steel, where it can react with iron carbide (Fe_3C) to form methane (CH_4). The larger CH_4 molecules become trapped at the grain boundaries and cause a network of discontinuous internal cracks to be produced. These cracks grow, and some will link up to cause a throughwall fracture.

Hydrogen damage is caused by operation of the boiler with low-pH water chemistry and the concentration of contaminants within the deposits on the internal tube wall. The electrochemical nature of hydrogen damage is shown in Fig. 13. Under acidic attack, H^+ ions are concentrated within the deposit so that the cathode site is localized and adjacent to the anode.

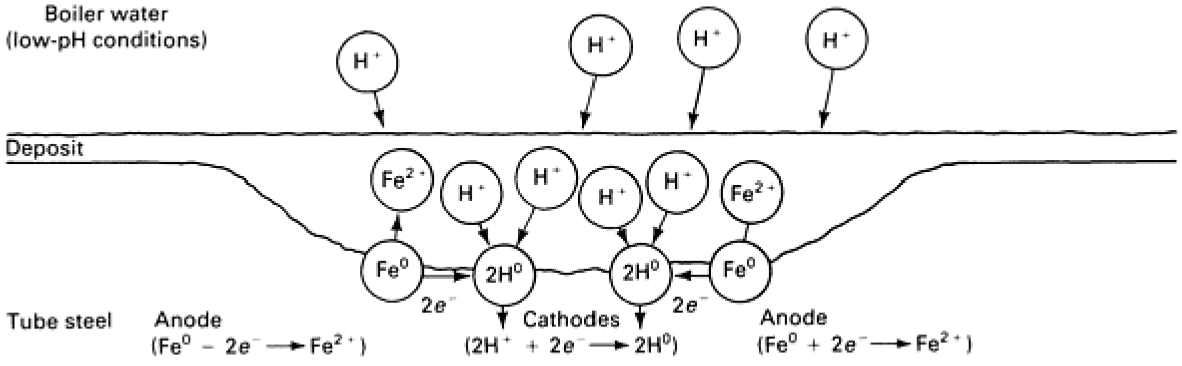

Fig. 13 Schematic of the corrosion mechanism of hydrogen damage. Acid (low-pH) boiler water conditions can result in concentration of H^+ ions in the deposit and generation of hydrogen gas atoms into the tube material. Source: Ref 5

Monitoring and control of boiler water chemistry are important in preventing internal tube deposits and hydrogen damage. The most common method of preventing increased corrosion and hydrogen damage is to develop operating guidelines for boiler water and particularly for the action to be taken when the boiler water is outside the guidelines (see the section "Boiler Water and Steam Chemistry" in this article). For example, chemical cleaning should be immediately considered when the boiler water pH has been below 7 for more than 1 h.

Pitting. Boiler tube failures caused by pitting or localized corrosion result from oxygen attack or acid conditions on the internal surfaces of the boiler tube. The localized corrosion produces perforations of the tube wall when a small area on the tube becomes anodic to the rest of the tube surface and preferentially corrodes. The anodic condition can develop from exposure of the tube to water with high acid or oxygen concentrations or at crevices.

The oxygen in the boiler water reacts with and rapidly removes the hydrogen produced at the cathodes (Fig. 13), thus accelerating the cathodic reaction. The oxygen will also oxidize the Fe^{2+} ion. Hematite iron oxide (Fe_2O_3) will form as the corrosion product and cover the craterlike perforation in the tube wall.

Pitting failure can occur anywhere in the boiler, particularly in economizers, superheaters, reheaters, and the nonheated portions of water wall tubes. For full protection against oxygen pitting during shutdown, it is necessary to keep the boiler full with hydrazine-treated water and blanketed or capped with nitrogen. Oxygen pitting attack of economizer tubing can be prevented by proper operation of deaerators and their heaters; by elimination of air in-leakage paths in low-pressure feedwater heaters, extraction piping, and condensate piping; and by injection of an oxygen scavenger chemical.

Superheaters and Reheaters

Unlike water wall and economizer tubes, the tubes in the superheater and reheater are designed for a finite life, which is not based on failure but on a conservative creep criterion. For steam temperatures of 540 °C (1000 °F), tube metal temperatures can exceed 600 °C (1110 °F), especially in the last stages of the superheat and reheat sections. Tube materials can vary from carbon steels to low-chromium ferritic (ASME SA-213, grades T-11, T-22) to austenitic stainless steels (ASME SA-213, grades T304, T321, and T347).

Normal Protective Oxide Growth. Chromium-containing steels exposed to high-pressure power station steam at metal temperatures from 550 to 650 °C (1020 to 1200 °F) initially form a spinel-type oxide consisting of two layers whose relative thickness depend on the chromium content of the steel. In superheaters and reheaters, however, the outer layer is essentially pure Fe_3O_4, and the inner layer is an iron-chromium spinel-type oxide containing the steel alloying elements.

Breakdown of the normal protective oxide in superheaters and reheaters occurs similarly to that in water walls and economizers. If the normal protective growth continues as described above, no problems will exist. There are two ways in which this protection can break down; the first is excessive growth and exfoliation, and the second is SCC.

Excessive Growth and Exfoliation. Although excessive internal growth of oxide can elevate the tube temperature, a much more serious problem is solid-particle erosion of the turbine components when the oxide exfoliates and travels into the turbine. For ferritic tube materials, corrosion initially occurs parabolically with time, but at a later stage, it can become linear, depending on the temperature.

The duplex scales produced during the parabolic period are approximately of equal thickness and are parallel sided. Any deviation of the corrosion rate from parabolic is associated with a multilayer scale. Exfoliation occurs only in ferritic materials when this multilayer growth occurs. Exfoliation of the scale is related to the stresses that are induced in the scale during temperature cycles by differences in thermal expansion between the scale and the tube.

Austenitic stainless steels generally corrode more slowly than ferritic stainless steels under the same steam conditions; as a result, the scales are somewhat thinner. This is because of the higher chromium content in austenitic stainless steels.

The initiation of scale exfoliation is not as easily defined for austenitic stainless steels, but may correspond either to the breakdown of the inner layer into a laminated structure or to some critical level of defects (voids) at the oxide/oxide interface. The cause of exfoliation is again due to the difference in thermal expansion between the scale and the tube. Replacement of existing superheater or reheater tubes with chromatetreated, chromized, or stainless steels (for the original ferritic tubes) is an effective method of reducing scale exfoliation.

Stress-corrosion cracking failures in a boiler usually occur in the austenitic stainless steels used for superheater and reheater tubing. However, SCC failures can occur in some ferritic reheater tubing when high levels of caustic are introduced from the desuperheating or attemperator spray water station.

Condition for SCC initiation and propagation arise from the contamination of boiler water or steam, the introduction of high tensile stresses from service conditions, or the production of high residual tensile stresses during fabrication and assembly. Common contaminants are chlorides and caustic, which result in transgranular cracks, and sulfur from chemical cleaning, which results in intergranular cracks.

Boiler Water and Steam Chemistry

The cycle chemistry is of paramount performance for all of the corrosion mechanisms that occur in water walls, economizers, reheaters and superheaters, operation, and control. Through proper understanding of these mechanisms, as well as the others around the cycle, it is possible to define water and steam quality limits in order to eliminate or lessen corrosion. The reliability and availability of the equipment can be improved by following water and steam quality guidelines for all types of operation (baseload, cycling, and peaking), by adopting target and action levels, and by taking the appropriate action.

Corrosion of Steam Turbines

Otakar Jonas, Consultant

The steam turbine is the simplest and most efficient engine for converting large amounts of heat energy into mechanical work. As the steam is allowed to expand, it acquires high velocity and exerts force on the turbine blades. Turbines range in size from a few kilowatts for one-stage units to 1300 MW for multiple-stage multiple-component units comprising high-pressure, intermediate-pressure, and up to three low-pressure turbines. For mechanical drives, single- and double-stage turbines are generally used. Most larger modern turbines are multiple-stage axial-flow units. Steam pressure and temperature conditions are governed by the boiler and range from less than 1.4 MPa (200 psi) saturated to more than 35 MPa (5000 psi) at 650 °C (1200 °F) superheated and supercritical (Ref 6).

Turbines are typically built for a 25-to-40-year life. Recently, a small 8-MW turbine built in 1908 was inspected and found to be in excellent condition. During this long life, corrosion and other material damage can accumulate and lead to premature failures. Corrosion usually results from a combination of water chemistry, design, and material selection problems.

From 1971 to 1980, steam turbines (excluding controls) contributed 6.7% of forced outages in United States utility units (Ref 7), which cost the utilities 192,575 GW·h in more than 9000 outages. Outages due to corrosion were a major part of

this total. A survey of about 500 utility turbines larger than 100 MW showed that corrosion failures occur in 4 to 5% of operating turbines each year (Ref 8, 9). Considering that it takes an average of 4 years for corrosion to result in a failure, about 20% of operational large turbines are under attack at any given time. A survey of industrial turbines conducted by the American Society of Mechanical Engineers (ASME) found a similar degree of corrosion and deposit problems (Ref 10).

It has been estimated that corrosion losses in utility steam systems amounted to about $1.5 billion of the $70 billion annual cost of corrosion in the United States in 1978 (Ref 11); the losses today are about $3.5 billion. The cost of corrosion of fossil turbine blades in the United States is about $300 million annually (Ref 12). Adding the estimated costs of disk, bolt, bellows, and piping corrosion, the total annual cost of utility turbine corrosion in the United States is about $600 million. The cost of replacement power can be as much as two orders of magnitude higher than that of replacement parts.

Major Corrosion Problems in Steam Turbines

Corrosion fatigue, SCC, pitting, and erosion-corrosion are the primary corrosion mechanisms in steam turbines. Figure 14 and Table 3 show the distribution of corrosion within the turbine. Pitting and corrosion fatigue of turbine blades and SCC of disks are currently the two costliest problems. Much research has been devoted to these two problems (Ref 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29), and progress is being made both in operation (better steam chemistry) and design (lower stresses, no crevices, limit on maximum strength to reduce susceptibility to SCC).

Table 3 Corrosion mechanisms in steam turbine components

Component	Material	Corrosion mechanisms[(a)]
Rotor	Forged Cr-Mo-V or Ni-Cr-Mo-V low-alloy steel	P, SCC, CF, E
Shell	Cast carbon or Cr-Mo-V low-alloy steel	SCC, E-C
Disks, bucket wheels	Forged Cr-Mo-V, Ni-Cr-Mo-V or Ni-Cr-Mo low-alloy steel	P, SCC, CF, E-C
Dovetail pins	Cr-Mo low-alloy steel	SCC
Blades, buckets	Stainless steels (12Cr or 17-4 PH), copper alloys	P, CF, SCC, E
Bucket tie wires	12Cr stainless steels (ferritic and martensitic)	SCC, P, CF
Shrouds, bucket covers	Stainless steels (12Cr or 17-4 PH)	P, SCC
Stationary blades	AISI type 304 stainless steel	SCC, SCC-LCF
Expansion bellows	AISI types 321 or 304 stainless steels, Inconel 600	SCC, SCC-LCF
Erosion shields	Weld-deposited or soldered Stellite type 6B; hardened blade materials (see above)	SCC, E
Bolts	Incoloy 901, Refractalloy 25, Pyromet 860	SCC, SCC-LCF
Wet-steam piping	Carbon steel	E-C
Valve bushings and stems	13Cr-Mo and other stainless steels	P, OX

(a) P, pitting: SCC, stress-corrosion cracking; CF, corrosion fatigue; E, erosion; E-C, erosion-corrosion; LCF, low-cycle fatigue; OX, oxidation in steam. General corrosion is experienced by all carbon and low-alloy steel components. Solid-particle erosion is experienced in high-pressure and intermediate-pressure inlets (nozzle blocks, stationary and rotating blades, and valves). It is caused by exfoliation of steam-grown oxides in superheater tubes and in steam pipes.

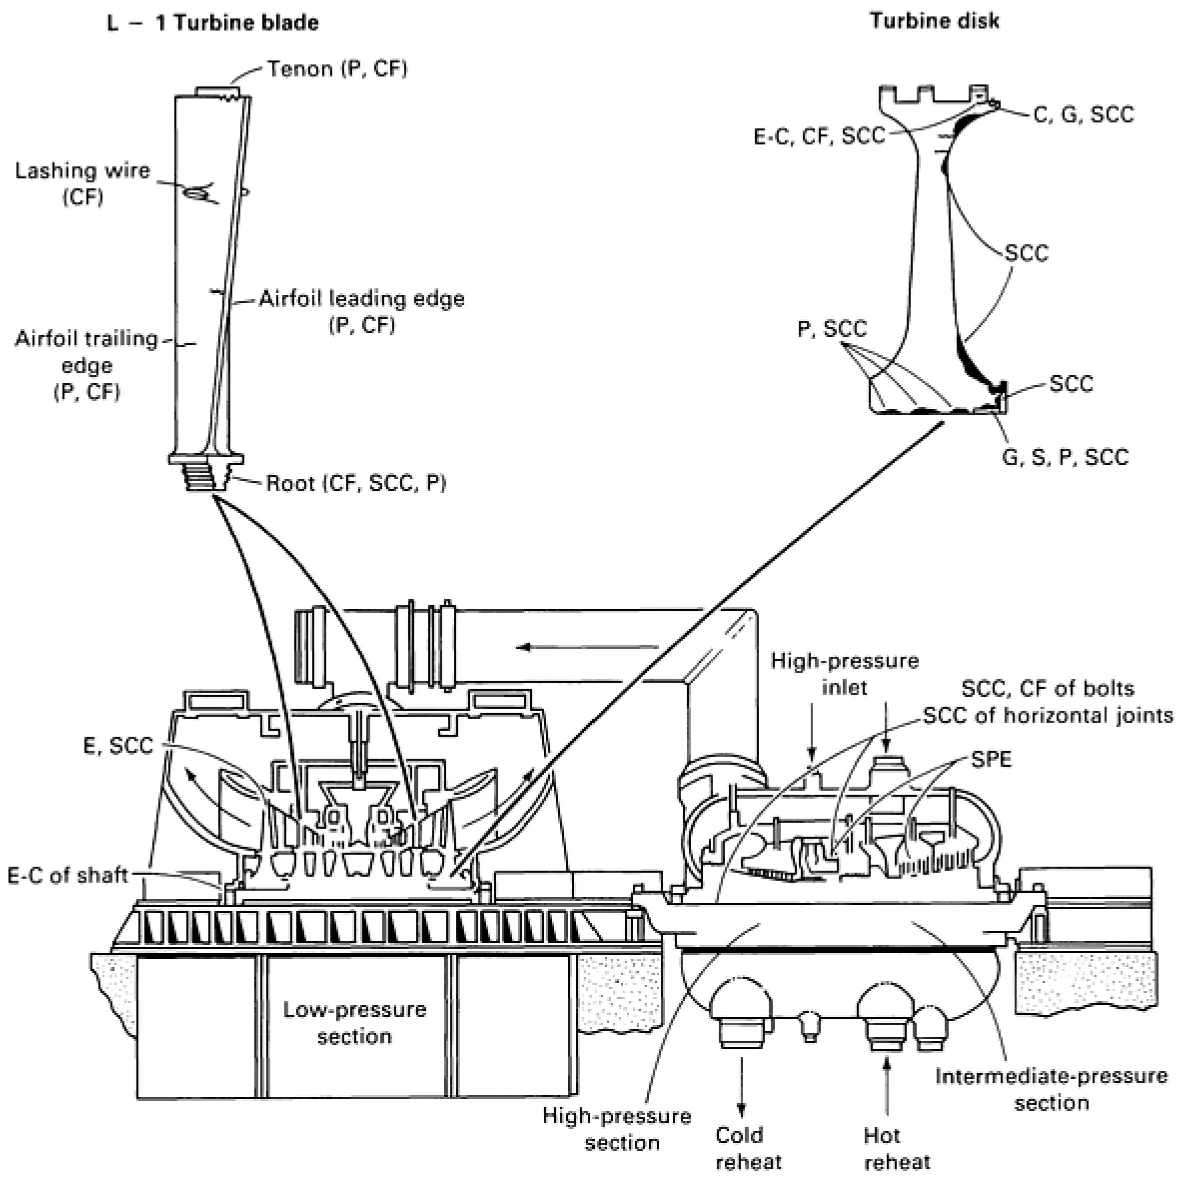

Fig. 14 Schematics showing locations of corrosion in steam turbine components. P, pitting; CF, corrosion fatigue; SCC, stress-corrosion cracking; C, crevice corrosion; G, galvanic corrosion; E, erosion; E-C, erosion-corrosion; SPE, solid-particle erosion

Statistics reveal interesting correlations. Blade failures are most frequent (in fossil utility turbines) in the L - 1 row, which is immediately before the saturation line (Ref 13, 14, 15, 16). In industrial turbines, blade failures are also most frequent in the first row after the stage in which first moisture occurs (Ref 17). Blade pitting and cracking are more frequent in once-through boiler units (these units use all-volatile water treatment and condensate polishers) than in drum boiler units (Ref 18). Statistics from West Germany, the United Kingdom, and Japan indicate a very low incidence of blade failures. A recent survey of 494 utility units in the United States reported that 167 (34%) of the units experienced blade failures between 1970 and 1981. In 1980, 1981, and 1982 the failure rate was about 4.7% (Ref 12).

Stress corrosion of low-pressure turbine disks is specifically distributed for each type of turbine and each disk location, indicating a correlation between cracking and surface temperature and steam condition. This correlation is often related to the impurity concentration by evaporation of moisture. The tendency toward cracking increases with yield strength, stress, and operating temperature (Ref 8, 19, 20, 21, 22, 23).

There are pronounced thermodynamic effects that cause the concentration of impurities at surfaces and a turbine component failure. They are most frequent where the metal surface temperature is slightly above the saturation

temperature of steam. For the low-pressure fossil utility turbines, this usually occurs on the L - 1 blades and on various surfaces of the last two disks. It is one of the reasons the L - 1 blades in fossil utility turbines have higher failure rates than any other blade row. Another reason for the high L - 1 blade failure rate could be the effects of transonic flow, vibratory stresses, and changing temperatures resulting from an interaction of the shock wave with the Wilson line (periodic destruction of the Wilson line) (Ref 30).

Erosion-corrosion of carbon steel wet-steam piping is of primary concern in industrial and nuclear turbine units. It is most pronounced in carbon steel pipes with high-velocity turbulent flow and low-pH moisture containing high concentrations of CO_2 or other acid-forming anions (Ref 31, 32, 33, 34, 35, 36).

Corrosion of other turbine parts is due to one or more of the same causes described above (Table 3). There is a strong SCC low-cycle fatigue interaction in many turbine materials (well recognized in piping) that may be important in stationary blade, bolt, expansion bellows, and turbine cylinder failures. The highest frequency of turbine bolting failures has been in high- and intermediate-pressure cylinders and nozzle blocks. Stress-corrosion cracking of expansion bellows (intermediate- and low-pressure pipes) used to be a problem in fossil units with high concentrations of NaOH (Ref 37). To find the true causes of corrosion, it is essential to analyze the local temperature, pressure, chemistry, moisture velocity, and stress and material conditions.

Turbine Materials

There is little worldwide variation in materials for blades, disks, rotors, and turbine cylinders, and only a few major changes have been introduced in the last decade. Titanium alloy blades are slowly being introduced for the last low-pressure stages. Also, improved melting practices, control of inclusions and trace elements, and weld repair techniques are being used for disks and rotors. In addition to the materials listed in Table 3, carbon steel is used for low-pressure casings (shells and cylinders), chromium-molybdenum steels and austenitic stainless steels for high-pressure piping, and miscellaneous other materials for other components.

Considering the typical design life of 25 to 40 years and the relatively high stresses, turbine materials perform remarkably well. Turbine steels are susceptible to SCC and corrosion fatigue in numerous environments, such as caustic, chlorides, hydrogen, carbonate-bicarbonate, carbonate-CO_2, acids, and, at higher stresses and strength levels, pure water and steam.

No turbine can permanently tolerate concentrated caustic, sodium chloride (NaCl), or acids. Under such conditions, disk and rotor materials would crack by SCC in a few hundred hours at stresses as low as 10% of the yield strength. Chromium steel (12% Cr) blades may tolerate NaOH, but would pit and crack by corrosion fatigue at very low vibratory stresses (as low as 6.9 MPa, or 1 ksi) in many other corrodents. With high concentrations of impurities for long periods of time, there would always be a weak link in the turbine or within the power cycle that would fail prematurely. Although titanium could be used for blades and would tolerate most of the impurities (except hydroxides), corrosion-resistant materials for the large forgings of rotors and disks are difficult to find because of the cost, forgeability, banding of alloying elements and impurities, and other problems. Plating and surface coatings appear to be only marginal temporary solutions (Ref 38).

In addition to the susceptibility to localized corrosion in concentrated impurities, the low-alloy and carbon steels used extensively in steam turbines have rather narrow ranges of passivity (Ref 39). This makes these steels vulnerable to pH and oxygen excursions and consequent pitting and other forms of localized corrosion during operation and layup. In chloride solutions, the pH region for passivation becomes even narrower. The material properties needed for designing against corrosion, failure analysis, and evaluation of residual life include fracture toughness (K_{Ic}), stress-corrosion threshold stress (σ_{SCC}), threshold stress intensity (K_{ISCC}), crack propagation rate ($\dot{a}_{SCC}$), corrosion fatigue limit, corrosion fatigue threshold stress intensity (ΔK_{th}), corrosion fatigue crack propagation rate (da/dN), pitting rate, and a pit depth limit.

Environment

Corrosive impurities are transported into the turbine steam from the preboiler cycle (in the feedwater) and the boiler as a total (mechanical plus vaporous) carryover (Ref 6, 8, 9). Their major sources include condenser leaks, air in-leakage, makeup water, and improperly operated condensate polishers. The turbine environment is controlled through a control of impurity ingress and various feedwater, boiler water, and steam chemistry limits (Ref 6, 8, 40, 41, 42, 43, 44, 45). The corrosiveness of the steam turbine environment is caused by one or more of the following:

- Concentration of impurities from low part per billion levels in steam to percent levels on surfaces and the formation of concentrated aqueous solutions (concentration by deposition or evaporation of moisture)
- Insufficient pH control (in both acid and alkaline regions)
- High-velocity, high-turbulence, and low-pH moisture

The situation is illustrated in Fig. 15, which shows a Mollier diagram with a typical turbine steam expansion line, the thermodynamic regions of impurity concentrations (NaOH and salts), and the resulting corrosion. The conditions on hot turbine surfaces (in relation to the steam saturation temperature) can shift from the wet-steam region into the salt zone and above. This is why SCC of disks often occurs in the wet-steam regions (Ref 19, 23, 29), and it emphasizes the need to consider local surface temperatures in design and failure analysis. The surfaces may be hot because of heat transfer through the metal (Ref 9, 22, 29) or because of the stagnation temperature effect (zero flow velocity at the surface and conversion of kinetic energy of steam into heat) (Ref 46). Depending upon their vapor pressures, impurities can be present as a dry salt or as an aqueous solution. In the wet-steam region, they are either diluted by moisture or could concentrate by evaporation on hot surfaces.

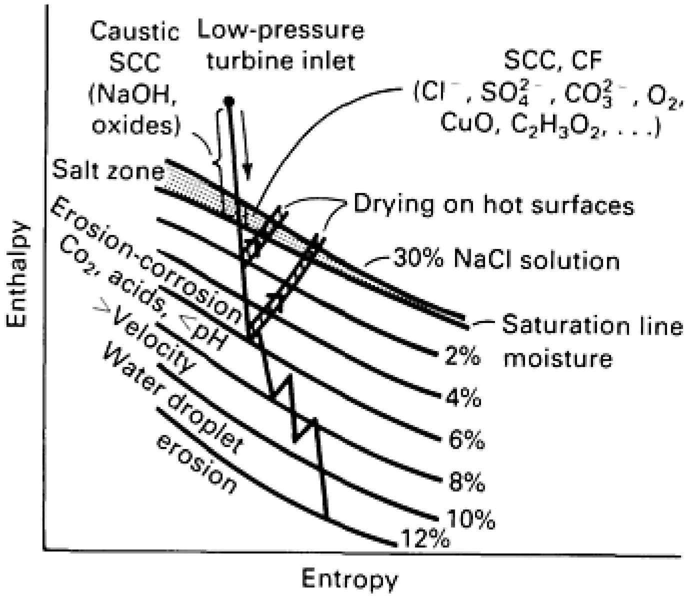

Fig. 15 Mollier diagram showing the low-pressure turbine steam expansion line, thermodynamic regions of impurity concentration (with impurities given in parentheses), and corrosion mechanisms. Source Ref 6 and 9)

The steam impurities that are of most concern include chlorides, sulfates, fluorides, carbonates, hydroxides, organic and inorganic acids, oxygen, and CO_2. Their behavior in turbine steam and deposits is well documented (Ref 6, 9, 14, 30, 46, 47, 48, 49, 50, 51, 52, 53), there are strong synergistic effects and interactions with metal oxides.

In addition to corrosion during operation, turbines can corrode during:

- Manufacture (machining fluids and lubricants)
- Storage (airborne impurities and preservatives)
- Erection (airborne impurities, preservatives, and cleaning fluids)
- Chemical cleaning (storage of acid in condenser hotwells)
- Nondestructive testing (cleaning and testing fluids)
- Layup (deposits plus wet air)

Many of the above substances may contain high concentrations of sulfur and chlorine, which could form acids upon decomposition. Decomposition of typical organics--for example, carbon tetrachloride (CCl_4)--occurs at about 150 °C (300 °F). Therefore, the composition of all of the above substances should be controlled (maximum of 50 to 100 ppm S and 50 to 100 Cl has been recommended), and most of them should be removed before operation. Molybdenum disulfide (MoS_2) is being increasingly implicated as a corrodent in power system applications (Ref 54, 55, 56, 57, 58).

Layup corrosion increases rapidly when the relative humidity of the air reaches about 60%. When deposits are present, layup corrosion can be in the form of pitting or SCC.

Design

Because of the long design life, steam turbines undergo a limited prototype testing in which the long-term effects of material degradation, such as corrosion, creep, and low-cycle fatigue, cannot be accurately simulated. When development was slow, relatively long-term experience was transferred into new products. Because of the rapid development of new turbine types, larger sizes, and new power cycles and water treatment practices during the last 25 years, the experience was short and limited, and some problems were developed that still need to be corrected and considered in new designs and redesigns. Design disciplines that affect turbine corrosion can be separated into four parts:

- Mechanical design (stresses, stress concentrations, and stress intensity, K_1)
- Heat transfer (surface temperatures and heated crevices)
- Flow (moisture velocity, location of the salt zone, stagnation temperature, and interaction of shock wave with Wilson line)
- Physical shape (crevices, obstacles to flow, and surface finish)

The various aspects of design against environment-sensitive fracture are well documented (Ref 9, 12, 13, 19, 20, 21, 24, 29, 30, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68), but only a few of these references deal with the complexity of the problem (Ref 9, 13, 14, 20, 60, 65, 66, 67, 68). Probabilistic approaches are discussed in Ref 67 and 69. Problems with such approaches include the lack of a large number of statistical data on corrosion properties of materials, service stresses, and environments. The mechanical design concepts for avoiding turbine corrosion should include evaluation of safety factors against σ_{SCC}, K_{ISCC}, $\dot{a}_{SCC}$, (da/dN), ΔK_{th}, corrosion fatigue limit, pitting rate, and a pit depth limit.

A more conservative approach should be taken for high multiaxial tensile stresses, strain (mechanical or thermal) fluctuations, other mechanical interactions, and large component sizes. True residual stresses, both microscopic and macroscopic, should also be considered. Implementation of the above concepts requires that corrosion testing generate quantitative data that are useful to the designer.

Hot Corrosion in Coal- and Oil-Fired Boilers

Ian G. Wright, Battele Columbus Division

Corrosion from the firing of coal or oil is essentially related to specific impurities in the fuels, which can lead to the formation of nonprotective scales or can disrupt normally protective oxide scales. The relevant impurities in coal are sulfur (about 0.5 to 5.2% in United States coals), sodium (0.01 to 0.7%), potassium (0.2 to 0.7%), and chlorine (0.01 to 0.28%). In oil, the important impurities are sodium, which from United States refineries may range up to 300 ppm by weight; vanadium (up to 150 ppm by weight); and sulphur (0.6 to 3.6%). During combustion, these impurities can be melted or vaporized and will deposit upon contact with surfaces at temperatures lower than the condensation temperatures of the specific species. This provides a mechanism for the accumulation of deposits of fly ash on cooled surfaces downstream of the burners (Ref 70, 71).

Water wall fire-side corrosion is generally found in regions around the burners. The thick, hard external scales formed may be quite smooth, but often exhibit cracks or grooves that can resemble an alligator hide. Cracking or grooving is usually circumferential, and it is more common in supercritical than subcritical boilers. It occurs in the areas of the water walls that receive the highest heat flux and is apparently a result of superimposed thermal stress. Figure 16 illustrates the appearance of grooving. Figure 17 shows the grooves to be sharp-pointed cracks filled with corrosion product (mostly

iron oxide) but with a central core of iron sulfide. Figure 18 shows a cross section of an ASME SA-213, grade T-11 water wall tube that has formed a thick, smooth scale. The outer scale is a mixture of iron sulfide and iron oxide, with the chromium from the alloy dipersed in the inner layer. The major causes of corrosion of the water wall tubes are, first, the reducing (substoichiometric) conditions caused by impingement of incompletely combusted coal particles and flames and, second, molten salt or slag-related attack.

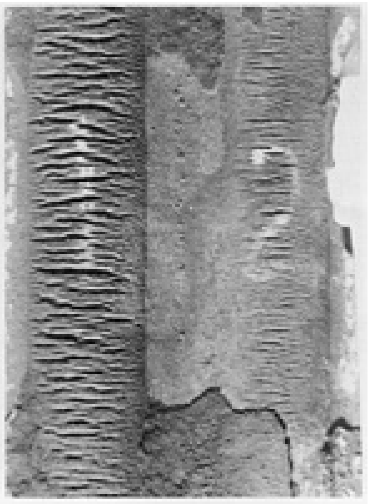

Fig. 16 Example of grooving in water wall tubes. Note the thick, adherent scale remaining in some areas.

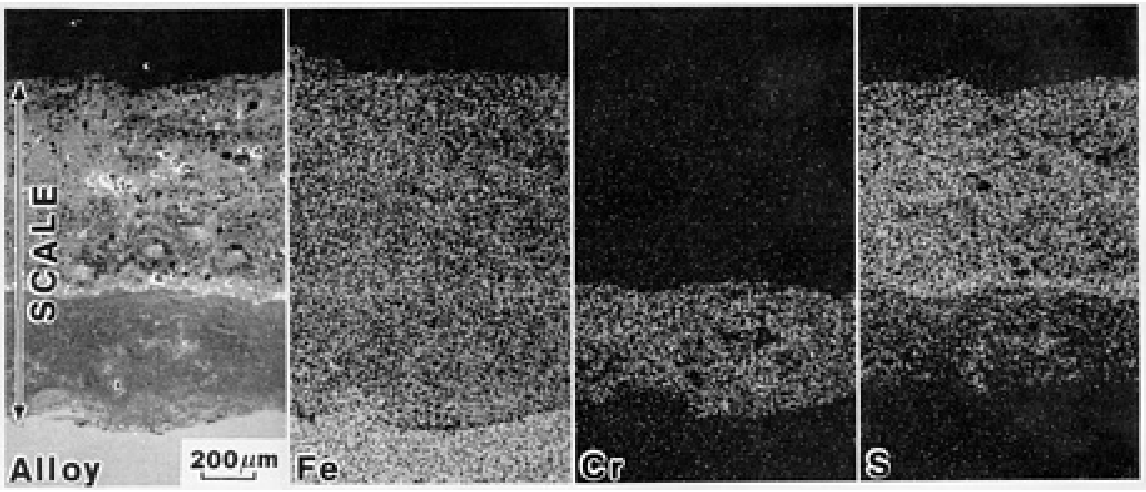

Fig. 18 Cross section of the fire-side face of water wall tube subjected to reducing (substoichiometric) combustion conditions. From left to right: optical micrograph of deposit and x-ray elemental dot maps for iron, chromium, and sulfur, respectively

Gas Phase Corrosion

Reducing atmosphere corrosion may be a result of direct reaction of the water wall tubes with a substoichiometric gaseous environment containing sulfur or with deposited, partially combusted char containing iron pyrites, which gives rise to a very localized corrosive environment. Reducing conditions have two main effects on corrosion. First, they tend to lower the melting temperature of any deposited slag, which increases its ability to dissolve the normal oxide scales on the tubes, and second, the stable gaseous sulfur compounds under these conditions include H_2S (Ref 73, 74, 75, 76), which is considerably more corrosive than the SO_2 that predominates under oxidizing conditions. Under reducing conditions, iron sulfide is the expected corrosion product on iron, rather than the oxides (Fe_3O_4 and Fe_2O_3). Sulfide scales allow significantly higher rates of transport of iron cations than oxides do and so are less protective. However, Cr_2O_3, which is a very protective oxide, would be expected to form on chromium under reducing conditions; therefore, alloys capable of forming Cr_2O_3 scales, such as AISI type 310 stainless steel, Inconel 671, or chromized coatings, would be expected to exhibit good corrosion resistance in this application.

Molten Salt Corrosion

Slag-related attack takes several forms. Local disruption of the normal oxide film on the wall tubes by intrusion of molten slag can lead to accelerated oxidation or (if sulfur species are present in the slag) to oxidation-sulfidation. In coal-fired boilers, alkali sulfates deposited on the water walls may react with SO_2 or SO_3 to form pyrosulfates, such as potassium pyrosulfate ($K_2S_2O_7$) and sodium pyrosulfate ($Na_2S_2O_7$), or possibly complex alkali-iron trisulfates. The latter compounds are formed in thicker deposits after long periods of time at about 480 °C (900 °F) (Ref 77). The (K_2SO_4-$K_2S_2O_7$) system forms a molten salt mixture at 407 °C (764 °F) when the SO_3 concentration is 150 ppm. The corresponding sodium system can become liquid at 400 °C (750 °F), but it requires about 2500 ppm SO_3 for this to occur; such levels of sulfur oxides are likely only under deposits (Ref 70). Thus, molten salt attack on the tube metal by $K_2S_2O_7$ is more likely and occurs according to the reaction

$$K_2S_2O_7 + 3Fe \rightarrow FeS + Fe_2O_3 + K_2SO_4 \qquad \textbf{(Eq 2)}$$

By such a mechanism, $K_2S_2O_7$ can react aggressively with any protective iron oxide scales on the tubes and lead to accelerated wastage through fluxing of the oxides and attack of the substrate metal. Differential scanning calorimetry of samples of deposits taken from water wall tubes typically indicates melting points in the range of 335 to 410 °C (635 to 770 °F) (Ref 78).

The role of chlorine in fire-side corrosion is difficult to define. However, it seems likely that under reducing conditions HCl or NaCl can render the oxide scales less protective by causing them to blister or crack or by reactions with the oxides or base metal to form volatile products (Ref 71).

Molten salt related corrosion of water walls is seldom encountered in oil-fired boilers. This is presumably related to the absence of chlorine in the oil and to the lower ash content of oil compared to coal (about 0.5% in oil, and up to 35% in U.S. coals); therefore, the deposits formed on the water walls of oil-fired boilers are very thin and do not provide the necessary conditions for the formation of pyrosulfates. In addition, the tube metal temperature in the water wall region of a furnace is usually below 400 °C (750 °F), which is lower than the melting points of any compounds possible between sodium and vanadium oxides. Therefore, any compounds formed are unlikely to melt and pose a corrosion threat under normal operating conditions.

Prevention of Corrosion

Solutions to fire-oxide corrosion of furnace water walls are available from changes in operating procedures and changes in tube materials. Where the corrosion results from the presence of reducing conditions near the water walls, operational actions include adjusting the air and fuel distribution to individual burners and among burners in order to promote better mixing and more uniform combustion conditions, as well as resetting to design specification the coal fineness delivered to the burners from the milling plant. Flame impingement can be rectified by changing the characteristics of the offending burners through adjustment of secondary air registers to control air flow and degree of swirl. The most accurate way of making such burner adjustments is by monitoring the composition of the gas close to the affected water walls to ensure that oxidizing conditions (or acceptably low carbon monoxide, CO, levels: <1%) are achieved.

Another method of countering reducing conditions near the water walls is to introduce a flow of air along the walls through opening in the membrane between water walls tubes. This is often referred to as air blanketing or curtain air, and it should also be implemented and adjusted in conjunction with local monitoring of the gas composition.

Furnace wall corrosion can also be lessened by reducing the levels of the chemical species in the coal that are responsible for corrosion. Approximately one-half the sulfur and alkali metal content of coal can be removed by standard coal-washing procedures. However, washing generally does not remove the chlorine-containing species from coal; therefore, the net effect is that the chlorine content of washed coal is increased. An alternative strategy is to blend the coal to reduce the average content of corrosive species. Both of these strategies may involve some increase in fuel costs, which must be weighed against the increased tube lifetimes. The same approaches for control of reducing environments near the water walls described for coal-fired boilers can be applied to oil-fired boilers.

Materials solutions to water wall fire-side corrosion problems involve either direct replacement with tubes of a more corrosion-resistant alloy or the application of a corrosion-resistant alloy as a cladding on the affected tube. Replacement of the tubes with the same material and the use of regular wall thickness monitoring where wastage rates are only slightly greater than allowable have been recommended to give the desired tube life (Ref 79). For more severe wastage, little difference in performance has been found for alloys containing less than 9% Cr. In this case, the materials choice is probably between thicker-walled carbon steel tubes and tubes with a coextruded outer layer of a high-chromium alloy, such as AISI type 310 stainless steel or 50Cr-50Ni. The technique of cladding a tube fabricated from the alloy typically chosen for the application (based on strength considerations) with an outer layer of a corrosion resistant alloy by coextrusion can provide a cost-effective solution to this problem. The Central Electricity Generating Board has found coextruded tubes of type 310 on low-carbon steel to be economically viable for base-loaded units and has used such tubes in boilers since 1974 (Ref 80).

Increased corrosion resistance can also be gained by enriching the surfaces to be protected with such elements as chromium or aluminum. This can be achieved by diffusion treatments or by the spraying of metal overlay coatings. Although pack aluminizing can be applied commercially to tubes up to about 6 m (20 ft) long (Ref 81), there are as yet no reports of utility boiler experience with such materials. Flame or plasma spraying has been used to apply high-chromium, high-aluminum, iron-chromium-aluminum alloy compositions to water wall tubes. Although such alloys have shown good corrosion resistance in laboratory tests, problems have been experienced in practice as a result of a lack of reproducibility of coating application techniques.

Hot Corrosion in Boilers Burning Municipal Solid Waste

H.H. Krause, Battelle Columbus Division

The corrosion problems experienced in boilers fueled with municipal refuse are different from those encountered with fossil fuels in that chlorine rather than sulfur is primarily responsibly for the attack. The average chlorine content of municipal solid waste is 0.5%, of which about one-half is present as polyvinylchloride (PVC) plastic. The other half if inorganic, principally NaCl. The chlorine in the plastic is converted to hydrochloric acid (HCl) in the combustion process. The inorganic chlorides are vaporized in the flame and ultimately condense in the boiler deposits or pass through the boiler with the flue gases. Zinc, lead, and tin in the refuse also play a role in the corrosion process by reacting with the HCl to form metal chlorides and/or eutectic mixtures with melting points low enough to cause molten salt attack at wall tube metal temperatures.

Gas Phase Corrosion

Hydrochloric acid alone has little effect on carbon steel at temperatures below 260 °C (500 °F) (Ref 82). However, in the presence of excess air in the boiler, the reaction to form ferrous chloride ($FeCl_2$) on the steel surface occurs more readily. This corrosion product is stable at water wall tube temperatures, and the curve for metal wastage versus time is parabolic. However, at a metal temperature of about 400 °C (750 °F), which may occur in the superheater, the $FeCl_2$ is further chlorinated to the readily volatile ferric chloride ($FeCl_3$) (Ref 83). If the gas temperature in the area exceeds 815 °C (1500 °F), the $FeCl_3$ will evaporate rapidly, and breakaway corrosion can then occur. These effects are shown in Fig. 19, which presents data from corrosion probe exposures conducted in a municipal incinerator.

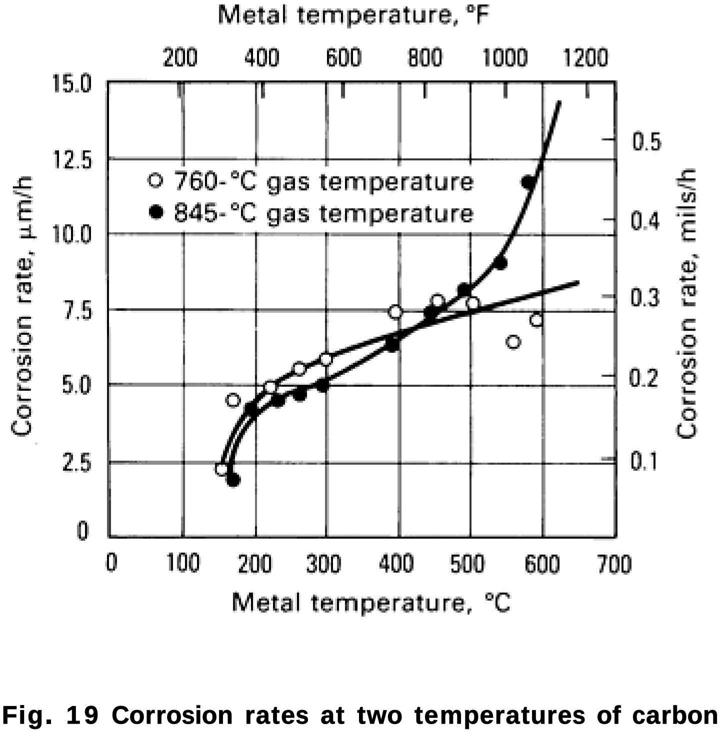

Fig. 19 Corrosion rates at two temperatures of carbon steel in a boiler burning municipal refuse. Source: Ref 84

The corrosion probe results also demonstrated that $FeCl_2$ was formed as a corrosion product at temperatures of 150 to 260 °C (300 to 500 °F); in this range, HCl is not particularly corrosive (Ref 85). This result can be explained only by attack from elemental chlorine rather than HCl. In one study, corrosion of carbon steel by chlorine reached the breakaway condition at 205 °C (400 °F) (Ref 82); therefore, this agent must be responsible for any low temperature attack.

A reducing atmosphere can also contribute to wall tube corrosion. This effect was first observed in European incinerators, in which excessive corrosion of side walls and furnace corners was found to be associated with reducing conditions in

addition to chloride deposits. A recent study investigated the combined effect of CO and HCl on corrosion (Ref 86). Corrosion rates were linear with time in a simulated flue gas containing 400 ppm HCl, 10% CO, 10% H_2O, 0.5% SO_2, and the balance nitrogen. At 400 °C (750 °F), the slope of the metal loss versus time curve was 1.14 mm/yr (45 mils/yr), without HCl in the gas mixture, a parabolic rate curve was obtained that leveled off at a maximum metal loss of only 127 μm (5 mils). The synergistic action of HCl and CO in promoting corrosion was attributed to disruption of the oxide layer on the metal surface, followed by spalling of the oxide, thus exposing the metal to further oxidation.

Molten Salt Corrosion

Incinerator boiler deposits usually contain several percent of zinc and lead, with a lesser amount of tin. In combination with chlorine, these elements can form low-melting compounds or eutectic mixtures that would be molted at tube metal tmeperatures. Thus, for example, stannous chloride ($SnCl_2$) melts at 246 °C (475 °F) and zinc chloride ($ZnCl_2$) at 283 °C (541 °F). The eutectic mixture of 50.2% lead chloride ($PbCl_2$) and 49.8% $FeCl_3$ melts at 175 °C (347 °F). Examination of the layer of scale at the corroded metal surface of boiler tubes an probe specimens by the electron microprobe and by energy-dispersive x-ray analysis has shown these metals to be associated with chlorine. Consequently, molten salt attack by these metal chlorides can occur and will be more severe than gas phase corrosion.

A recent investigation of an incinerator wall tube that was corroding at a rate of 2 mm/yr (80 mils/yr) showed that zinc and sodium were both associated with chlorine in the deposit (Ref 87). The presence of NaCl was confirmed by x-ray diffraction. However, the high corrosion rate could not be accounted for in terms of attack by NaCl or HCl. Consequently, laboratory tests were conducted to demonstrate that the corrosion could be caused by the eutectic mixture of 84% $ZnCl_2$ and 16% NaCl, which has a melting point of 262 °C (504 °F). After a 336-h exposure to this mixture at 315 °C (600 °F), carbon steel had a corrosion rate of 23 mm/yr (910 mils/yr), indicating that such molten salt attack was the likely mechanism in the incinerator. There is as yet no evidence for participation of $SnCl_2$ in the incinerator corrosion reactions. However, its low melting point and the possibility of forming a eutectic mixture with NaCl that melts at 199 °C (390 °F) make it a likely contributor to molten salt corrosion.

Prevention of Corrosion

Most of the methods of preventing incinerator wall tube corrosion exact some penalty in boiler efficiency. The practice of studding the tubes and covering them with silicon carbide refractory has been widely used in European incinerators, but this remedy reduces heat transfer. Increasing overfire air or blanketing the walls with air to prevent reducing conditions in the flue gas has been effective, but either approach will reduce boiler efficiency. Lowering tube metal temperatures by operating at lower steam pressure also has a cost in efficiency.

However, upgrading the boiler tube material to a corrosion-resistant alloy does not involve an efficiency penalty. Although capital costs will be greater, the extended tube life resulting from the use of more resistant alloys can offset the initial expense and can be a cost-effective solution to the problem. Extensive corrosion prove studies in municipal incinerator showed that in the temperature range of 150 to 315 °C (300 to 600 °F) a number of alloys provided good performance in resisting high-temperature corrosion (Ref 88). In decreasing order, the better alloys, were Incoloy 825; AISI types 446, 310, 316L, 304, and 321 stainless steels; and Inconel alloys 600 to 601. However, when subjected to moist deposits, simulating boiler downtime conditions, all of the austenitic stainless steels underwent chloride SCC. The type 446 stainless steel. Inconel 600 and Inconel 601 suffered pitting. Consequently, uniess the boilers were to be maintained at a temperature above the HCl dew point during downtime, only Incoloy 825 was recommended.

The laboratory tests discussed in Ref 87 showed that Inconel alloys 600, 625, and 690, Incoloy 800, and type 304 and 309 stainless steels were resistant to the $ZnCl_2$-NaCl mixture at 315 °C (600 °F). In addition, an overlay of Inconel 625 applied to the carbon steel tubes in the incinerator offers promise. Recent field tests conducted at a municipal waste incineration boiler indicated that alloy 556 (iron-nickel-cobalt-chromium) has excellent resistance in such applications (Ref 89). The test rack was exposed to flue gases at 800 °C (1475 °F) for 950 h. Maximum depths of attack, that is, metal loss and maximum internal penetration, were 0.21 mm (8.2 mils) for alloy 556, 0.34 mm (13.4 mils) for AISI type 309 stainless steel, 0.69 mm (27 mils) for Hastelloy X, and more than 1.1 mm (45 mils) for Inconel 690. The Inconel 690 coupon was perforated. Sulfidation was reported to be the major made of attack. Consequently, Inconel 625, Incoloy 825, alloy 556, and possibly Incoloy 800 are the preferred materials solutions to wall tube corrosion in municipal incinerators.

Corrosion of Superheaters and High-Temperature Air Heaters

John Stringer, Electric Power Research Institute

Corrosion of superheaters and air heaters is inevitable in coal-fired boilers and in fluidized-bed combustors. This section will discuss factors that cause corrosion as well as measures that can be taken to minimize corrosion in these applications.

Superheater Corrosion in Coal-Fired Boilers

The fire-side corrosion of superheaters in pulverized coal-fired utility boilers is one of the principal problems that have limited main steam temperatures to 540 °C (1000 °F) for the last 30 years. Allowing for the temperature decrease through the tube walls and the typical non-uniformities in the temperature distribution across a superheater bank, this corresponds to an outer maximum metal surface temperature of approximately 620 to 650 °C (1150 to 1200 °F). The metals and alloys used for superheater tubing are primarily determined by the ASME Boiler Code, which is concerned only with the strength of the materials.

For typical steam pressures and tube wall thicknesses, Table 4 shows the maximum-use temperature for several boiler alloys for which code standards exist. These are the wall midsection temperatures, which are typically 25 °C (45 °F) lower than the outer surface temperature. A further limitation is imposed by the oxidation resistance of the steels. The ASME code does not mention oxidation, and some allowance can of course be made by increasing the tube wall thickness. However, for typical conditions, Table 4 also lists the maximum metal surface temperature that can be tolerated from an oxidation wastage point of view.

Table 4 Temperature limits of superheater tube materials covered in ASME Boiler Codes

Material	Maximum-use temperature			
	Oxidation graphitization criteria, metal surface[a]		**Strength criteria, metal midsection**	
	°C	**°F**	**°C**	**°F**
SA-106 carbon steel	400-500	750-930	425	795
Ferritic alloy steels				
0.5Cr-0.5Mo	550	1020	510	950
1.25Cr-0.5Mo	565	1050	560	1040
2.5Cr-1Mo	580	1075	595	1105
9Cr-1Mo	650	1200	650	1200
Austenitic stainless steel				
Type 304H	760	1400	815	1500

(a) In the fired section, tube surface temperatures are typically 20 to 30 °C (35 to 55 °F) higher than the tube midwall temperature. In a typical U.S. utility boiler, the maximum metal surface temperature is approximately 625 °C (1155 °F)

The fire-side corrosion discussed in this section is the process by which the wastage rate is increased above these design rates. The enhanced corrosion is generally associated with the formation of a deposit on the tube walls. Although the presence of a deposit does not necessarily indicate accelerated corrosion, accelerated corrosion is never experienced in the absence of such a deposit.

Nature of the Deposit. Figure 20 shows an illustration of the deposit formed on superheater tubes. The deposit may be several inches thick, with the outer layers formed of loosely sintered fly ash. The outer part of this deposit will be essentially at the gas temperature. The white inner layer is rich in alkali sulfate. The black layer is largely Fe_3SO_4. Sulfur prints indicate that sulfide is present at the metal surface.

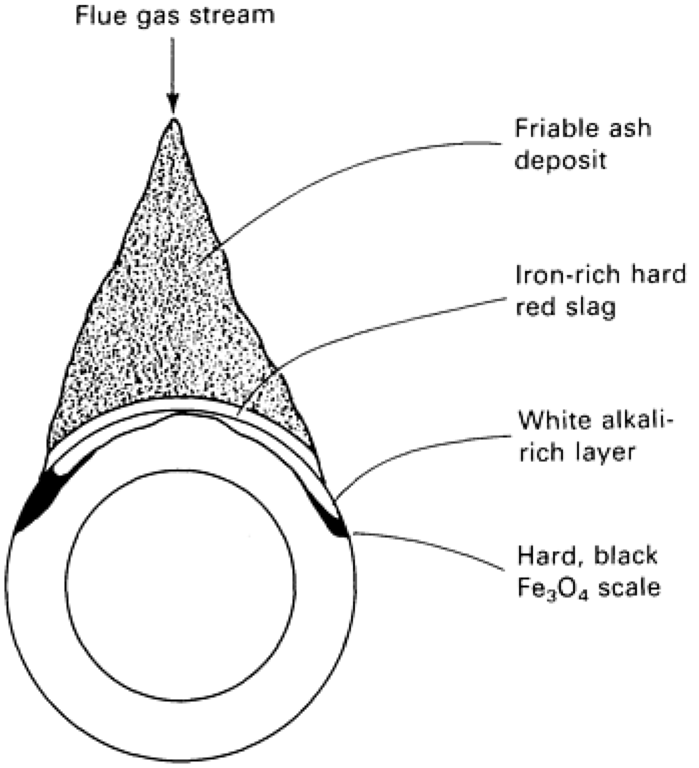

Fig. 20 Deposit layers on a corroding superheater or reheater tube

It has been shown that deposition of alkali sulfate, as well as corrosion, is often a more or less linear function of the chlorine content of the coal. It is now generally believed that chlorine plays no direct role in the corrosion process; instead, it acts as a release agent for the alkali metals in the coal.

It is generally believed that the salt deposit must be molten for accelerated corrosion to occur. The melting point of sodium sulfate (Na_2SO_4) is 884 °C (1623 °F); that of potassium sulfate (K_2SO_4) is 1069 °C (1956 °F). The maximum melting point of a mixture of the two is 823 °C (1513 °F). Because the molten phase must be close to the metal, there is no possibility that temperatures as high as this could be attained. In the deposit on tubes cooled to room temperature, a complex sulfate having the general formula $(Na,K)_3Fe(SO_4)_3$ has often been identified. This phase has a minimum melting point of 554 °C (1029 °F) at a sodium:potassium ratio of 2:3. However, it is relatively unstable and at 540 °C (1000 °F) will decompose to the solid constituent oxides unless the local SO_3 partial pressure exceeds 25 Pa (0.004 psi). This is approximately five times the normal SO_3 partial pressure within a boiler, but it has been shown that the local partial pressure may be significantly higher near the corroding surface.

Corrosion beneath the deposit is at a maximum toward the edges of the deposit at the 5 and 7 o'clock positions. The metal temperature will be highest under the deposit at these locations because beneath the thick part of the deposit the metal surface will be insulated from the hot gas. Generally, corrosion consists of pits with relatively smooth metal/scale interfaces. There is little evidence of internal penetration of internal sulfidation. The pits eventually overlap to produce an apparently general corrosion.

It is difficult to obtain much information on the influence of different factors on the corrosion from in-service data because the corrosion is very specific to a particular boiler burning a particular fuel under a definite set of conditions. In addition, different materials are usually not exposed simultaneously. On the basis of laboratory tests, it appears that the accelerated attack is present only for metal temperatures in the range of 560 to 700 °C (1040 to 1290 °F), with a maximum at approximately 670 °C (1240 °F). It is believed that the minimum temperature corresponds to the solidus temperature of the salt deposit and that the maximum is the dissociation temperature of the low-melting complexes. Figure 21 shows the relative rates of attack for a range of typical boiler tube materials, including some coating and cladding alloys.

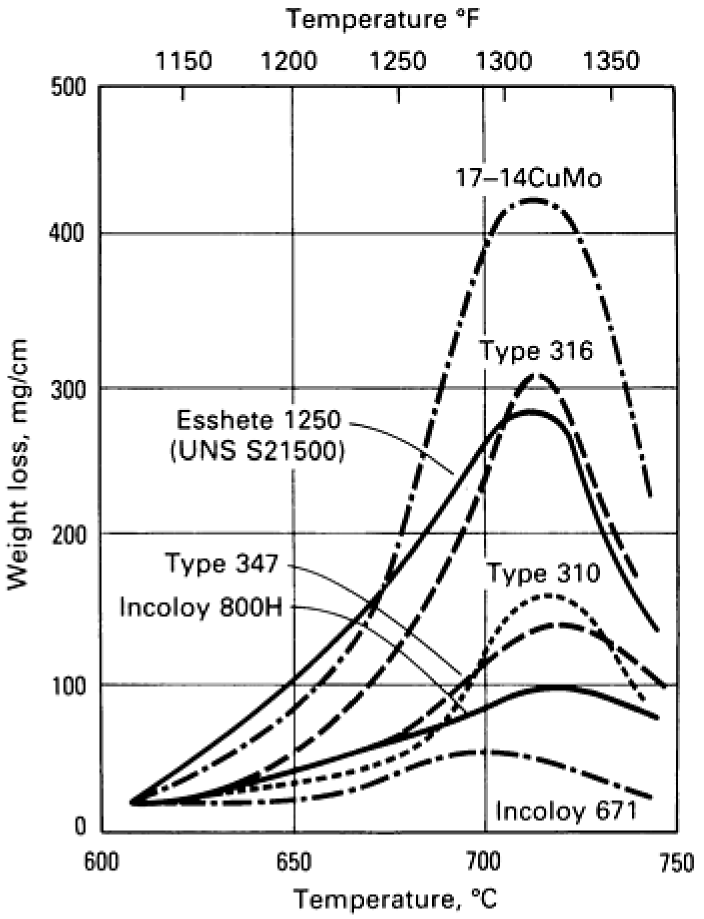

Fig. 21 Corrosion rates of alloys in a laboratory test using synthetic ash (37.5 mol% Na_2SO_4, 37.5 mol% K_2SO_4 and 25 mol% Fe_2O_3) in a synthetic flue gas (80% nitrogen, 15% CO_2, 4% oxygen, and 1% SO_2 saturated with water). Exposure time: 50 h

For a given metal temperature, the corrosion rate increases with gas temperature. Corrosion rate increases by a factor of three at a metal temperature of 650 °C (1200 °F) as the gas temperature rises from 800 to 1400 °C (1470 to 2550 °F).

Corrosion Prevention. Empirical procedures are available for predicting the probable corrosivity of a given coal. A known corrosive coal may be blended with another to produce a less corrosive ash, and it may also be possible to use additives, such as limestone. If it is known at the design stage that a corrosive coal must be burned, the superheater can be positioned further back along the gas path where the gas temperature is lower. Such positioning also reduces the amount of corrosive material reaching the superheater, because some corrodent is deposited on upstream tubing.

If control of coal chemistry or design changes are not feasible, corrosion-resistant materials must be used. For a boiler that has exhibited corrosion, it may be sufficient to wrap strips of AISI type 310 stainless steel around the leading tubes in a platen; this is termed bandaging. If bandaging is insufficient, it may be necessary to replace the finishing superheater tubing with a coextruded material, in which the inner layer is a strong coded alloy and the outer layer is a corrosion-resistant material, such as type 310 stainless steel or Incoloy 671 (Ni-50%Cr). Over the years, there have been many efforts to develop coating systems that could be applied in the field by such techniques as plasma spraying. However, the results have generally been disappointing, although for a particular situation this may still be a cost-effective approach.

Corrosion of Superheaters and High-Temperature Air Heaters in Fluidized-Bed Combustors

A recent development as an alternative to the pulverized coal-fired boiler is the fluidized-bed combustor. In this unit, the coal is burned in a fluidized bed of particles; very good combustion efficiency is achieved at relatively low temperatures

(typically 850 to 900 °C, or 1560 to 1650 °F). This results in low NO_x emissions. In addition, sulfur can be captured in the bed by adding an absorbant, such as CaO.

Because of the low combustion temperature, it was anticipated that there would be no ash fusion, little or no ash deposition on the in-bed heat-exchanger surface, and limited alkali release. It was therefore assumed that in-bed fire-side corrosion of superheaters by a mechanism similar to that described in the preceding section would be unlikely. This appears to be true. However, a different mechanism of corrosion does present a potential problem; this will be described in the section "Corrosion Mechanism" in this article. In addition, the in-bed environment is potentially erosive, and the combination of erosion and corrosion can result in accelerated wastage.

The In-Bed Environment. The bed consists of particles with an average size typically close to 0.8 mm (30 mils). The major constituent is $CaSO_4$, and there are relatively minor amounts of coal ash, still smaller amounts of unreacted CaO, and typically less than 2% C. At metal temperatures above approximately 500 °C (930 °F), reddish-brown deposits form that consist mostly of $CaSO_4$, with about 15% coal as related material. The deposit is extremely dense; its porosity is below the limits of detection of most conventional techniques. It is very well bonded to the oxide on the metal, and when it detaches, for example, upon thermal cycling, it generally takes the metal oxide with it.

The oxygen potential in the bed varies from approximately 10^{-1} to 10^{-14} atm. The oxygen potential fluctuates relatively rapidly (a frequency of the order of 0.5 to 2 Hz). In some regions, the oxygen potential is generally low, with peaks to high values; in other regions of the bed, the potential is generally high, with peaks to low values. If local equilibrium were established, this low oxygen potential, combined with the $CaO/CaSO_4$ equilibrium, would generate a sulfur partial pressure of the order to 10^{-5} atm.

The Corrosion Mechanism. Materials within the bed can suffer a form of corrosion in which the normally protective oxide (usually Cr_2O_3) is disrupted; this allows the rapid growth of the less protective oxides of the base metal. Within the metal itself, chromium-rich sulfides are present. In extreme cases, with nickel-base alloys at temperatures above about 650 °C (1200 °F), liquid nickel sulfides may appear, and the degradation of the alloy becomes catastrophic. It has been shown that corrosion is more severe in regions of the bed where the oxygen potential is generally low, with peaks to higher values; regions near the coal feed ports are particularly corrosive.

Materials for In-Bed Superheaters and Air Heaters. The conditions for in-bed superheaters are similar to those in a conventional boiler in terms of the internal temperature and pressure and the lifetime generally required for commercial success. The maximum metal temperature is of the order of 650 °C (1200 °F), and the available materials are those defined by the ASME Boiler Code. The conditions for an air heater generating hot air to be expanded through a gas turbine are somewhat different. The internal pressures are significantly lower than those in utility boiler tubes (of the order of 1 to 1.5 MPa, or 145 to 218 psi, as opposed to 17 to 25 MPa, or 2465 to 3625 psi), but the temperatures are considerably higher. The maximum metal temperature is essentially equal to the bed temperature.

Nickel-base alloys are generally very sensitive to this form of corrosion, and their use should be avoided within fluidized beds unless low local oxygen activities can absolutely be eliminated. Stainless steels, such as type 304 and type 347, are relatively resistant. Type 310 is very resistant to the corrosion, but its mechanical properties at elevated temperatures make it unsuitable for boiler tubes, although it could be used as a cladding. Incoloy 800 has a higher nickel content and good high-temperature properties. Its behavior in the bed is intermediate; that is, in locations where the oxygen activity is always high, it has excellent corrosion resistance, but it can suffer very rapid attack in regions of low oxygen activity.

Therefore, the materials of choice for the superheater are the austenitic stainless steels. The principal question is whether these steels may suffer breakdown corrosion in several thousand hours in this type of environment. Long-term investigations of this question are in progress or have recently been completed. If it is demonstrated that breakdown does take place or if the simultaneous action of erosion leads to accelerated attack, coextruded tubes may be necessary.

Selection of materials for air heaters is considerably more difficult because many of the alloys with adequate strength at the higher temperatures have high nickel contents. In some cases, the corrosion-sensitive alloy Incoloy 800H has been selected, with efforts to locate the hotter tubes in regions of the bed with high oxygen activities. This presents a long-term risk because it is difficult to be sure that the conditions within the bed will remain constant, and fluctuations in the distribution of coal of air in the bed can profoundly affect local oxygen activities. Again, coextruded tubes may be necessary.

Corrosion of Combustion Turbines

R. Viswanathan, Electric Power Research Institute

Combustion turbine components are susceptible to aqueous corrosion and to oxidation-sulfidation corrosion occurring at elevated temperatures. Aqueous corrosion problems are encountered in the compressor section, but oxidation and sulfidation problems are encountered by blades and vanes in the hot-gas path of the turbine section.

Corrosion of Compressor Blades and Disks

Compressor components are generally made of ferritic stainless steels or low-alloy steels. At many utilities, the humidity in the atmosphere is sufficiently high that water condenses on these components during operation. In addition, water often collects on the compressor components of peaking units that are idle; some utilities heat their turbines when they are not used to avoid this problem. General corrosion and pitting can occur as a result of the accumulation of water on compressor blades and disks. The corrosion product fouling of compressor blades associated with corrosion reduces the efficiency of the compressor and therefore increases the heat rate of the turbine. If corrosion is extensive, parts may need to be replaced. Extensive corrosion is often encountered in the low-pressure compressor section of turbines, in which the disks are made of low-alloy steel. Corrosion problems are compounded when aggressive environments are present, such as salt air or air containing contaminants from other units at the plant.

Periodic cleaning of the compressor has been known to restore the efficiency lost because of corrosion. Utilities use many methods of cleaning, including nutshelling (abrasive blasting using crushed nutshells) as well as washing with water, water plus detergent, or water plus organic solvents. Cleaning often cannot be performed without interrupting the operation of the turbine; this presents problems for the operators of turbines used in intermediate- or baseload service. Nutshelling may also lead to clogging of the fuel nozzle and does not provide any cleaning to the turbine section.

Many coatings have been used with mixed results in an effort to reduce the extent of corrosion in compressors. The most disappointing has been the nickel-cadmium family of coatings. These coatings are subject to pitting in acidic environments. They are cathodic to the blades and therefore can accelerate the rate of localized blade corrosion at coating defects. In addition to pitting, bare spots in the coating are often present where the electrodes were placed during electrodeposition of the coating, and this further accelerates corrosion. In some turbines, nickel-cadmium coatings on the blades of the latter stages have been lost, reportedly by vaporization of the cadmium.

More recently, sacrificial coatings (that is, anodic to the blades) have been used in the compressor section. These aluminum-base coatings have met with moderate success; many utilities have reported reduced corrosion. In some cases, however, the rate of corrosion (or at least the rate of fouling) was essentially unchanged, presumably because of the porosity of the coatings. This problem is reportedly being addressed by some coating suppliers through use of a subsequent sealer overcoating. In the cases in which coated blades become fouled, the coatings still have been found to be beneficial because the coating facilities cleaning of the blades. In these cases, the recovery of efficiency by cleaning was greater for coated blades than that for uncoated blades.

Hot Corrosion of Turbine Blades and Vanes

Blades and vanes located in the hot-gas path in the turbine section are subject to a combined oxidation-sulfidation phenomenon that is commonly referred to as hot corrosion. These components are generally made from nickel- or cobalt-base superalloys. Three basic types of hot corrosion attack have been recognized (Fig. 22). In the temperature range of 650 to 705 °C (1200 to 1300 °F), layer-type corrosion characterized by an uneven scale/metal interface and the absence of subscale sulfides is observed. At temperatures above 760 °C (1400 °F), nonlayer-type corrosion (type I) is observed. Type I corrosion is characterized by a smooth scale/metal interface and a continuous, uniform precipitate-depleted zone containing discrete sulfide particles beneath the scale. The transition from one type to the other, which occurs in the range of 705 to 760 °C (1300 to 1400 °F), is characterized by an uneven scale/metal interface containing intermittent pockets of subscale precipitate- depleted zones and sulfides. The layer-type and the transitional corrosion to gather are variously referred to as type II hot corrosion, low temperature hot corrosion, and low-power corrosion.

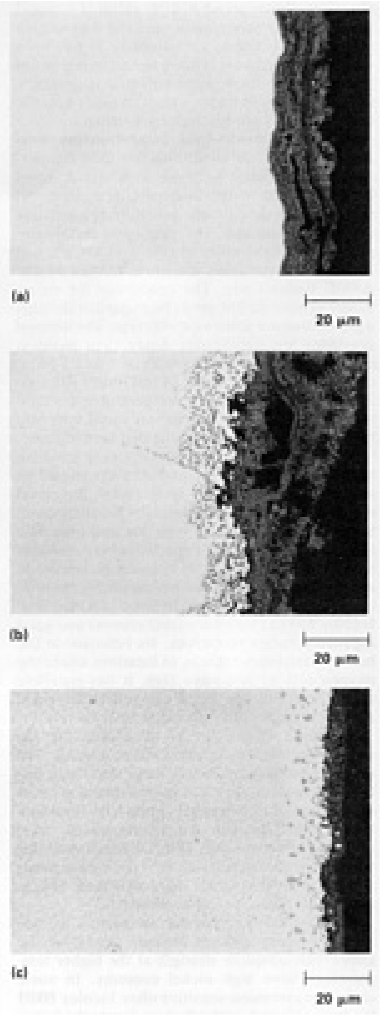

Fig. 22 Three forms of hot corrosion in Udimet 710 turbine blades. (a) Layer type. (b) Transition type. (c) Nonlayer type

Figure 23 shows the essential features of the corrosion products associated with the three types of corrosion. In the nonlayer-type high-temperature form of hot corrosion (Fig. 23c), discrete chromium and titanium sulfide particles are present in a region of the matrix depleted in these elements, adjacent to the base metal. The surface scales consist of protective Cr_2O_3 with some titanium oxides. With decreasing temperature, the chromium and titanium sulfides are increasingly agglomerated into large interconnecting sulfide networks, and the surface scales contain predominantly the oxides of nickel and cobalt (Fig. 23b). Complete layer-type corrosion (Fig. 23a) is characterized by the chromium and titanium sulfides forming a continuous layer. The surface scale in this case contains only the unprotective oxides of nickel and cobalt.

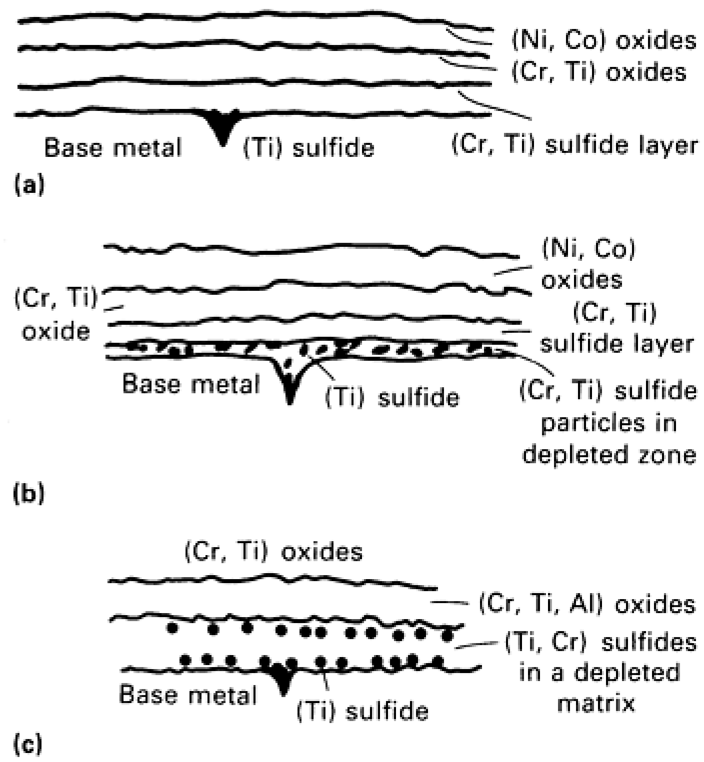

Fig. 23 Schematic of corrosion products formed in the three types of hot corrosion of turbine blades. (a) Layer type. (b) Transition type. (c) Nonlayer type

In addition to the corrosion features described above, grain-boundary spikes (sharp-pointed cracks) are present in the zone of transition-type corrosion. The spikes usually contain sulfides alone or sulfides followed by oxide penetration. They occur over a narrow region of the blade in a manner suggesting that spike formation is dependent on stress.

The high temperature form of hot corrosion involves the formation on the hot-gas path parts of condensed salts that are often molten at the turbine operating temperature. The major components of such salts are Na_2SO_4 and/or K_2SO_4, which are apparently formed in the combustion process from sulfur from the fuel and sodium from the fuel or the ingested air. Because potassium salts act very similarly to sodium salts, specifications limiting alkali content in fuel or air are usually taken to be the sum total of sodium plus potassium.

Very small amounts of sulfur and sodium or of potassium in the fuel and air can produce sufficient Na_2SO_4 in the turbine to cause extensive corrosion problems because of the concentrating effect of the turbine pressure ratio. For example, a threshold level has been suggested for sodium in air of 0.008 ppm by weight; hot corrosion will not occur below this level. Therefore, nonlayer-type hot corrosion is possible even when premium fuels are used. This has been especially true in aircraft-derivative turbines, which have turbine blades made from B-1900 (UNS N13010). Alloy B-1900 has performed well with ultraclean aircraft fuels, but has experienced numerous corrosion problems in land-based service. Other fuel (or air) impurities, such as vanadium, phosphorus, lead, and chlorides, may form with Na_2SO_4 mixed salts having reduced melting temperatures and thus broaden the range of conditions over which attack by molten salts can occur. Agents such as unburned carbon can also promote deleterious interactions in the salt deposits.

Research over the past 15 years had led to better definition of the relationships among temperature, pressure, salt concentration, and salt vapor-liquid equilibria so that the location and rate of salt deposition in an engine can be predicted. In addition, it has been demonstrated that a high chromium content is required in an alloy for good resistance to type I hot corrosion. The trend toward lower chromium levels with increasing alloy strength has therefore rendered most superalloys inherently susceptible to this type of corrosion. The effects of other alloying additions, such as tungsten, molybdenum, and tantalum, have been documented; their effects on rendering an alloy more or less susceptible to hot corrosion are known. The near standardization of such alloys as IN-738 and IN-939 for first-stage blades and buckets, as well as FSX-414 (Co-0.25C-29.5Cr-10.5Ni-7W-2maxFe-1maxMn-1maxSi-0.012B) for first-stage vanes and nozzles, implies that these are the accepted best compromises between high-temperature strength and hot corrosion resistance. It has also been

possible to devise coatings with alloying levels adjusted to resist type I hot corrosion. The use of such coatings is essential for the protection of most modern superalloys intended for duty as first-stage blades or buckets.

The low-temperature form of hot corrosion produces severe pitting and results from the formation of low-melting eutectic mixtures of essentially Na_2SO_4 and cobalt sulfate ($CoSO_4$), a corrosion product resulting from the reaction of the blade surface with SO_3 in the combustion gas. The melting point of the Na_2SO_4-$CoSO_4$ eutectic is 545 °C (1013 °F). Unlike type I hot corrosion, a partial pressure of SO_3 in the gas is critical for the reactions to occur in low-temperature hot corrosion. Knowledge of the relationships between SO_3partial pressure and temperature inside a turbine allows some prediction of where layer-type hot corrosion can occur. Because first-stage blade metal temperatures in heavy-duty engines range from about 650 to 855 °C (1200 to 1575 °F), all three types of hot corrosion can occur when sulfur and sodium are present in sufficient quantities.

To avoid hot corrosion in stationary combustion turbines, fuel specifications for sulfur, sodium, potassium, and vanadium are typically set at approximately 1% S, 0.2 to 0.6 ppm Na + K, and 0.5 ppm V. Impurity content limitations can be varied if blade coatings are used, and corrosion inhibitors, such as magnesium, can be added to the fuel. Where the ambient air at the site is contaminated, as in industrial or coastal locations, air filtration is also often practiced.

Problems have been experienced with occasional batches of fuel containing higher-than-specified levels of impurities. A problem that has had to be addressed is the difficulty in accurately measuring low levels of elements such as sodium in fuel oil. Compliance with stringent specifications requires careful supervision and the use of such techniques as centrifuging the oil, which result in increased costs. Impurities from other sources, such as the plum stones (which contain sodium and potassium) used in a carboblast cleaning technique at low engine power, have led to cracking of aluminide coatings and corrosion of blades and vanes. Entrapment of plum stone fragments in these components places the corrosive species in contact with the alloy surfaces.

Air filtration is not a panacea. It is expensive and requires proper maintenance and monitoring to prevent the periodic release into the engine of material captured on the filters. For example, there are reported instances of collected contaminants being washed off of high-efficiency filters and into engines by sudden heavy storms.

Overall, with stringent control of fuel specifications and good air filtration, essentially no unexpected corrosion-related problems are encountered. The life limitation is then the creep strength or thermal fatigue strength of the first-stage blades or vanes. Where such controls cannot be exerted, alloys with some inherent corrosion resistance are used, together with a coating. The alloy used and the type and thickness of the coating are generally the least costly options that correspond to the planned engine maintenance schedules.

Historically, the development of corrosion-resistant coatings was aimed at combating high-temperature hot corrosion. The earliest coatings were the diffusion aluminides. It was found that chromium-modified aluminides offered little additional protection against high-temperature hot corrosion compared to the basic aluminides, but that the platinum-aluminides offered superior protection compared to the basic aluminides. The chromium-modified have since been found to be particularly beneficial against low-temperature hot corrosion, giving results equivalent to those of the platinum-aluminides; both modified aluminides performed better than the basic aluminides.

Although these diffusion aluminides have been successful in reducing hot corrosion, the chemistry of these coatings is not readily modified for further improvement in corrosion resistance. Thus, increased attention has been given to the development of overlay coatings, which offer significant compositional flexibility.

The actual compositions of these coatings depend on their intended use. Because Al_2O_3 is used for protection against high-temperature hot corrosion, coatings that exhibit the greatest high-temperature protection are generally high in aluminum (11%) and low in chromium (<23%). Low-temperature hot corrosion, on the other hand, depends primarily on Cr_2O_3 for protection; therefore, coatings exhibiting the greatest low-temperature corrosion protection are high in chromium (>30%) and low in aluminum. Other elements, such as silicon, hafnium, tantalum, and platinum, are added to these coatings in an attempt to improve resistance to corrosion and spalling. High-chromium MCrAlY coatings have been developed to offer superior low-temperature protection without sacrificing high-temperature protection because industrial gas turbines sometimes operate under varying load conditions that could result in exposures to both low- and high-temperature conditions. Overlay coatings have been applied by such techniques as electron beam physical vapor deposition, plasma spray, and sputtering.

Apart from overall material wastage due to hot corrosion, an additional concern has been the degradation of mechanical properties, particularly creep and fatigue resistance. Figure 24, based on accurate laboratory tests, depicts for several alloys the variation of the ratio of time to rupture in a salt environment to the time to rupture in air with applied stress at 705 °C (1300 °F). The pronounced degradation of the stress rupture life (sometimes by a factor of as much as 10^5) due to the corrosive action of the salt mixture is evident. The plots tend to converge at low stresses; this indicates that a threshold stress level may exist for each alloy, below which rupture life may become insensitive to corrosion. Additional studies are needed to understand the mechanism of and implications of the environmentally induced mechanical property degradation in the context of the field performance of components.

Components Susceptible to Dew-Point Corrosion

W.M. Cox, D. Gearey, and G.C. Wood, Corrosion and Protection Centre, Industrial Services, University of Manchester Institute of Science and Technology

Dew-point corrosion is the attack in the low-temperature section of combustion equipment resulting from acidic flue gas vapors that condense and cause corrosion damage to the plant materials. It occurs when gas is cooled below the saturation temperature pertinent to the concentration of condensable species contained by the gas. Waste flue gas produced by the combustion of fossil fuels may contain several components, such as SO_3, HCl, and H_2O, and therefore may display several dew-point temperatures at which the various species begin to condense. Corrosion rate peaks related to individual condensation processes may appear, but the formation of protective corrosion products and the deposition of soot ash can

moderate the corrosive effects of deposited acids. In conventional boiler plants, the risk areas normally include the posteconomizer flue gas handling section, that is, air heaters, ducting and precipitators, induced-draft fans, and chimney stacks.

Dew-point corrosion problems in nominally dry flue gas handling systems will be discussed in this section. Problems in wet FGD systems are covered in the section "Corrosion of Flue Gas Desulfurization Systems" in this article. This section will emphasize the large coal- and oil-fired power generation equipment, but similar problems are found in many other combustion systems. The underlying mechanisms of attack are similar, but their detailed natures are affected by the operation variables. Dew-point corrosion and the secondary factors affecting it are thoroughly discussed in Ref 90 and 91.

Most fossil-fired power plants are constructed of carbon steel, and past work has largely been) conducted on this material. In specialized applications, low-alloy steels, stainless steels, stainless, nickel-base alloys, and organic and inorganic coatings are also use. Much recent dew-point corrosion work is reported in Ref 90. The following discussion draws heavily on the information in Ref 90 and on a recent 6-years collaborative investigation sponsored by the United Kingdom Department of Trade and Industry (Ref 91).

Areas Susceptible to Attack

A conventional coal-fired power generation boiler is illustrated in Fig. 25; the locations of items prone to dew-point corrosion are indicated. The most susceptible areas are discussed below.

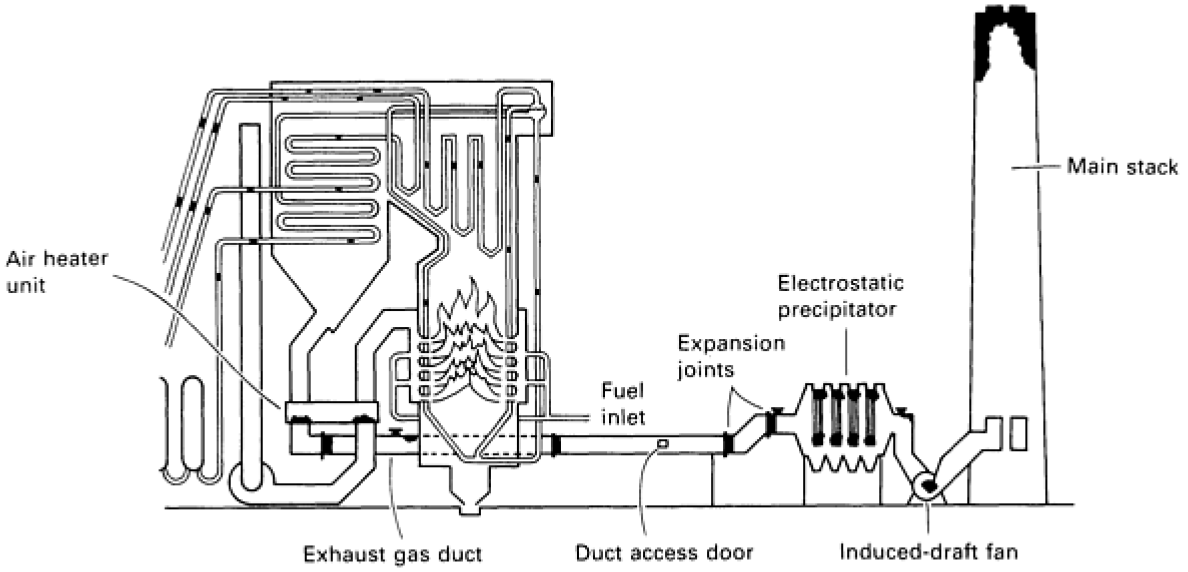

Fig. 25 Schematic of a fossil-fired power generation boiler showing areas susceptible to dew-point corrosion (black areas)

Penthouse Casing and Hanger Bars. The penthouse casing encloses the tube header pipework above the boiler furnace roof. Flue gas leakage from the furnace can cause corrosion of the casing and furnace support steelwork. The hanger bars holding the furnace tube bundles are particularly susceptible to attack near the seals retaining the bars passing from the casing to the external environment (Fig. 26). Bars can corrode such that insufficient cross section remains to support the load, and failure allows collapse of the furnace roof and superheater tube bundles.

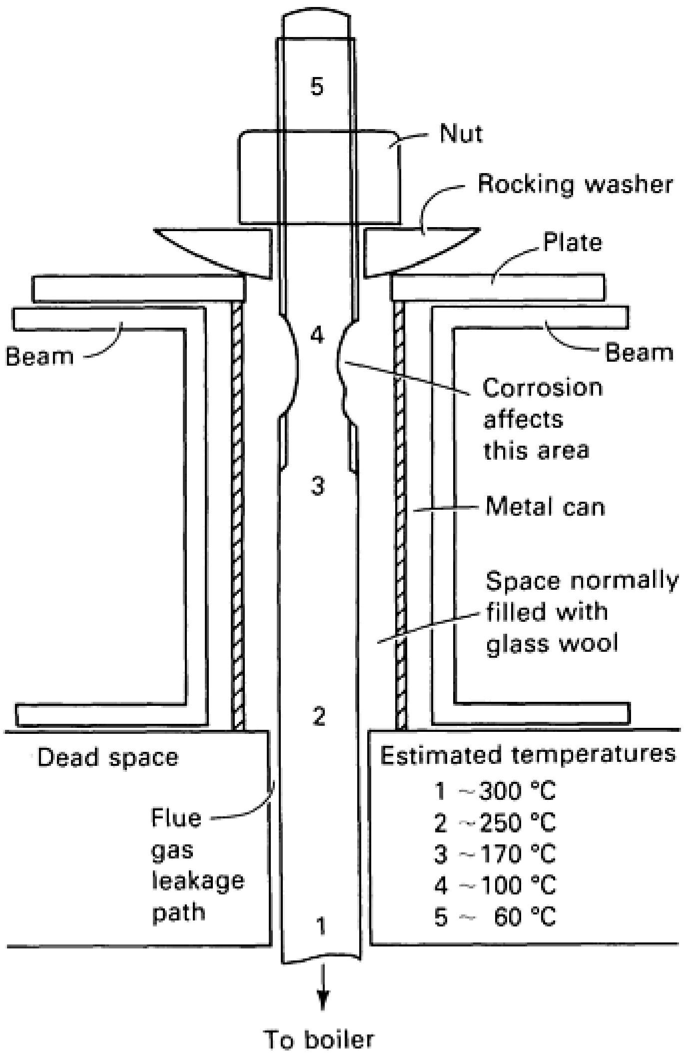

Fig. 26 Schematic of a hanger bar packing box showing areas prone to corrosion. Source: Ref 90

Air Heater Cold Ends. Air heaters are commonly either of honeycomb matrix (Ljungström or Rothemühle) or shell and tube construction. For both, damage is usually most severe at the cold end.

A Ljungström rotating matrix air heater is shown schematically in Fig. 27. Rothemühle air heaters are similar except that the matrix is stationary and the flue gas/inlet air is supplied by an arrangement of rotating hoods. In the Ljungström type, the ductwork is stationary, and the heat-exchanger matrix rotates in either a horizontal or a vertical plane.

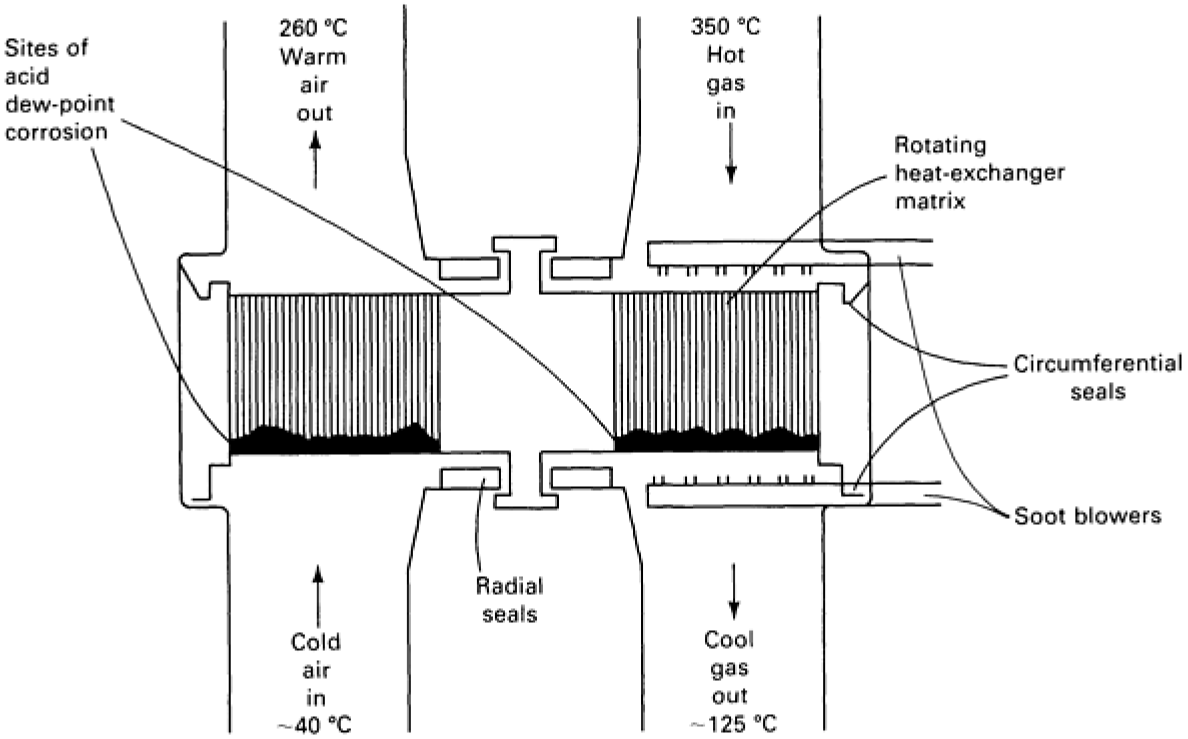

Fig. 27 Schematic of a Ljungström air heater showing location of the air seal and cold end basket corrosion sites

Corrosion damage is sustained by the thin steel heat-exchanger elements and by support steel-work and air seal materials. It is partly caused by cold air leaking from the inlet to the outlet duct (bypassing the air heater matrix), but damage is often worsened by mechanical interaction between the rotating and fixed components as well as by displaced heat-exchanger elements that have fallen from their baskets. The highest dew-point corrosion rates are often associated with operation of a cold-end sootblower, which removes fouling deposits by steam or air jets. Increased dew-point attack seems linked to moisture droplets entrained in the blowing medium impinging directly on the lower edges of the air heater elements, causing dissolution of aggressive salts, removal of protective bonded deposits, mechanical abrasion or erosion of the element surface, and fatigue cracking of the element plates. The local injection of considerable moisture may also tend to increase the acid dew-point temperature of the flue gas in a region where the metal temperature may already approach this dew point.

In tube-type air heaters, corrosion is again normally found at the cold end. The same temperature and sootblowing parameters described for matrix air heaters also apply to tube-type heaters, but bypass air leakage is not a problem until tubes have been perforated. However, tube air heaters are often prone to poor gas distribution across the heat-exchanger surface. This leads to localized cool spots where dew-point corrosion takes place.

Ductwork, Expansion Joints, Inspection or Sampling Ports, and Access Doors. Damage at the locations shown in Fig. 25 is often caused by constant low operating temperatures, which are normally related to air entry at fabrication faults, leaking expansion joints and door seals, or careless replacement of sampling port covers. Such leaks can cause an appreciable reduction in duct metal temperature due to stratification effects within the gas stream. Attack rates of 5 mm/yr (200 mils/yr) have been reported in precipitator outlet manifold ductwork. Such damage substantially affects ductwork integrity and frequently leads to increased attack rates on plant components downstream, particularly on the electrostatic precipitator housing and fittings and on the chimney stack.

Electrostatic Precipitators and Filter Bag Houses. Fly ash precipitators are not normally used on oil- or gas-fired equipment, but are usually present on coal-fired systems or furnace exhaust streams. Filter bags are sometimes used instead; however, both methods of dust collection are located in large insulated housings, and their internal components are expensive to maintain and replace.

Precipitator housing are normally constructed of low-carbon steel and concrete. Corrosion attack of the housing is often associated with high levels of air in-leakage upstream due to inadequate maintenance or poor housekeeping. Occasionally, poor internal gas flow distribution may allow cool zones to develop, especially under low-flow conditions. Damage appears as casing perforation and sulfation or spalling of concrete, corrosion of rebars, and loss of structural integrity.

Damage to precipitator components is very expensive and necessitates plant shutdown for repair or replacement. Low-carbon steel collector plates and emitter wires may sustain attack during in-service periods of low flue gas temperature, which result from excessive air entry upstream of the precipitators or from inadequate sealing of the dust discharge doors and plate suspension masts (Fig. 28). Off-line attack resulting from the sweating of acid-saturated pulverized fuel ash may also be important. Precipitator plate attack is more marked because the thin-age plates are attacked simultaneously from both sides; that is, the plate thinning rate is doubled.

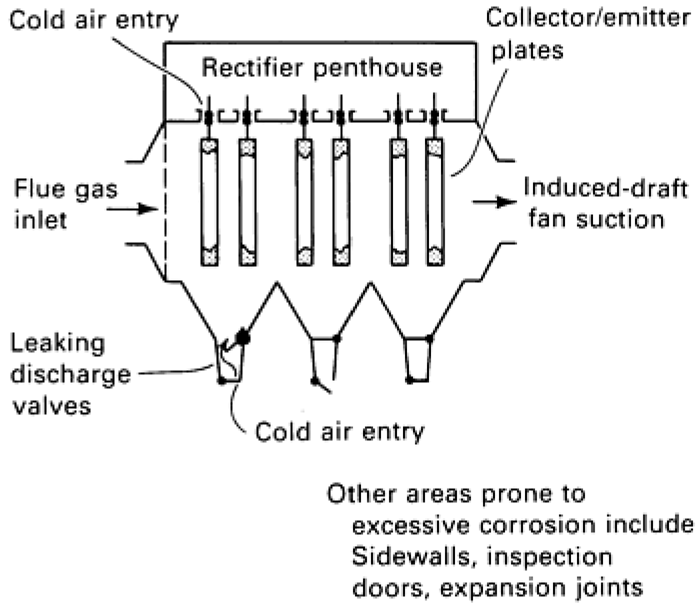

Fig. 28 Schematic of an electrostatic precipitator showing areas prone to excessive corrosion (shaded)

Filter bag installations are normally less expensive than precipitators, but require more maintenance. Dew-point corrosion is frequently displayed on the housing because repeated access to replace holed or detached bags tends to cause wear to access door seals. Low-temperature operation or frequent start-up routines may subject the bag house, bag support, and rapping equipment to extended periods of corrosion attack; this causes blinding of bags and premature holing of the bag material due to chafing during operation or rapping cycles.

Induced-Draft Fan Seals. Corrosion damage to the induced-draft fan housing, control vanes, and impeller seals is again due to air in-leakage. Severe damage is normally associated with neglect of seal condition, and attack of the fan housing itself can rapidly become severe if neglected. Fan housing washing drains should not be left open when the fan is in service. Impeller damage is less common because this component contacts the bulk flue gas.

Chimney Stacks. The stack is often the most vulnerable unit in the gas-handling system because it experiences the results of poorly controlled operation of the furnace and other components of the gas train. Damage is normally due to continuous condensation during operation and build-up of the agglomerated deposits, which insulate the stack inner surface. Stack temperature monitoring is often ignored or neglected. Stacks frequently suffer severe attack before the damage is evident, and inconvenient emergency repairs, necessitating unscheduled unit shutdown, must be made. Damage can occur to liners and/or to the body of the structure, whether it is low-carbon steel, nickel alloy, or concrete (Fig. 29). In prefabricated sectional steel stacks, corrosion occurs preferentially on the inner surface near the external flanges or ladder attachments because of local cooling effects.

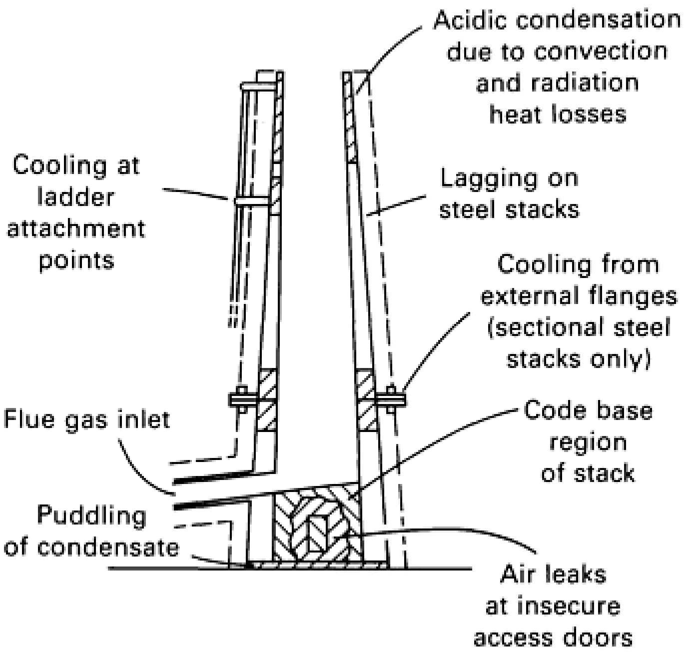

Fig. 29 Schematic of a chimney stack showing sites prone to corrosion (shaded)

Mitigation of Dew-Point Corrosion

In boiler technology, the "acid dew point" usually means the H_2SO_4 dew-point temperature, because this is the highest temperature at which acid condensation occurs. Earlier studies showed that, in dust-free flue gases, low-carbon steel corrosion reaches a maximum at about 25 to 50 °C (45 to 90 °F) below the acid dew-point temperature. More recently (Ref 90) it has been seen that at much lower temperature (below 60 °C, or 140 °F) the corrosion rate of low-carbon steel increases rapidly to at least twice the high-temperature maximum, and to at least three times the high-temperature maximum if HCl is present (Fig. 30).

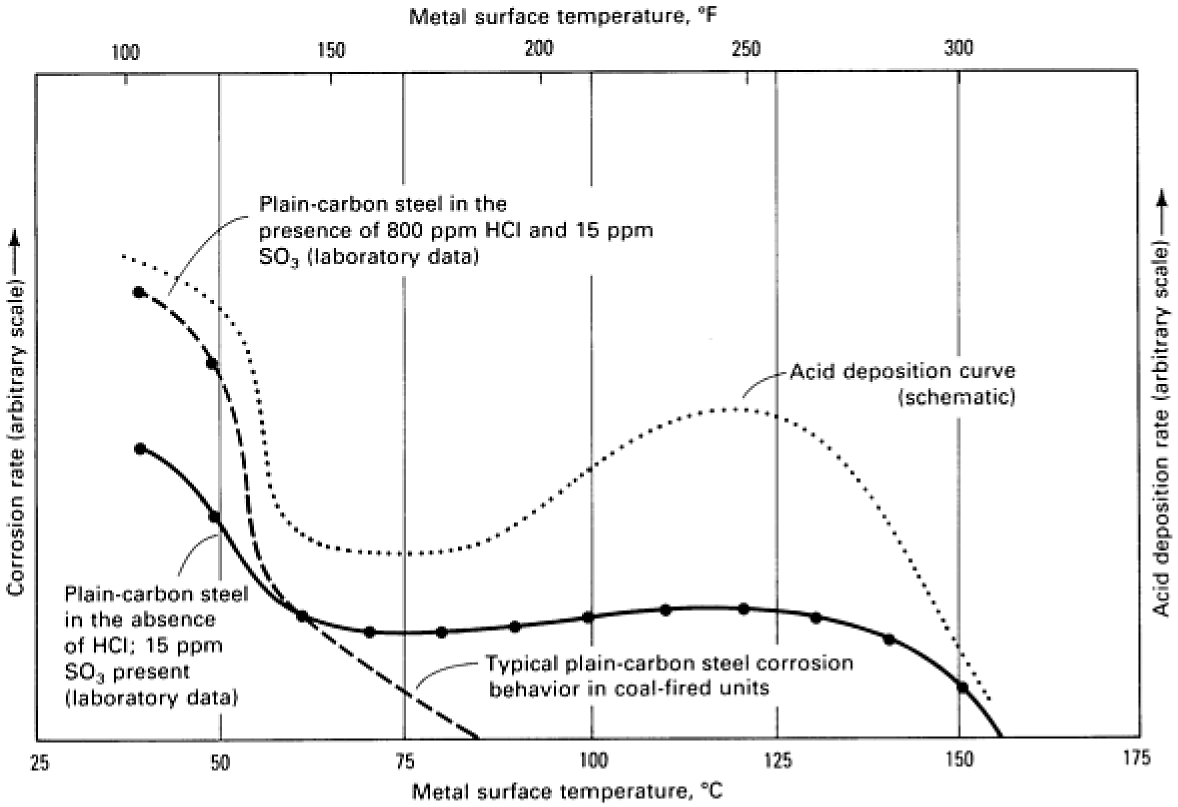

Fig. 30 Modified dew-point curve showing the corrosion rate of a freshly prepared plain-carbon steel surface exposed to dust-free flue gas in a laboratory test rig. The increase in corrosion rate at lower temperatures in the presence of HCl is shown (Ref 91). Modification of classic dew-point corrosion behavior in coal-fired power plants is also shown.

During the period from 1942 to 1955, it was found difficult to define a precise temperature below which rapid corrosion would start and continue; therefore, a threshold figure was sought above which the plant could be operated confidently. A dew-point probe and meter was developed to identify the dew-point temperature, and maintenance of the flue gas temperature at 20 to 30 °C (36 to 54 °F) higher than the dew-point temperature was recommended to avoid condensation and corrosion.

Increasing fuel costs, higher overall efficiencies, and environmental considerations have focused renewed effort on this subject and the reexamination of earlier philosophies. The drive toward less expensive low-grade (more sulfur-rich fuels), together with improved heat extraction process, has produced a move toward lower back-end temperatures with better combustion control, materials selection, and use of additives to minimize dew-point corrosion. A further refinement arises from the development of continuous in-plant monitors of dew-point corrosion that can identify harmful operating regions directly.

It is difficult to give blanket advice on lessening dew-point corrosion because much depends on the precise plant configuration and service environment. However, general comments on materials selection, plant operation, use of neutralizing additives, maintenance, good housekeeping, and lagging (insulation) are offered below.

Materials Selection

Most power boiler exhaust components are made of carbon steel. The material can last indefinitely in conventional plants if metal temperature is maintained above the acid dew-point temperature when the plant is in service and if reasonable case is taken to prevent excessive off-line attack during shutdown periods. In marginal conditions, cast iron may extend service life, but normally, this is simply due to its greater cross section.

A few low-alloy steels have shown superior performance to low-carbon steel in particular applications. Notably, Cor-Ten, a high-strength low-alloy weathering steel, has been used with fair success for cold-end air heater elements. The improved corrosion performance seems related to the formation of a thin protective layer of corrosion product.

Expensive alloy materials have been used where plain-carbon steel corrosion is severe, but they have not always been successful. The good but sometimes unreliable performance of such materials is due to the presence of a performed protective oxide. Failure is associated with deposit formation, which causes differential aeration and concentration cell, producing pitting attack.

Coating uses is hazardous because of difficulties in surface preparation, quality of application, physical durability, adhesion under cycling temperature, and dust abrasion. However, in certain practical application tests, good performance has been reported. For concrete stack lining in power stations, an expensive fluoroelastomer has given outstanding service. Less expensive modified coal tar epoxy and glass flake polyester coatings have performed well, and an isocyanate-cured epoxy material has also been successful in less troublesome plant conditions. For air heater elements, double-dipped enamel coatings are likely to be most effective. Major difficulties in ensuring defect-free adherent coatings have occured with arc-sprayed aluminum, chromia, and alumina materials, but arc-sprayed aluminum has been reported to be generally satisfactory for high-temperature gas turbine stack applications. However, in these stacks, severe thermal conditions can lead to exfoliation and acidic rust flaking.

Plant Operation

Although materials selection can be pertinent in certain plant components, careful plant operation, good housekeeping, and comprehensive maintenance represent a major and more general route to technically efficient, fuel economical. And cost-effective operation. Classical dew-point conditions do not necessarily yield unacceptably high corrosion rates in practice. Control of the secondary factors alone can lead to significant savings by minimizing replacement costs in key areas. Improved on-line monitoring capabilities allow the onset of corrosion to be detected and avoided, often by minor operational refinement, and the possibility of lowering back-end temperatures without risk to the plant can be explored confidently. Precise operational control is important. The inherent variability of excess oxygen, furnace temperature, combustion method, and fuel ashing characteristics can affect low-temperature corrosion more than changes in fuel sulfur content.

Maintenance, Good Housekeeping, and Lagging

A good housekeeping list can be established adequate planned maintenance procedures introduced for any particular installation because practical dew-point factors are now better understood. Poorly designed or maintained thermal insulation, badly sealed inspection doors, leaking expansion joints, and so on, are unacceptable if future installations are to operate at optimum levels.

Additives

Neutralizing additives, usually calcium or magnesium oxide/hydroxide, tend to have an *ad hoc* usage, especially in oil-fired situations, Their benefit in preventing acid smuts is proven, but their ability to reduce corrosion rates consistently is less certain. Modern electrochemical monitoring techniques can provide a continuous means of assessing additive performance, although in many cases fluctuations in fuel composition and operational control may mask the contribution of the additive. Direct injection of NH_3 has been employed to reduce flue gas acidity, but the resultant formation of sticky bisulfite deposits can lead to severe fouling.

Guidance for Specific Sections of the Plant

Penthouse Casing and Hanger Bars. The casing and hanger bars should be maintained during operation at a temperature in excess of the acid dew-point temperature. This is achieved by external insulation of all items. Hanger bar packing boxes should be routinely checked to ensure that excessive clearance has not developed between the packing and the bar, allowing flue gas leakage. This is especially important above the superheater pendant tubes, which tend to require more maintenance than other tube bundles.

Air Heater Cold Ends. In matrix-type air-heaters, air leakage should be controlled, possibly by allowing only a predetermined acceptable leakage rate, and condensate injection should be prevented, especially that due to leaking sootblower steam isolation valves. Compressed air is preferred as the blower medium, and slight preheating to dry the air

should be considered. Adequate condensate drainage facilities must be maintained for all types of blowers. Air heaters should not be water washed on line unless absolutely necessary, but thorough water washing off line is recommended. In many cases, the need to do this may point inadequate operational control, for example, during low-road conditions. For lower outlet flue gas temperature units, the use of Cor-Ten steel or double-dipped enameled elements should be considered for severe service. Adequate specification and coating quality control must be ensured when using enameled elements. Good gas distribution across the air heater minimizes cold spots. The use of fuel additives should be considered for combating unavoidable corrosion attack.

Special care should be taken in shell and tube air heaters to ensure good temperature distribution across the unit. Buildup of gas-side deposits, which may allow sub-dew-point metal temperatures to occur beneath, must not be permitted. Leakage from perforated cold-end tubes must be minimized.

Ductwork, Expansion Joints, Sampling Ports, and Access Doors. All air in-leakage must be prevented. Door seals should be replaced routinely, and a gastight fit ensured. Thermal insulation should be maintained in good condition, leaking expansion joints replaced, and sampling port covers properly refitted after use.

Electrostatic Precipitators and Filter Bag Houses. Adequate maintenance can prevent cold air entry, especially at discharge doors and electrode support masts, and access door seals. External lagging must be in good condition to maintain housing temperature above the acid dew-point. Air entry upstream of the precipitator or bag house should be minimized. If possible, the unit should be kept warm during hot-standby conditions. Operation periods in low gas flow or start-up conditions should be minimized.

Induced-draft fan seals should be maintained in good condition on a routine basis. Fan housing washing drains should not be left uncovered.

Stacks. Adequate temperature monitoring should be ensured at top and bottom. Stack operating temperature should be maintained within design limits at all times. For low-carbon steel stacks, adequate insulation and lining condition must be ensured. Stacks should not be run wet or cold unless specifically designed to do so. Routine inspection programs for monitoring stack lining and structural integrity should be initiated.

Corrosion of Flue Gas Desulfurization Systems

G.H. Koch and H.S. Rosenberg, Battelle Columbus Division

The control of SO_2 emissions is a primary concern in coal-fired power plants. This can be done either by removing sulfur from the coal before combustion or by FGD in scrubbers. A variety of methods of both types are being developed, and some are already in commercial operation.

Among the FGD processes, lime and limestone wet scrubbing are the most developed. A schematic of a typical system of this type is shown in Fig. 31. Hot, dry flue gas at about 150 °C (300 °F) contacts a spray of an aqueous lime or limestone slurry in the absorber. The SO_2 in the flue gas dissolves in the slurry to form sulfites, which may be oxidized to sulfates by oxygen in the flue gas. The pH of the absorber slurry typically ranges from 5 to 6.5. Scrubbed and cooled gas at 50 to 55 °C; (120 to 130 °F) passes through mist eliminators and outlet ducting to the stack. The scrubber gas is sometimes reheated to 60 to 95 °C (140 to 200 °F) to increase its buoyancy by mixing with unscrubbed gas (bypass reheat) or by using special reheaters. When bypass reheat is used, the SO_2 and SO_3 in the gas readily react with the water in the scrubbed gas to form H_2SO_4, which can create an extremely oxidizing condensate on the duct wall. Supplemental information on corrosion of and materials for FGD systems is available in the article "Corrosion of Emission-Control Equipment" in this Volume.

Materials for FGD Systems

A variety of construction materials have been used in operating FGD systems. These include metals, organic linings and plastics, and ceramic and inorganic materials. Metals ranging from carbon steel to nickel-base alloys have been used in most components of FGD systems.

Unlined carbon steel or high-strength low-alloy steels, such as Cor-Ten, can be used where alkaline (pH >7) conditions are maintained--for example, in lime/limestone storage silos or in the piping that carries the fresh slurry to the absorber. Rubber-lined carbon steel is frequently used for protection against abrasion. Under more acidic conditions, the steels must be protected by a lining. Where unlined metal is exposed to acidic environments, corrosion-resistant alloys are required. Stainless steels--for example, type 316L, type 317L, and alloy 904L--have been used in such FGD system components as prescrubbers, absorbers, spray nozzles, reheaters, and dampers. In critical locations with more aggressive environments, such as outlet ducts, outlet dampers, and reheaters, nickel-base alloys (Inconel 625, and Hastelloy alloys C-276 and G3) and titanium (grades 2 and 7) have been used. When the alloys fail, it is usually be general corrosion, pitting, crevice corrosion, erosion-corrosion, or SCC.

Organic linings have been extensively used in various FGD components, including prescrubbers, absorbers, tanks, outlet ducts, and stacks. These linings include epoxies, vinyl-esters, polyesters, fluoroelastometers, and rubber. The use of organic linings is attractive because it can provide the lowest-initial-cost material for many of these components.

The linings are generally applied in liquid form by brushing, rolling, or spraying. To provide an effective barrier, the organic linings used in FGD systems are often applied in several layers to achieve a thickness greater than that of typical coatings. Moreover, the linings often contain a flake-type filler, which decreases the permeability of the lining and provides reinforcement. In such components as venturi prescrubbers, in which high abrasion resistance is required, organic linings reinforced with glass cloth or inert matting have been used. These linings may also contain special abrasion-resistant fillers, such as Al_2O_3, to improve wear resistance. Although rubber is an organic lining, it is often placed in a separate category because it is applied in sheet rather than liquid form. Failure of organic linings can occur by blistering, debonding, and wear from abrasive slurries. Excursions to high temperatures can damage or destroy organic linings.

Nonmetallic inorganic materials are used in prescrubbers, spray nozzles, slurry pumps, outlet ducts, and stacks. The materials used for these components include prefired bricks and shapes, hydraulically bonded concretes and mortars, and chemically bonded concretes and mortars, all of which are used as lining materials where temperature resistance,

chemical resistance, or abrasion resistance are required. Prefired shapes are also used for spray nozzles and pump components. Acid-resistant bricks are commonly used as construction materials for stack linings. Alumina bricks are more abrasion resistant than acid-resistant bricks and will also withstand hot H_2SO_4; therefore, they have been used to line venturi throats. Silicon carbide shapes have high abrasion and chemical resistance and are used for spray nozzles and pump components as well as for lining venturi throats. Design aspects that could cause failure include mechanical stresses from shrinkage, insufficient thermal expansion allowances, vibration, and thermal or mechanical shock.

Hydraulic-setting cement-bonded concretes (hydraulic concretes) are used as linings for prescrubbers, outlet ducts, and stacks. These concretes contain calcium aluminate ($CaAl_2O_4$), which can withstand temperatures of 260 °C (500 °F) without strength degradation. However, in H_2SO_4 solutions (pH <4), the cement is attacked because of dissolution of the $CaAl_2O_4$. This dissolution of the bond results in loosening of the aggregate and erosive wear of the lining.

Chemically bonded mortars are commonly used to bond acid-resistant brick stack linings. Chemically bonded concrete mixes can also be used as linings. They generally contain siliceous aggregates; a sodium silicate (Na_2SiO_3), potassium silicate (K_2SiO_3), or colloidal silica bond phase; and a silicofluoride, phosphate, or organic bond gelling agent. Because chemically bonded concretes can withstand hot acidic environments, they offer an abrasion-resistant alternative to organic linings. However, like hydraulic cements, the chemically bonded cements have a finite permeability; therefore, any condensed acid will ultimately reach the substrate to which they are applied, unless the substrate is protected by an impermeable membrane. More information on chemically bonded concrete linings is available in the article "Chemical-Setting Ceramic Linings" in this Volume.

Borosilicate glass block is used in outlet ducts and stacks. The blocks are usually bonded with urethane asphalt. The combination of these two materials results in a lining that is extremely resistant to permeation by aggressive condensate. Moreover, the thermal insulating properties of the glass block and the flexibility of the membrane material contribute to the good performance of the lining. However, the borosilicate glass can be easily damaged, and failures can occur due to abrasion, puncturing, and cracking. Also, scale that forms on the lining cannot be easily removed. Specific materials of construction that are currently used in major FGD components (prescrubbers, absorbers, outlet ducts, and stacks) will be reviewed in the following sections.

Materials for Specific FGD Components

Prescrubbers. The flue gas from the air preheater (about 150 °C, or 300 °F) is cooled in a prescrubber to the adiabatic saturation temperature of about 50 °C (120 °F). There are basically three types of prescrubbers:

- A quench or saturation duct with water sprays, which cools hot gas already cleaned of particulates by an electrostatic precipitator
- A quencher zone in the bottom of the absorber or in a separate vessel
- A rod, constricted throat, plumb bob, or flooded disk venturi system that cools the gas and removes particulates

Scrubbing liquor is usually used in the prescrubber so that it operates at a pH of about 4 to 6. In some cases, makeup water or reclaimed water is used in quench ducts, and the operating pH is then 1 to 3. This low-pH solution can be extremely aggressive toward materials of construction, particularly when the SO_2 scrubber operates in a closed-loop mode, which can increase the chloride concentration to 40,000 to 50,000 ppm.

Quench ducts and quench zone systems are usually constructed of either concrete-lined carbon steel or an alloy ranging from type 317LM stainless steel to nickel-base alloys, such as Hastelloy C-276. In cases where the pH is low (<3), the concrete deteriorates and spalls off the carbon steel substrate, exposing the carbon steel to the aggressive solution. In these environments, stainless steel and low nickel-base alloys fail by pitting and crevice corrosion, and only highly resistant alloys, such as Hastelloy C-276 and titanium grade 7 (titanium-palladium), can withstand this extremely aggressive environment.

Absorbers. The flue gas enters the absorber at either about 50 °C (120 °F) or about 150 °C (300 °F), depending on whether or not a prescrubber is used. The conditions in absorbers are similar to those in prescrubbers in which lime or limestone scrubbing is used, that is, pH of 5 to 6.5. The chloride concentration of the scrubbing liquor depends on how the

prescrubber and absorber loops are tied together and whether an open- or closed-loop water system is used. Depending on these conditions, the chloride concentration can range from a few hundred to 50,000 ppm.

Absorbers incorporate a variety of designs and many different materials of construction. Generally, absorbers use a combination of materials, the primary categories being stainless steel, rubber-lined carbon steel, organic-lined carbon steel, and ceramic-lined carbon steel.

Molybdenum-containing stainless steels, such as types 316L, 316LM, 317L, and 317LM, and alloy 904L have been used for construction of several FGD absorbers, as well as such components as trays, plates, supports, and fasteners. High chloride concentrations of the scrubber slurries can result in pitting and crevice corrosion, and abrasion by these slurries can sometimes cause wear failures.

Natural rubber and synthetic rubber (neoprene and chlorobutyl) are widely used as lining materials for absorber walls. Generally, rubber linings perform well in absorber environments. Failures as a result of improper application or curing occur as debonding or blister formation. In addition, the absence of industry standards for composition and formulation of rubber products also plays an important role in rubber lining failures.

Several absorbers are in operation with glass flake filled polyester or epoxy linings. The organic linings have generally performed satisfactorily in the relatively mild absorber environments.

Outlet ducts carry the flue gas from the absorber to the stack and are thus exposed to saturated (wet) flue gas at about 50 °C (120 °F) and/or reheated flue gas, depending on the existence and location of a reheater. Part of the outlet duct may also the exposed to hot flue gas during periods of scrubber shutdown if the FGD system has a bypass duct that joins the outlet duct ahead of the stack. The outlet duct has been a major problem area, particularly in units with duct sections that handle both hot gas and wet gas. Failure of an outlet duct may require complete boiler shutdown and loss of generating capacity for long periods of time because of the lack of standby components or bypass capability.

The severe attack of metallic and nonmetallic materials of construction has been attributed to low-pH conditions (<3) and to the presence of chlorides. The low pH is attributed to the presence of unscrubbed SO_2 and HCl in the flue gas, which can reach high concentrations when bypass reheat is used, and to the absence of the buffering effect of lime or limestone. The chlorides, which come from the coal as well as the makeup water, can reach very high concentrations when FGD systems are operated in a closed-loop mode. Recent laboratory studies on several stainless steels, nickel-base alloys, and titanium-base alloys have indicated that trace elements originating from the coal and the makeup water, such as iron, aluminum, chromium, copper, phosphorus, and fluorine, have a significant effect on the corrosion performance of alloys.

Operating experience in wet SO_2 scrubber outlet ducts has indicated that many types of organic and inorganic linings provide good service in wet-gas and reheated-gas environments. However, wet-gas and hot-gas conditions caused by bypass for reheat or for scrubber maintenance typically result in less than 2 years of service for many linings. Although lining application conditions and procedures are considered to be very important to the success of a lining, environmental conditions in the duct, such as temperature distribution and condensate chemistry, have a considerable effect on the life of a lining.

Glass flake polyester, vinyl-ester, fluoroelastomer, and multifunctional epoxy are the most commonly used lining materials in outlet ducts. The performance of the linings is generally excellent in wet outlet duct environments, but may be poor in wet-dry environments that result from bypass.

Inorganic cementitious linings are generally not used in wet environments, because of their high permeability, but their use in hot environments is increasing because of the temperature problems with organic linings. Hydraulically bonded concrete has failed in several wet environments, but can give reasonable life under dry conditions. The use of an organic membrane between the carbon steel substrate and the cementitious lining has proved effective in keeping the condensate away from the steel. However, corrosion will occur when holidays are present in the organic membrane. The ability of concretes to absorb the condensates that form on the surface is being used to develop a method of protecting the metallic substrate by means of electrochemical potential control.

Finally, borosilicate glass blocks with urethane asphalt mortar and membrane have been successfully applied in several outlet ducts. As indicated earlier, the primary disadvantage of this lining is its low mechanical strength, which renders it susceptible to abrasion by fly ash or scrubber slurry carryover and damage due to impact from tools and maintenance equipment. When heavy scale forms on the surface, its weight may tear off part of the glass blocks. Also, it is extremely

difficult to clean a scaled surface. To overcome this shortcoming, cementitious coatings are often applied over the glass block surface, particularly in floor applications.

Until recently, alloys were not commonly used in outlet ducts. Type 316L and 317LM stainless steels, alloy 904L, and Hastelloy G have been used in a few ducts, but all have experienced pitting and crevice corrosion. Recent application of high nickel-base alloys and titanium have proved successful. Particularly, the application of a 1.5-mm ($\frac{1}{16}$-in.) thick sheet of Hastelloy C-276 onto a carbon steel substrate has provided a cost-effective alternative to full-thickness alloy walls and nonmetallic linings.

Stacks. The flue gas from an FGD system exits to the atmosphere through a chimney or stack. The stack consists of an outer shell constructed of concrete or carbon steel and one or more flues constructed of brick, metal, or fiberglass-reinforced plastic (FRP) that carry the flue gas (Fig. 32). A stack is a critical component in that, as in the case of outlet ducts, failure may require complete shutdown of the boiler, which results in loss of generating capacity for extended periods of time. The performance of a stack lining depends strongly on whether the flue gas is wet or reheated and whether the stack is also used for hot bypassed gas.

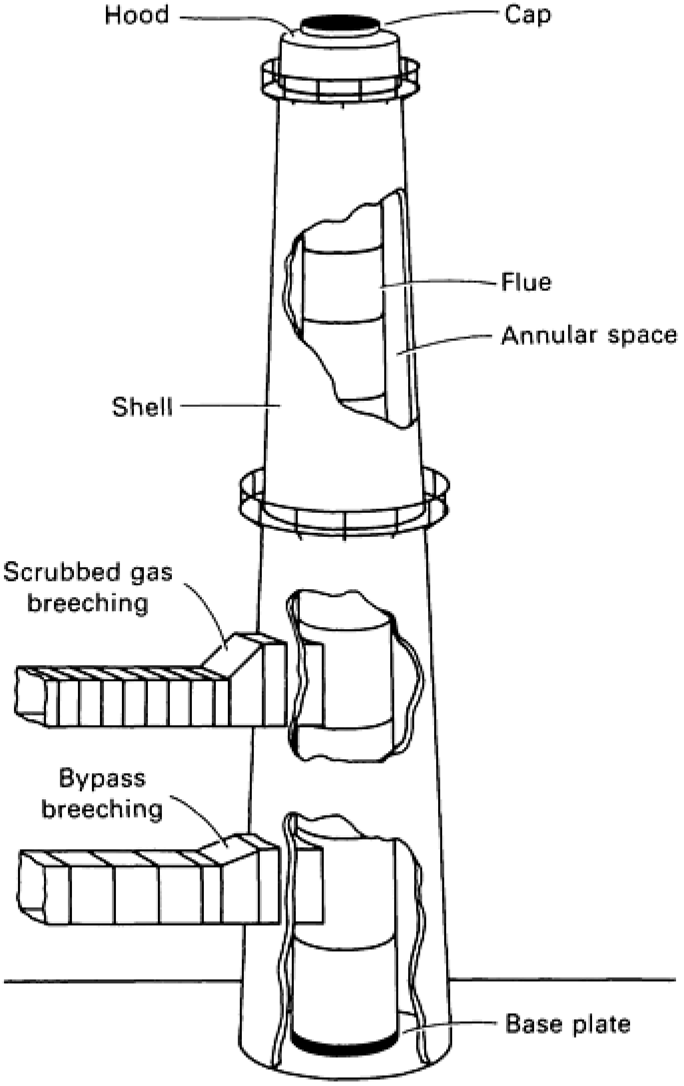

Fig. 32 Schematic of a typical stack

Stack flues that are exposed only to wet gas are located downstream from FGD systems without any type of reheat and without FGD bypass ducts. The flue gas is typically at 50 to 55 °C (120 to 130 °F), and the flue is not exposed to high temperatures. Under these relatively mild operating conditions, several materials of construction can be used. For

example, Inconel 625, FRP, inorganic-lined carbon steel (borosilicate glass block), and organic-lined carbon steel have been installed in stacks and have generally performed well. Furthermore, acid-resistant brick is being widely used as a material of construction for stacks.

Although acid-resistant brick linings have exhibited good performance in all categories of operating conditions, a leaning phenomenon has recently been reported for several free-standing brick flues. This phenomenon has required some utilities to perform considerable maintenance work near the top of the stack to eliminate rain cap rubbing and/or to provide adequate clearance to accommodate the wind load deflections of the concrete shell. In one case, the flue was completely rebuilt.

The leaning phenomenon appears to correlate with mixing wet gas and hot gas in the stack, that is, separate breechings for scrubbed gas and bypassed gas. Less severe leans have occurred when wet gas and hot gas have been mixed in the outlet duct near the breeching in the flue. Preliminary results from the analysis of core samples from several leaning flues indicate that differential moisture expansion of the bricks is a primary cause of the lean phenomenon.

Corrosion of Generators

R. Viswanathan, Electric Power Research Institute

The most significant corrosion problem in generators in SCC of retaining rings. Retaining rings are massive steel rings that are shrunk onto the generator rotor to retain the circumferential conductor coils wound around the two ends of the rotor. The rings currently in use are made of an austenitic steel containing 18% Mn and 5% Cr. Retaining rings are highly stressed, critical components of a generator, and several catastrophic incidents involving failures of these rings have occurred worldwide.

Forms of Corrosion

Stress-corrosion cracking is the single major cause of failure of retaining rings. The stress required can arise from the residual stresses from cold fabrication and machining, shrink-fit assembly stresses, or operating stresses. The aggressive environments causing cracking may include lubricating oils and fluids used during machining, solvents and paints used for cleaning and dye penetrant inspection, condensed moisture, salt water and industrial air environments encountered during storage and shipping, and moist hydrogen or water used for generator cooling. Residual stresses from fabrication alone are sometimes sufficient to cause cracking of the rings, as evidenced by instances of cracking in storage.

For machines with hydrogen-cooled rotors, the periods of highest risk are frequently during storage and assembly, that is, before the machine is closed. During this time, retaining rings are exposed to the ambient plant environment, and their temperature may easily drop below the dew point. Humidity may enter the machine in a number of ways during operation--for example, imperfectly dried hydrogen; from leaks in water-fed heat exchangers; in the oil of the hydrogen seal circuits; or, in the case of direct water cooling of the rotor, from simple leakage. In general, however, the increased temperature of rings in operation is enough to avoid condensation, which will more readily accumulate on the cold surfaces of the water circuit. As a further precaution, the dew point should be correctly monitored and maintained at an acceptable level.

The generator rotor must be kept dry during manufacture, transportation, storage, and periodic shutdown to protect the electrical insulation and to prevent general rusting of the rotor. In addition, water condensation should be prevented from forming on the retaining ring surface. Several methods are possible, but application of each is determined by considering such factors as the climate of the site location and the shipping route. For example, special packing is applied to keep the rotor dry when it is shipped to tropical countries. The packing is opened immediately before the start of rotor assembly.

The rate of crack growth *da/dt* as a function of stress intensity *K* in dry hydrogen, moist hydrogen, and water environments is illustrated in Fig. 33. No crack growth occurs in dry H_2 even up to *K* values of 100 MPa$\sqrt{m}$ (91 ksi$\sqrt{in.}$), which indicates that the threshold stress intensity for crack propagation in dry hydrogen K_H exceeds this value. On the other hand, in moist hydrogen, rapid crack growth occurs at all values of K > 10 MPa$\sqrt{m}$ (9.1 ksi$\sqrt{in.}$). The same behavior is observed in distilled water. It is clear from these data that the threshold value of *K* for SCC propagation

in aqueous environments (K_{ISCC}) is as low as 10 MPa$\sqrt{m}$ (9.1 ksi$\sqrt{in.}$). Other investigators have reported slightly higher K_{ISCC} values in the range of 15 to 25 MPa$\sqrt{m}$ (13.7 to 22.8 ksi$\sqrt{in.}$). Once this value is exceeded, the crack propagates rapidly (within a matter of hours or days) to reach the critical crack size a_{crit}. Therefore, in the presence of corrosive environments, failure is no longer governed by K_{Ic} but by K_{ISCC}.

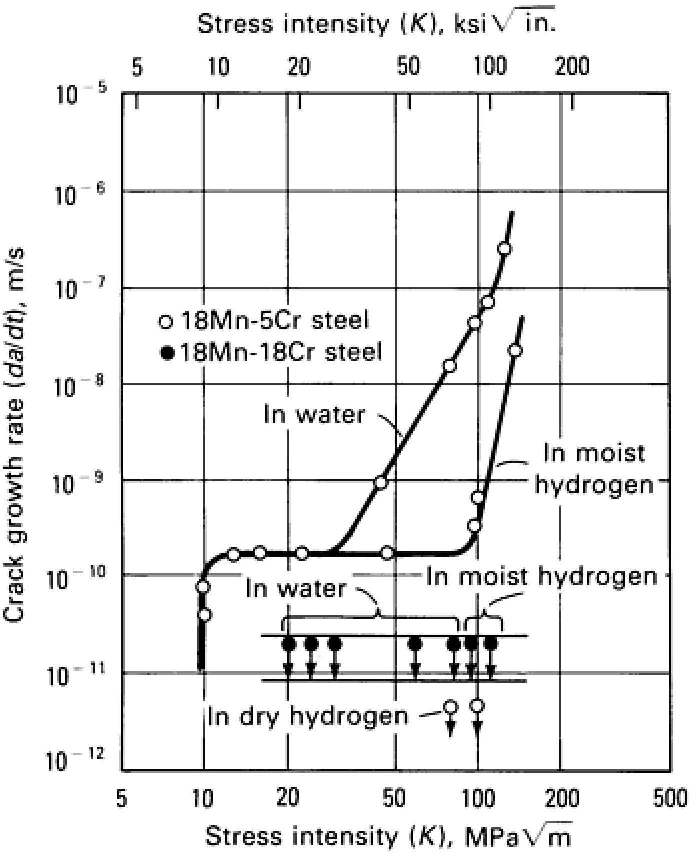

Fig. 33 Crack growth rate versus stress intensity for two generator retaining ring steels in three environments. In dry hydrogen, neither material showed any crack growth at *K* up to 100 MPa$\sqrt{m}$ (91 ksi$\sqrt{in.}$). The 18Mn-5Cr alloy, however, exhibits crack growth in moist hydrogen and water; the 18Mn-18Cr steel does not.

Based on K_{ISCC} = 10 MPa$\sqrt{m}$ (9.1 ksi$\sqrt{in.}$), a_{crit} for various values of stress can be estimated with the help of fracture mechanics evaluations. It can be shown that over the range of working stresses of practical interest a_{crit} is much below the sensitivity of detection by current nondestructive testing techniques. In fact, at a stress level of 690 MPa (100ksi), even pits only as deep as 0.14 mm (5.4 mils) appear to be capable of causing rapid crack propagating. This means that any crack that is detectable during an inspection or any pitting that is present can potentially compromise ring integrity and therefore indicate the need for immediate corrective action. For this reason, the concept of a tolerable defect size does not exist, and inspection procedures have placed more emphasis on crack detection than on crack sizing. Furthermore, visual inspections that can readily detect rusting and pitting have a prominent role among inspection techniques.

Despite the extreme susceptibility of 18Mn-5Cr steel to SCC crack growth, retaining rings made of this steel have served the industry well. The reasons for this are twofold. First, initiation of pits and/or cracks is also a function of stress, and it can take many years to occur. Second, the propagation of cracks is a discontinuous process because exposure to moist environments occurs only intermittently.

In view of the extreme susceptibility to SCC of 18Mn-5Cr steel rings, manufacturers have recently developed an alternative steel containing 18% Mn and 18% Cr. Extensive laboratory tests have shown the 18Mn-18Cr steel to be very resistant to SCC. Rings made of the new alloy are currently being used in new and replacement generator rotors by most

manufacturers. With the introduction of the new material, it is anticipated that ring corrosion problems in generators will cease to be of concern in the future.

Corrosion of Ash-Handling Systems

L.D. Fox, Tennessee Valley Authority

Ash handling is a major problem for utilities and industrial owners using coal as a primary fuel. The firing concept used, that is, cyclone, pulverized-coal, or fluidized-bed firing, determines the type and characteristics of the ash. Waste ash (fly ash and bottom ash) is generated in large volumes and must be disposed of in an environmentally acceptable manner. Fly ash comprises small dustlike particles (100 μm or less in diameter); bottom ash consists of much larger slag particles removed at furnace bottoms.

Conventional ash-handling systems collect, convey, and dispose of waste ash by methods that depend on site-specific considerations, regulatory (local, state, and federal) requirements, and economic considerations. Generally, the ash will be handled wet or dry, but the handling system may include combinations of wet and dry conveying. Fly ash is collected dry and is generally conveyed dry to storage or disposal. Wet conveying and storage of fly ash has become environmentally more difficult, and regulations now favor dry conveying systems. Bottom ash is collected in a water bath and is almost always handled wet. Most ash-handling systems convey bottom ash and fly ash separately to storage or disposal, but conveyance in the same pipeline is also acceptable. Typical operating problems associated with conventional fly ash/bottom ash handling systems may be grouped into two categories:

- Corrosion and erosion (material deterioration)
- Scaling and plugging (material buildup)

The above problem areas must be addressed by designers of ash-handling systems and plant operators, who should consider such factors as equipment selection, material applications, maintenance policy, and system concept. The handling system concepts for fly ash/bottom ash are dry/dry, dry/wet, wet/dry, or wet/wet. The subject of ash handling is discussed in detail in Ref 92. Corrosion and corrosion-related problems are more prevalent in wet systems than in dry systems. Corrosion-related problems by system concept are reviewed below.

Fly Ash Systems

Dry Fly Ash Systems. The pneumatic conveying of coal ash particles can produce plugging of conveying lines, sticking of the ash to chutes and hoppers, and erosion of internal parts of ash-handling equipment. Corrosion of internal components is normally small to nonexistent. Only the introduction of unwanted moisture will create an environment that will produce corrosion that is severe enough to cause system outages or to require frequent maintenance.

Wet Fly Ash Systems. The transport of fly ash with water as the conveying medium is normally achieved by using a slurry of 10 to 15% ash by weight. The introduction of conveying water sets up an array of water chemistry situations that can lead to scaling and/or corrosion. The tendency for scaling and corrosion depends in part on the chemical characteristics of the ash sluice water and in part on the composition of coal ash.

Table 5 shows the variations in coal ash composition with coal rank. The soluble ash species of such elements as iron, calcium, sodium, magnesium, potassium, and a variety of trace elements will produce a wide range of pH levels in the ash slurry. For example, a dramatic change in coal supply can result in changes of 1 to 2 pH units. The dominant alkaline constituents are Fe_2O_3, CaO, MgO, Na_2O, and K_2O; the acid constituents are SiO_2, Al_2O_3, and TiO_2 (Ref 93). This interaction of water and ash is the cause of most corrosion problems.

Table 5 Variations in coal ash composition by coal type

Coal type	Composition, %									
	SiO_2	**Al_2O_3**	**Fe_2O_3**	**TiO_2**	**CaO**	**MgO**	**Na_2O**	**K_2O**	**SO_3**	**Ash**
Anthracite	48-68	25-44	2-10	1-2	0.2-4	0.2-1	. . .	. . .	0.1-1	4-19
Bituminous	7-68	4-39	2-44	0.5-4	0.7-36	0.1-4	0.2-3	0.2-4	0.1-32	3-32
Subbituminous	17-58	4-35	3-19	0.6-2	2.2-52	0.5-8	. . .	. . .	3-16	3-16
Lignite	6-40	4-26	1-34	0-8	12.4-52	2.8-14	0.2-28	0.1-1.3	8.3-32	4-19

Source: Ref 92

Scale formation on equipment internals and pipeline walls is always a frequent maintenance problem. A characterization of typical scale indicates that compounds of calcium, magnesium, sodium, and silica go into solution, concentrate, and precipitate out on internal surfaces. The reduction in pipeline diameter by heavy scale buildup, pump and valve scaling (reduction in internal clearance), and plugging of small control lines will require dismantling and descaling, or replacement. Most corrosion or erosion-related failures are complicated by scale formation.

Wet Bottom Ash Systems

Hot ash (clinkers or agglomerated slag) deposits of varying sizes are quenched and collected for conveying in the bottom ash system. As noted above, bottom ash systems are generally conveyed wet from collection to final disposal. However, some systems, incorporate, dewatering equipment and haul the ash by mobile equipment or belt conveyors to suitable disposal sites. The pumping and pipeline conveying of bottom ash slurries (normally 15 to 20% ash by weight) generally results in a highly abrasive but only moderately corrosive condition. Agglomerated granular (fused) bottom ash, with its irregular shape and large size, gives the slurry its abrasive nature. As compared to fly ash, it is inert and insoluble; therefore, chemical interaction between the bottom ash and conveying water is less worrisome.

Current environmental regulations have resulted in the development of the zero discharge (closed-loop) system. The reuse of conveying water in either bottom ash or fly ash systems will concentrate soluble salts and will usually result in a more corrosive water chemistry. Therefore, most failures result from erosion, scaling, or plugging, but corrosion may become a problem if soluble salts are allowed to accumulate too long in closed-loop systems.

Mitigating the Problems

Operating problems due to corrosion, erosion, scaling, and plugging can be minimized by consideration of the following:

- Piping systems should have gradual bends, turns, and transitions and should be without sharp angles to reduce erosion and/or plugging
- Materials of construction (metals, nonmetals, and coatings) that are resistant to acid attack should be selected
- All storage vessels should have constant agitation to keep solids in suspension; this facilitates pumping
- Pipe diameters and line velocity must be such that suspended solids do not cause plugging
- Piping systems should be flushed during shutdown to remove solid before solids cementation reactions can occur
- Abrasive-resistant liners (replaceable metal, plastic, ceramic, and elastomers) should be selected for system components (pump impellers and casings, agitator blades, and pipe liners) for better control of erosion and corrosion of wetted parts

It is not possible to recommend a single approach or a material of construction that will work for every ash-handling application. Corrosion problems are reduced and equipment lifetime is extended by good case-by-case material selection, the existence of adequate quality control, operational simplicity, and the use of inspection/maintenance practices.

The Future

Present and pending regulations (mainly federal) tend to restrict the wet-dry options for utility and industry owners. Systems of the future will be dry processes for fly ash and will require suitable reuse or environmentally safe disposal of the ash. Wet systems for both bottom ash and combined fly ash/bottom ash will drift to the zero discharge concept and recycle their conveying water. Corrosion considerations will take on a new dimension, and the existing experience base will be used to solve future corrosion problems.

Corrosion in the Automotive Industry

Introduction

CORROSION has in recent years become a major concern of automakers around the world. The use of deicing chemicals has increased tenfold in North America since the mid-1950s (Ref 1) and is the major cause of corrosion of automobile body panels in the "salt belt" (Fig. 1). Other environmental factors, including air pollution in industrial areas, exposure to marine atmospheres in coastal regions, acid (low-pH) precipitation, and dust control procedures on rural roads, also contribute to the increased corrosion of automobile body panels and other components.

Fig. 1 Map showing the severity of automotive corrosion environments in the United States and southern

Canada. Source: Ref 1

The auto industry has responded to the corrosion problem in a number of ways, including the use of more corrosion-resistant materials, improved paint systems, and better design practices. This article will discuss the use of precoated sheet steels, paint systems and methods of application, and the use of new, more corrosion-resistant materials to combat corrosion.

Forms of Corrosion

The automotive environment can result in several forms of corrosion. Chief among these are uniform or general corrosion, crevice corrosion, galvanic corrosion, poultice corrosion, and pitting corrosion. Other forms include inside-out corrosion, outside-in corrosion, scab corrosion (similar to outside-in corrosion, but it usually occurs at joints and crevices where dirt and moisture are trapped), saponification, cathodic delamination, and filiform corrosion. These are further discussed in Ref 1.

Uniform corrosion occurs over the entire exposed surface of a component in the form of a general thinning of the material. Because of the uniform nature of the attack, this is the least damaging of the forms of automotive corrosion. More information on this form of corrosion is available in the article "General Corrosion" in this Volume.

Crevice corrosion (Fig. 2) is a severe form of localized attack that is normally associated with small pockets of stagnant electrolyte that can form at holes or joints or under fasteners. The attack in this form of corrosion is rapid, and it can result in early failure. The section "Crevice Corrosion" of the article "Localized Corrosion" in this Volume gives detailed information on this form of attack.

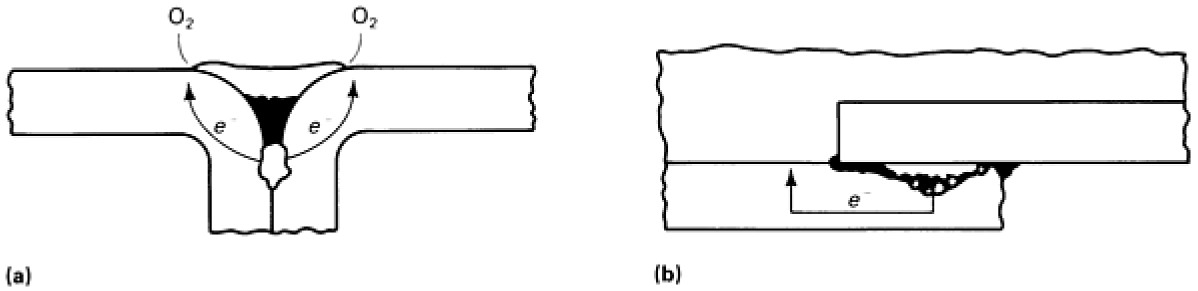

Fig. 2 Schematics showing the mechanism of crevice corrosion at a joint. Crevice corrosion is common at weldments or sheet metal joints (a) and rough surfaces where electrolyte can be trapped, and it can occur at tightly sealed lap joints, as in (b). Source: Ref 2

Galvanic corrosion results from the contact of two dissimilar metals in the presence of an electrolyte. The more active metal or alloy becomes the anode of the couple and may be subject to rapid attack. This type of corrosion has limited the automotive applications for aluminum alloys, because aluminum will corrode preferentially in contact with steel. For this reason, aluminum must be insulated from direct contact with steel through the use of nonconductive or barrier-type spacers or sealers (Ref 1). Figure 3 illustrates schematically the mechanism of galvanic corrosion. More information on this form of corrosion is available in the section "Galvanic Corrosion" of the article "Localized Corrosion" in this Volume.

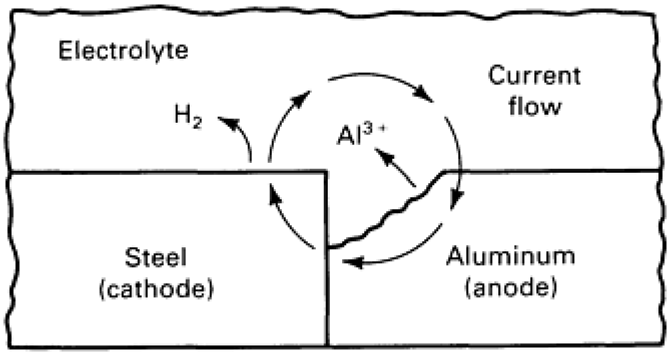

Fig. 3 Schematic showing the mechanism of galvanic corrosion, which occurs when two dissimilar metals are placed in contact with one another in the presence of an electrolyte. The more electrochemically active of the two metals will act as an anode and will corrode preferentially, while the less active metal is protected. Source: Ref 2

Poultice corrosion is a form of crevice corrosion that occurs under deposits of road debris, such as mud that may be deposited on the underside of fenders and at other locations. The deposits hold corrosive substances such as road salt in contact with the body material and retard or prevent runoff. Electrolyte composition gradients (Fig. 4) are thought to be the most common cause of this form of corrosion (Ref 2).

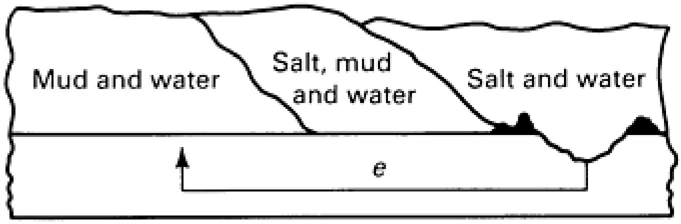

Fig. 4 Schematic showing the mechanism of poultice corrosion. The most common cause of this type of corrosion is thought to be electrolyte composition gradients. In the example shown, clumps of mud and water have collected, and the varying concentrations of salt and water within the clump encourage corrosion. Source: Ref 2

Pitting corrosion (Fig. 5) is similar to crevice corrosion in that it is a localized attack. It occurs most often in areas of low pH that are depleted in oxygen but have a relatively high concentration of chlorides (Ref 2). Once pitting is initiated, the mechanism is similar to that of crevice corrosion, with the pit itself acting as the crevice (Ref 1). Pits can initiate at metal inhomogeneities, breaks in a protective coating, surface deposits or other defects. More information on pitting corrosion is available in the section "Pitting" of the article "Localized Corrosion" in this Volume.

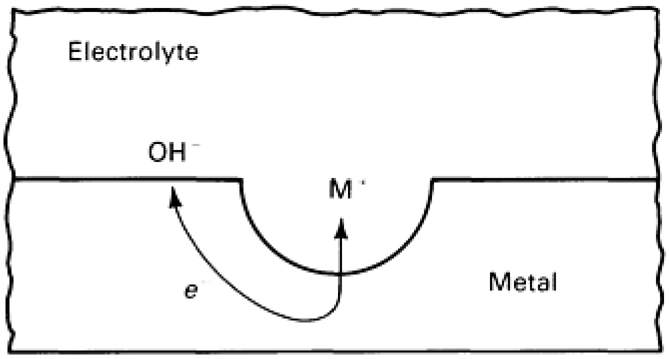

Fig. 5 Schematic showing the mechanism of pitting corrosion. Like crevice corrosion, pitting occurs at localized areas depleted of oxygen, low in pH, and high in chlorides. Source: Ref 2

All of these forms of corrosion are the result of reaction with the environment and all require the presence of water. These and other forms of corrosion that are prevalent in the automotive environment are discussed further in Ref 1.

Precoated Steels

Beginning in the late 1950s, automakers responded to the challenge of increased corrosion of body panels through the use of precoated sheet steels, especially galvanized (zinc-coated) steels. The use of zinc-coated steels has steadily increased ever since, reaching an estimated total of 156 kg (344 lb) in the typical U.S. automobile in 1986 (Table 1). This represents an increase of 13.5% over the 137 kg (303 lb) of zinc-coated steel per car used in 1985 (Ref 3).

Table 1 Use of zinc-coated steel for a typical 1986 model U.S. car

Type	Amount of steel		Amount of zinc	
	kg	**lb**	**kg**	**lb**
One-side galvanized	33.5	4	0.55	1.21
Two-side galvanized	93	205	3.05	6.72
Zincrometal	29.5	65	0.19	0.41
Net total	156	344	3.8	8.34

The auto industry has also employed other types of coatings, including zinc-aluminum and zinc-iron alloys, aluminum, tin, and long terne (lead-tin alloy). Composite coatings are being developed that offer better corrosion resistance in laboratory tests than Zincrometal, which is steel coated with a zinc-rich organic primer.

Coatings have traditionally been designated according to standard American Society for Testing and Materials coating weight designations, but the desire for more consistency in formability and weldability has placed an increased emphasis on tighter coating weight limits. Automakers are specifying more and more coated steels in terms of grams of coating per square meter (g/m^2) (Ref 1) or ounces per square foot (oz/ft^2). Some coatings are still described by coating thickness; for example, Zincrometal generally has a coating that is 5 μm thick.

Zinc-Coated Steels

Zinc-coated (galvanized) steels are the most common coated steels used as body panels in the automotive industry (Fig. 6). They can be obtained with widely varying coating weights (20 to 160 g/m^2) and with one side coated, both sides coated equally, or different coating weights on each side.

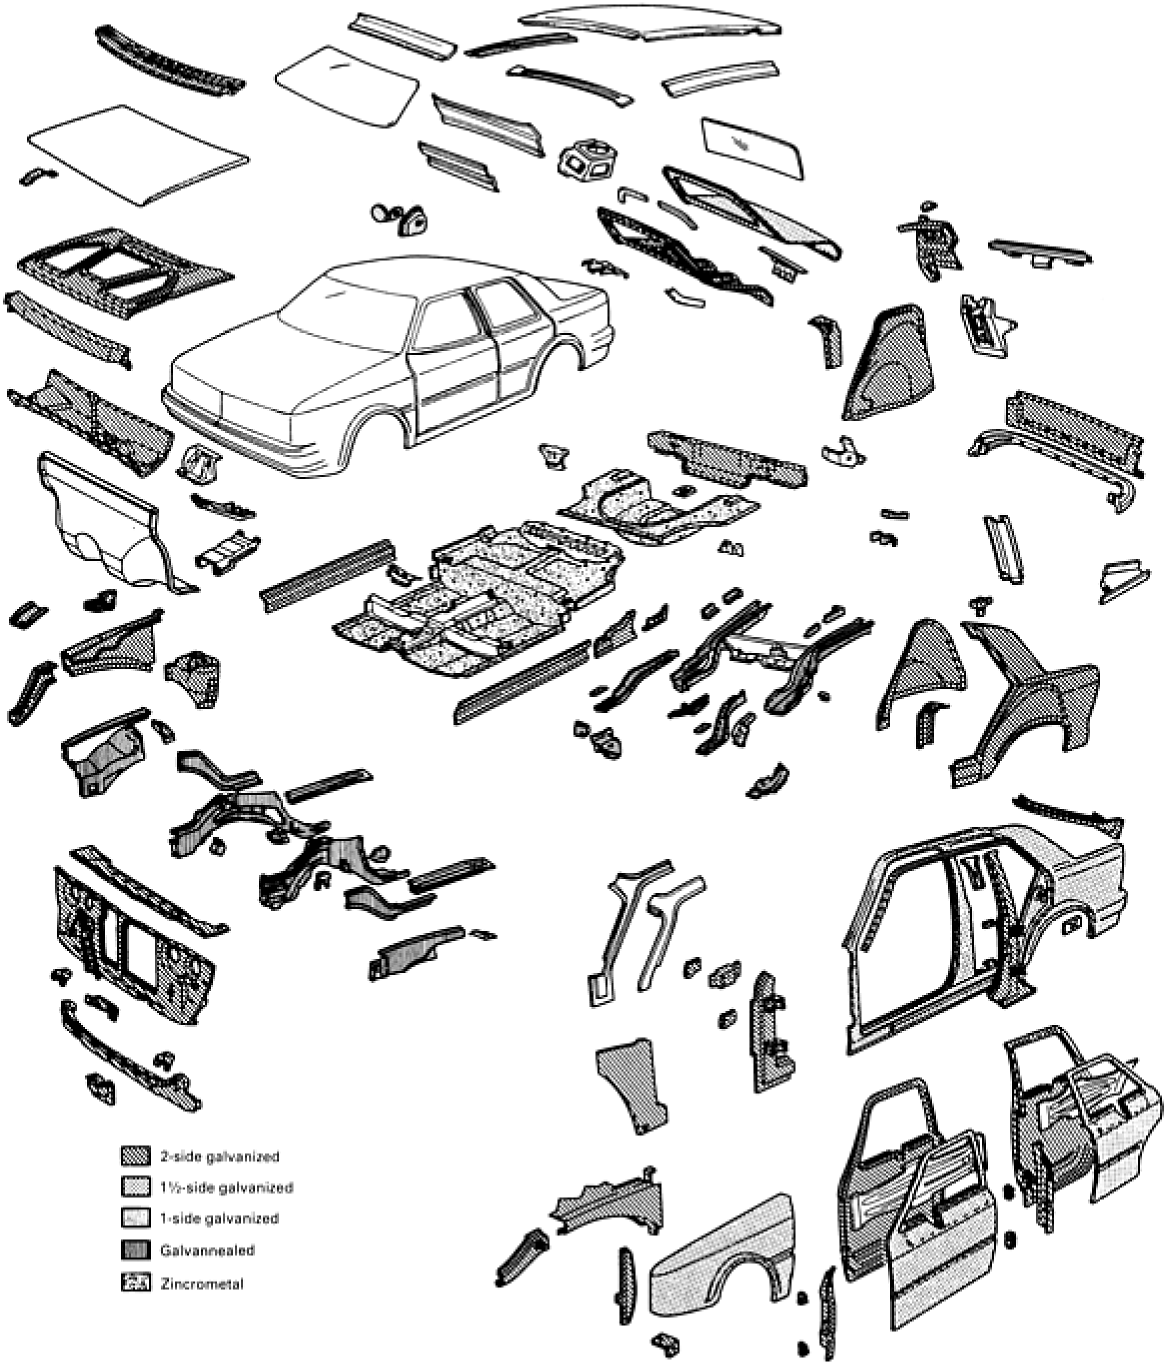

Fig. 6 Use of zinc-coated steels in a 1987 model by one U.S. automaker. Source: Ref 4

One-side galvanized steel is produced by either hot dipping or electrogalvanizing. The zinc-coated surface faces inward in the body panel to prevent inside-out corrosion. One-side galvanized steel is commonly used for hoods, doors, and quarter panels (Ref 4).

One-and-a-half side galvanized steel uses pure zinc on interior body surfaces and a zinc-iron alloy on the outer surface. This enhances cosmetic corrosion resistance on exterior surfaces of body panels in the same types of applications as one-side galvanized steel.

Two-side galvanized steel uses pure zinc coatings on both sides of the steel sheets in such applications as floor pans, wheel houses, and interior and exterior structural surfaces (for example, door inner panels and structural components).

Hot-dip galvanized steel has seen the widest application by automakers. It provides effective corrosion protection and is more economical than steels coated by other processes for a given coating weight (Ref 5).

Hot dip galvanized steel is produced from cold-rolled steel by heat treating or normalizing on the coating line to obtain the desired mechanical properties, followed by hot dipping. The coated strip can then be postannealed to improve formability and is finally tempered to obtain the required flatness and surface texture. Formability and weldability vary with coating thickness and with the number of coating defects (Ref 5). Two-side hot dip galvanized steel is currently being used in most auto body panels by one U.S. automaker. Paintability is being enhanced by blowing a fine zinc powder onto the surface of the steel as it emerges from the molten zinc-bath (Ref 6).

Hot dip galvanizing is also being used to improve the corrosion resistance of various automotive components after fabrication (Ref 7). This type of process is beneficial in combating undervehicle corrosion; suspension parts, other undervehicle components, and (on an experimental basis) even entire floor pans have been galvanized after fabrication. Parts can be readily formed and fabricated without fear of damaging a prefabrication coating (Ref 7).

Another two-side hot dip product, galvannealed steel, uses a zinc-iron alloy coating on both sides of the sheet. It is produced by hot dipping and then annealing or wiping the steel sheet to form the zinc-iron alloy. Galvannealed steel offers better weldability and paintability than hot dip galvanized steel, and accelerated corrosion tests have shown it to possess corrosion resistance equal to or better than that of conventional hot dip galvanized steel (Ref 4). Galvannealed steel is being used in both body and underbody applications. Steelmakers have recently focused their development efforts on improving the formability, mechanical properties, fabricability, and paintability of hot-dip galvanized steels for the automotive industry (Ref 8).

Electrogalvanized steels have had limited application in the automotive industry mainly because of their higher cost relative to hot dip galvanized steels. Production costs are largely related to the amount of electricity required to produce coatings of sufficient thickness. Despite this, at least one U.S. automaker plans to employ a differentially coated, two-side electrodeposited zinc alloy (Zn-15Fe) coated steel for body panels (Ref 4).

Although initial reports based on laboratory salt spray corrosion tests indicated that electrodeposited zinc and zinc alloy coatings offered two to forty times the corrosion resistance of hot dip coatings of equivalent thickness, a comprehensive undervehicle testing program revealed that this is not the case (Ref 9). These tests compared a variety of electrogalvanized zinc and zinc alloy coatings with heavier hot dip zinc and zinc alloy coatings, and they showed that the heavier hot dip coatings were superior in resistance to all forms of corrosion investigated (Table 2). The performance of the hot dip galvanized steels was rated as excellent. The poor performance of the electrogalvanized steels was attributed to the rougher surface of the electro-deposited coatings, which resulted in higher electrochemical corrosion currents. Current work is focusing on characterizing the surface roughness and texture of electrodeposited coatings and on correlating surface characteristics and corrosion resistance in undervehicle tests (Ref 9).

Table 2 Corrosion of unpainted coated steel tests coupons after 2 years of undervehicle exposure

Material	Coating weight per side		Steel thickness		Surface area showing base metal attack, %		Average pit depth			
							Vehicle 1		**Vehicle 2**

The surface roughness of electrogalvanized steels is advantageous for paint adhesion, however, and electrocoated steels also offer better formability and better weldability than hot dip steels (Ref 1). Electrogalvanized surfaces generally contain fewer defects than hot-dip steels, so it is easier to achieve a Class A paint finish on electrocoated steels. For these reasons, use of electrocoated steels (both pure zinc and zinc alloy coatings) in the automotive industry is on the rise; this trend can be expected to continue if research into more efficient electrodeposition processes proves beneficial and if the cost of these materials is lowered.

Zincrometal is also used extensively for outer body panels in automobiles. First introduced in 1972, Zincrometal is a coil-coated product consisting of a mixed-oxide underlayer containing metallic zinc particles and a zinc-rich organic (epoxy) topcoat. It is weldable, formable paintable, and compatible with commonly used adhesives. Zincrometal is used primarily in one-side applications to protect against inside-out corrosion. The corrosion resistance of Zincrometal is not as good as that of hot dip galvanized steels (Ref 4), and its use is expected to decline as more electrogalvanized steels and other types of coatings are employed.

Zinc-alloy coated steels have also been developed. Coatings include zinc-iron (15 to 80% Fe) and zinc-nickel (10 to 14% Ni) alloys. These coatings have been developed for the most part by Japanese steelmakers and are applied by electrodeposition. Zinc-iron coatings offer excellent corrosion resistance and weldability. Zinc-nickel coatings are more corrosion resistant than pure zinc coatings, but problems include brittleness from residual stresses and the fact that the coating is not completely sacrificial, as is a pure zinc coating. This can lead to accelerated corrosion of the steel substrate if the coating is damaged (Ref 10). Multilayer coatings that take advantage of the properties of each layer have been developed in Europe. An example of this is Zincrox, a zinc-chromium-chromium oxide coating (Ref 10): The CrO_x top layer of this coating acts as a barrier to perforation and provides excellent paint adhesion and weldability (Ref 10).

Another relatively new development is zinc alloy coatings is Galfan, a Zn-5Al-mischmetal alloy coating applied by hot dipping. Applications in the United States are limited, but European automakers have used Galfan in such applications as brake servo housings, headlight reflectors and frames, and universal joint shrouds (Ref 11). Galfan is also being considered for oil pans, fuel tanks, and heavily formed body panels. Table 3 compares the undervehicle corrosion resistance of Galfan with that of hot dip galvanized steel. More information on zinc coatings is available in the articles "Corrosion of Zinc," "Electroplated Coatings," and "Hot Dip Coatings" in this Volume.

Table 3 Corrosion of hot-dip galvanized and Galfan coated steel specimens in undervehicle testing

Exposed in Buffalo and Detroit for the entire winter of 1981-1982

Material	Specimen orientation	Coating weight				Change in coating weight, %	Pitting	Surface appearance
		Exposed side		**Protected side**				
		g/m^2	**oz/ft^2**	**g/m^2**	**oz/ft^2**			
Buffalo								
Galfan	Horizontal	216	0.71	223	0.73	3	Slight	Smooth, uniform gray
Galvanized	Horizontal	174	0.57	272	0.89	36	Severe[(a)]	Rough, dirty brown
Detroit								
Galfan	Vertical	216	0.71	238	0.78	9	Slight	Smooth, uniform gray
Galvanized	Vertical	207	0.68	253	0.83	18	Severe[(a)]	Rough, dirty brown

(a) Galvanized samples averaged 53 times as many pits per unit area than Galfan samples.

Other Coated Steels

Aluminum-coated (aluminized) steels containing 8 to 12% Si in the coating are used by automakers for applications involving high-temperature corrosion resistance, such as in exhaust systems, heat shields, and underhood components. The Al-45Zn coated steels are used in similar applications (Ref 1).

Long terne coated (lead-tin alloy, usually 3 to 8% Sn) steels offer corrosion protection in gas tanks, fuel lines, and brake lines and do not contaminate gasoline (Ref 1). Terne is cathodic to the steel substrate and therefore does not offer the sacrificial corrosion protection of galvanized coatings. Terne-coated steels are also sometimes given a thin coating of electrodeposited nickel as an intermediate layer; this material is used in applications similar to those of regular terne (Ref 1).

Organic composite coated steels have been developed mainly by Japanese steelmakers in cooperation with automakers in that country, although development is underway in other countries as well. These coil-coated products generally employ an electroplated zinc alloy base layer and a chemical conversion coating under a thin organic topcoat containing a high percentage of metal powder (Ref 12, 13, 14). The thinnes of the organic topcoat allows for good formability without the risk of damaging the coating.

Figure 7 (Ref 12) compares the corrosion resistance of one of these organic composite coated sheet steels to cold-rolled steel and to Zincrometal. Another of these products uses an organic-silicate composite topcoat only about 1 μm thick and has corrosion resistance and weld-ability superior to that of Zincrometal (Ref 13). A bake-hardenable version of this material has also been developed (Ref 13). Researchers at a third Japanese steel company have developed a bake-hardenable organic composite coated sheet steel with a 0.8- to 1.5-μm thick organic topcoat. The material possesses corrosion resistance, formability, and weldability equivalent to that of Zincrometal-KII, which uses a 7-μm thick top coat (Ref 14). Production of these composite coated materials in increasing in anticipation of increased demand from Japanese automakers.

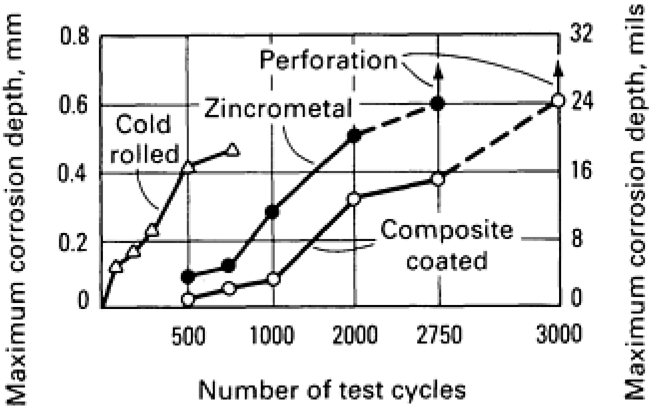

Fig. 7 Corrosion of heavily worked samples of a composite coated steel, Zincrometal, and cold-rolled steel in a laboratory cyclic test. Test consisted of 28-min cycles of dipping in 5% saline solution at 40 °C (100 °F), humidifying at 50 °C (120 °F), and drying at 60 °C (140 °F). Source: Ref 12

A similar material has been developed in the United States. This material has an electrodeposited zinc alloy base coat, a mixed intermediate layer of chromium oxide and zinc dust, and an organic topcoat for barrier protection (Ref 15). Figure 8 is a micrograph showing the cross section of the composite coated steel. In salt spray tests comparing this material to electrodeposited zinc-nickel and Zincrometal, zinc-nickel failed after 216 h, Zincrometal at 480 h, and the composite coating at 960 h (Ref 15). This material was developed to have weldability, formability, and adhesive compatibility similar to that of Zincrometal, and developmental work is continuing.

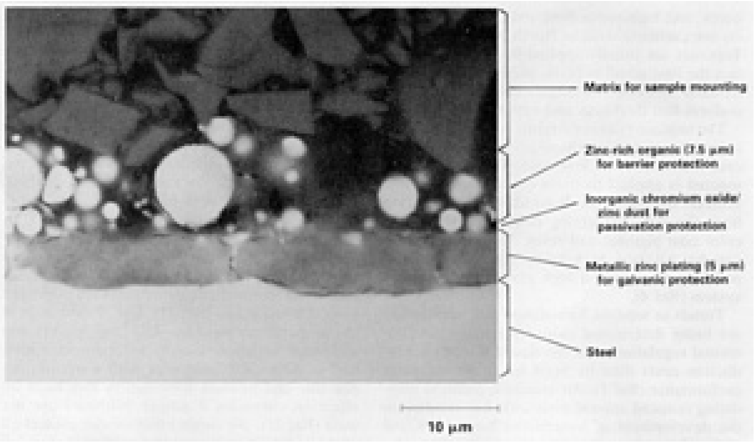

Fig. 8 SEM micrograph of across section through a composite coated sheet steel. Source: Ref 15

Paint Systems

The primary function of automotive part systems is to provide a protective barrier against corrosive substances in the outside environment. This is accomplished through the use of a paint system comprising a conversion coating, one or more coats of primer, and a colored topcoat. A typical system might employ a conversion coating, an electrodeposited primer 30 μm thick, a base color coat 15 μm thick, and a clear topcoat 40 μm thick. Because corrosion usually initiates at coating defects, emphasis is placed on obtaining the most defect-free coating system possible. Detailed information on the types of paint formulations available, the application of paints, and corrosion of painted metals is available in the article "Organic Coatings and Linings" in this Volume, and Table 4 outlines the development in the last 25 years of primer and paint systems at one U.S. automaker.

Table 4 Evolution of primer and paint systems at one U.S. automaker

Primer or paint	Year of introduction	Curing temperature		Minimum thickness mm (mils)
		°C	**°F**	
Primers				
Water-reducible dip primer	1960	165	325	0.015 (0.6)
High-solids spray primer	1981	165	325	0.019 (0.75) interior, 0.03 (1.2) exterior
Cathodic electrodeposited primer	1983	180	350	0.013 (0.5) interior, 0.03 (1.2) exterior
Color coats				
Conventional high-efficiency acrylic enamels	1979	120	250	0.043 (1.7)
Basecoat/clear coat acrylic enamels	1981	120	250	0.02 (0.8) basecoat, 0.03 (1.2) clear coat

Surface Preparation

Metal Cleaning. Surface preparation for painting begins with cleaning of the metal. Cleaning usually involves the use of an alkaline cleaner and one or more water rinses to remove dirt and contaminants--for example, oil left from the stamping operation--that can limit adhesion of the subsequent coatings. More information on chemical cleaning of metals is available in the article "Cleaning for Surface Conversion" in this Volume.

A phosphate conversion coating is then applied to the clean metal by either spraying or immersion. A typical process sequence involves application of the phosphate solution to the metal, a cold water rinse, and a chromic acid rinse to seal the conversion coating and to enhance corrosion resistance. More information on the application and corrosion resistance of phosphate conversion coatings is available in the article "Phosphate Conversion Coatings" in this Volume; chromate conversion coatings are discussed in the article "Chromate Conversion Coatings" in this Volume.

The conversion coating enhances the corrosion resistance of the metal surface, but more importantly, the crystalline nature of the coating provides excellent paint adhesion for subsequent application of primer and topcoats. For this reason, a conversion coating with small, dense crystals and minimal porosity is desirable (Ref 4).

Primers

Primers are applied to body panels to enhance corrosion resistance, to give a better surface appearance to the finished panel, and to provide an adherent surface for subsequent organic coatings. Parts are primed immediately after the conversion coating process. Currently, the most frequently used primer materials are the high-film build epoxy resins, usually with corrosion-inhibiting pigments and a small amount of solvent added to aid in flow during the priming operation (see the article "Organic Coatings and Linings" in this Volume for more information on paint formulations). Most primers are thermosetting compounds that require curing after application. Either single or multiple primer coats can be applied by spraying, dipping, flowing, or the cathodic electrocoat process (Ref 16).

Spray application of primer can be accomplished either manually or automatically, depending on the complexity of the parts being processed. Both electrostatic and airless spraying are employed. The spraying process gives uniform coating thicknesses and flexibility (coating thickness and areas to be covered are easily varied) (Ref 16).

In dip coating, the parts to be primed are immersed in a large tank containing the primer. Care must be taken when dipping parts containing inner panels or other features that could result in the formation of air bubbles, which prevent paint coverage in the area of the bubble. Adequate drainage must be provided to prevent collection of excess primer in crevices and shelf areas of the workpiece. Both of these potential problems can be minimized by good part design (for example, adding vent holes to parts with inner and outer panels, such as hoods).

In flow coating the primer is dispensed through large nozzles; excess primer is then allowed to drip off of the part and is collected for reuse. Flow coating usually gives better coverage of multipiece components than spraying, because the primer is allowed to flow around and through the part.

Electrocoating. The state-of-the-art in primer application is electrodeposition. Cathodic electrodeposition has become the dominant method of primer application for automakers around the world. In 1982, 33.4 million of the approximately 37 million cars and trucks built throughout the world used electrodeposited primers; of these, 25.4 million were coated by the cathodic electrodeposition process (Ref 17).

In the cathodic electrodeposition process, the workpiece is negatively charged and is immersed in a large tank containing the primer, which is positively charged. The primer is electrically attracted to the metal, resulting in a uniform coating thickness, excellent adhesion, a smooth surface, and excellent corrosion resistance. The electrodeposition process lends itself to automation, saves paint, is free from dripping and sagging, and is extremely reliable. Film thicknesses of 13 to 18 μm can easily be deposited, and high-film build primer formulations can allow deposition of thicknesses up to 35 μm (Ref 17).

Topcoats

The colored organic topcoat in automotive applications provides an additional barrier against the outside environment as well as a pleasing appearance. A wide range of topcoat formulations have been used in the automotive industry; nonaqueous acrylic dispersion enamels, high-solids solution enamels, thermoplastic acrylic lacquers, and high-solids basecoat/clear coat enamels are currently used in North America (Ref 1). Topcoats are usually applied by spraying to obtain the best possible finish and high gloss. Electrostatic spraying techniques help to maintain a uniform film thickness and appearance.

The topcoats system currently used by one U.S. automaker uses a urethane-acrylic enamel color coat followed by a clear coat. The clear acrylic topcoat is applied to the wet color coat, and it protects the color coat from ultraviolet radiation from the sun, preventing color changes in the color coat pigment and resin. The clear topcoat can be polished to remove dirt and defects; polishing also gives a high gloss to the topcoat system (Ref 4).

Trends in topcoat formulation and application are being determined more by stricter environmental regulations and the desire to reduce production costs than by need or improved paint performance (Ref 1). Air quality legislation mandating reduced solvent emissions has resulted in the development of waterborne base coats and high-solids paints; automated

cathodic electrode-position of primers and electrostatic spraying of topcoats has increased production efficiency and reduced costs (Ref 1).

Corrosion in Other Automotive Systems

This article thus far has dealt mainly with corrosion and corrosion protection for automotive body materials. This section will discuss other areas of the automobile that are subject to corrosion. Underhood and underbody corrosion affects such vital components as fuel systems, cooling systems, electrical systems, and exhaust systems. Although perhaps not of cosmetic concern, corrosion in these areas can affect the safe operation of the vehicle.

Fuel Systems. As mentioned earlier in this article, fuel tanks and lines are generally fabricated in the United States from long terne (lead-tin) coated steels. Terne-coated steel has good overall corrosion resistance in this application, but is subject to pinhole-type corrosion if water is trapped in the fuel tank (Ref 18). Electrogalvanized steel is also used by some overseas manufacturers, and it has good resistance to pinhole-type corrosion. Over time, however, the inner surfaces of an electrogalvanized fuel tank may form white zinc corrosion products (white rust), with subsequent attack of the base metal (Ref 18). For other components of the fuel system, such as fuel lines, hot dip Zn-5Al-mischmetal (Galfan) coated steel is being employed (Ref 11).

Cooling Systems. Corrosion of automotive cooling systems is accelerated by dissimilar-metal couples, exhaust gas leakage, high operating temperatures, aeration, poor quality water, and coolant flow (Ref 19). A wide variety of materials are used in the typical automotive cooling system. Wrought brass or aluminum is used for radiators and heater cores, stamped steel for various small components and housings, and aluminum for parts such as coolant pumps (Ref 19).

Radiator tubes can be attacked by general corrosion, and brass tubes are subject to dezincification on both internal and external surfaces. Also, because brass tubes are fabricated by soldering, solder flux may cause stress-corrosion cracking (SCC) (Ref 20). A Cu-35Zn-0.3Al-0.2Sn-0.02P alloy has been developed that gives resistance to dezincification equal to that of arsenical brass in laboratory tests, and it has higher resistance to SCC than other brasses tested (Ref 20).

Components such as the coolant pump are subject to cavitation damage from collapsing vapor bubbles in the coolant; excessive coolant flow can also cause impingement damage to radiator tubes. Because of the variety of materials used in the cooling system, galvanic corrosion is of concern when dissimilar-metal parts are placed in electrical contact by the conducting coolant. Both of these problems can be alleviated somewhat by good design practices (Ref 19).

Proper maintenance is also important in minimizing cooling system corrosion, but surveys show that proper maintenance practices and manufacturers' recommendations are often neglected in the United States (Ref 21). Use of antifreeze at the proper concentration--U.S. automakers and antifreeze suppliers usually recommend a mixture of 50 to 70% antifreeze with water--is important, and coolant formulation can have an effect on corrosion if proper inhibitors are not used (Ref 21). No single inhibitor can protect all of the metals in an automotive cooling system, so many coolant formulations use a combination of inhibitors (Ref 19).

Electrical systems are subject to a wide variety of corrosion problems caused by the severity of the automotive environment. Corrosion problems in conventional electrical systems can be minimized at the design stage by sealing components whenever possible. A wide variety of organic and inorganic compounds are used for this purpose, including paints and primers, silicone compounds, varnishes, numerous plastics, and oils and greases (Ref 22).

The use of electronic components in automobiles has increased dramatically in the past decade. These systems were first used for engine control, but they now perform a wide variety of control and monitoring functions (Ref 23). Electronic components are subject to a variety of corrosion problems, including corrosion-induced leakage and shorts on printed circuit boards, metal migration problems, and corrosion in plastic-packaged devices (see the article "Corrosion in the Electronics Industry" in this Volume). Proper design, manufacturing, and quality assurance procedures can help to minimize these types of problems in automotive electronic systems.

Automotive exhaust systems are subject to general and localized external corrosion and to internal corrosion caused by exhaust gas condensates (Ref 24). Exhaust gas temperatures near the exhaust manifold have been measured at up to 870 °C (1600 °F), with corresponding metal temperatures as high as 595 °C (1100 °F) (Ref 24); therefore, exhaust system components are subject to high-temperature oxidizing conditions.

The materials used to combat corrosion in exhaust systems include aluminized steel and type 409 stainless steel. The use of type 409 stainless steel is increasing because of its relatively low cost and good resistance to corrosion and high-temperature oxidation.

The use of catalytic converters, which began in the United States in the 1975 model year, has presented some special problems for automakers. Because of the oxidizing, catalyzed reaction that takes place in the exhaust gas stream in the converter, exhaust gas temperatures and the amount of corrosive substances, such as sulfuric acid, in the exhaust gas stream are increased (Ref 24). The converter itself essentially consists of a noble metal coated ceramic substrate, often housed in a type 409 stainless steel canister. The location of the converter between the exhaust manifold and the exhaust pipe has prompted the use of more corrosion-resistant materials down-stream from the converter.

Other Automotive Systems. A variety of coated steels are used for automotive suspension components, including hot-dip galvanized and galvannealed steels, electrogalvanized steel, aluminized steel, and cathodic electrocoated or epoxy powder coated steels. Some suspension components (for example, rear cross members) and structural components (such as bumper reinforcements and body side rails) are being fabricated from high-strength low-alloy steels to reduce weight, but formability problems with these materials have thus far limited their used to structural-type applications (Ref 25). High-strength steels, although thinner in section than carbon steels, are protected in much the same way by a variety of coating materials. More information on the types of microalloyed steels used, the strength ranges employed, and the automotive applications for such materials is available in Ref 26, 27, 28, 29, 30, 31, and 32.

Clad metals are used in the auto industry for their decorative appearance and corrosion resistance, for example, in automotive trim applications (Ref 33). Figure 9 shows a stainless steel clad aluminum alloy used for trim applications. The aluminum inner surface, being more electrochemically active than steel, acts as a sacrificial anode to prevent corrosion of the adjacent steel body panel. The outer stainless steel surface provides corrosion resistance, abrasion and dent resistance, and a decorative appearance. This material is also used for auto and truck bumpers to reduce weight while maintaining corrosion resistance (see the article "Corrosion of Clad Metals" in this Volume).

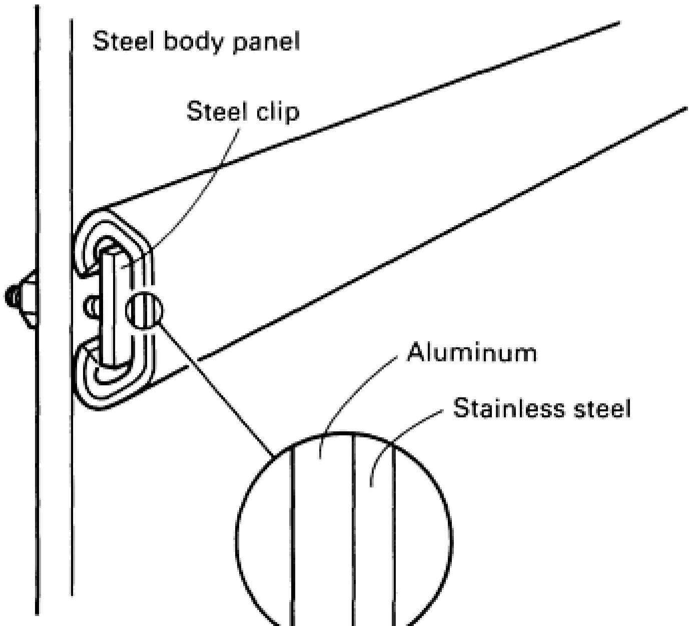

Fig. 9 Stainless steel clad aluminum alloy used in automotive trim applications. The use of steel clips to attach the trim strip prevents galvanic corrosion of the aluminum in contact with the steel body panel.

Design Considerations

As mentioned earlier in this article, design can play an important role in determining the corrosion resistance of an automotive assembly or component. In fact, the configuration of a part or assembly is often the determining factor in the

type and severity of corrosion that occurs in service (Ref 1). Design factors that can influence corrosion resistance are reviewed in Ref 34 and 35, and additional information on this subject is available in the article "Design Details to Minimize Corrosion" in this Volume.

Corrosion Testing

The automotive industry employs many common corrosion test methods; for example, laboratory salt spray and electrochemical tests are often used in the development and evaluation of new materials (see the article "Laboratory Testing" in this Volume). Tests that are specific to the industry also are used, such as proving ground vehicle testing, mobile testing using underbody test racks, and field surveys. Recent emphasis has been on the development of laboratory tests that can closely approximate the results of much longer and more costly proving ground or undervehicle tests. This section will focus on both field and laboratory testing methods that are specific to the automotive industry.

Mobile testing using test racks mounted under or on the vehicle is commonly used to evaluate as-received precoated steels and primed and painted specimens. Of the commonly used test methods, mobile testing probably comes the closest to simulating actual service conditions (Ref 1), but it requires test periods of up to several years. The measurements taken usually include percent surface area of base metal attacked and depth and density of pitting. The test methods used and the results of two of these tests are documented in Ref 36 and 37, and Ref 38 correlates the results of an undervehicle testing program with those obtained from a laboratory test method.

Proving Ground Testing. In this method, prototype or production vehicles are corrosion tested on the proving grounds of the company. Test cycles that produce accelerated attack are used, with test times varying from 10 weeks to 10 months (Ref 1). Proving ground testing can simulated service conditions for some types of corrosion, but other forms, such as perforation corrosion, are more difficult to accelerate.

Field surveys, when properly conducted, offer a direct method of comparing the performance of various types of coatings and other materials. These surveys often involve the destructive inspection of actual vehicles with well-defined service histories in corrosive environments (Ref 1). The results of one recent survey of 5- and 6-year-old vehicles are documented in Ref 39.

Laboratory Tests. Cyclic laboratory tests have been developed in recent years to simulate in a relatively short time the effects of many years of actual operation. One such test uses three environment chambers to subject the test material to extreme climatic conditions, and it uses other equipment, such as a gravel blower, to simulate actual road use as closely as possible (Ref 40). This test is intended to simulate 6 years of actual service over a 14-week test period. Other such tests have been developed, but correlation to actual service tests has not been good. More development is required to make these tests reliable indicators of the corrosion resistance of materials for automotive use.

Corrosion in the Aircraft Industry

Introduction

CORROSION CONTROL is of the utmost concern in the aircraft industry because of its potential impact on human safety and on extremely expensive aircraft. In the military, winning the war on corrosion is essential to military preparedness and national security. Military aircraft are very expensive; some, such as the B-1B strategic bomber, cost over $200 million each. To achieve high levels of payload and performance in military aircraft, materials are chosen more for their mechanical properties than for their inherent corrosion resistance. They depend on coatings and routine maintenance to preserve their integrity. Military aircraft are flown throughout the world and are therefore exposed to the most severe corrosive environments on earth. The contracting agency imposes numerous specifications on suppliers to control on military aircraft.

An excellent text on corrosion is MIL-HDBK-729, *Corrosion and Corrosion Prevention--Metals.* The military services sponsor a Tri-Service Corrosion Conference every 2 or 3 years to provide a forum for corrosion control and experiences with various weapon systems. In addition, the Corrosion Information Analyses Center serves the Department of Defense (DOD) as part of the Metals and Ceramics Information Center. Each of the military branches have corrosion control centers and laboratories serving them.

Corrosion control of commercial aircraft is also of paramount importance for similar reasons. Flight safety is essential to the airline industry. Again, commercial airlines are exposed to highly corrosive environments all over the world.

Commercial aircraft represent investments of up to $100 million per unit for some of the widebody aircraft. Fullscale inspections to determine structural integrity often exceed $2.5 million. Even more severe economic consequences could result from lawsuits or the loss of a manufacturer's reputation in the event of a corrosion-related mishap. Consequently, although only a short reference to the need for corrosion control to ensure airworthiness and safety is found in Federal Aviation Administration regulations (Federal Airworthiness Regulation 25.609), commercial aircraft manufacturers take as much care in this area as the military.

Commercial airlines, which are responsible for corrosion control once the aircraft is delivered, are provided with detailed documents from the aircraft manufacturers, such as corrosion control handbooks and customer service documents, to ensure proper servicing and inspection. Nevertheless, in spite of extensive corrosion control efforts, problems are experienced. This article will present typical examples of corrosion problems in the aircraft industry to provide additional insight into the causes and corrective actions.

Corrosion of Airframes

Michael L. Bauccio, The Boeing Company

The potential for corrosion of aircraft structures is a major consideration in the design of the aircraft. Corrosion can be related to various types of material deterioration. This is because the corrosion process can be defined as the degradation of a material or materials by a reaction with the environment. Usually, the reaction is electrochemical, and the material or materials are metallic (Ref 1).

Corrosion phenomena often occur on the surfaces of aircraft structures (Ref 2). As shown in Fig. 1, the physical effects of corrosion can be categorized as follows:

- Local pitting or crevice corrosion (one-dimensional local irregularity)
- General surface roughening due to uniform, filiform, or fretting corrosion (two-dimensional discontinuity)
- Intergranular and transgranular cracking, which is observed in stress-corrosion cracking (SCC) (two-dimensional discontinuity)
- Degradative transformation of materials that occurs on a larger scale, which is referred to in Fig. 1 as a three-dimensional bulk reduction of material. This is observed in galvanic and exfoliation corrosion

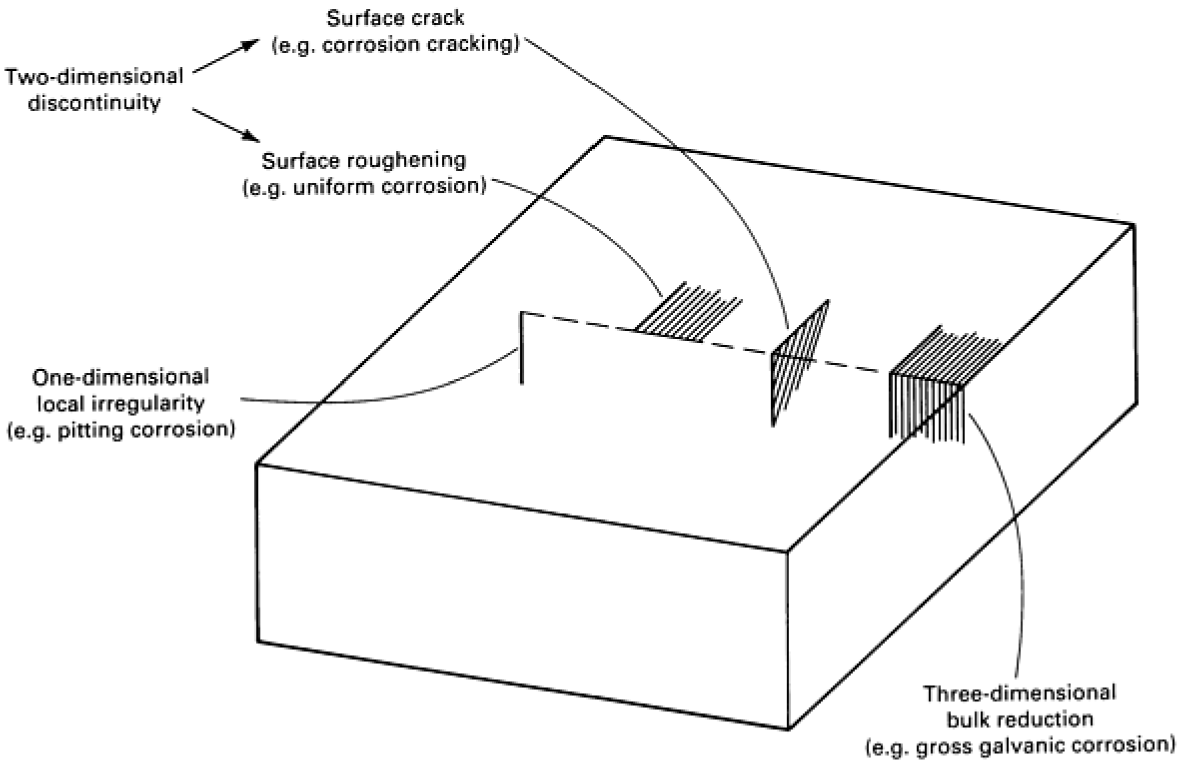

Fig. 1 Schematic showing the physical effects of corrosion on metallic aircraft materials. See text for details.

The detrimental effects of aircraft corrosion are not due to corrosion alone, but to the interaction of corrosion with fatigue, wear (including erosion and fretting), erosion, and stress resulting in premature fracture. The most significant aspects concerning aircraft corrosion that will presented in this section are that:

- Airframe corrosion problems vary in severity
- Cosmetic corrosion, which simply mars the appearance of airframe surfaces, can develop into a widespread form of material deterioration
- Catastrophic mechanical failures can develop from corrosion that is permitted to spread and cause a significant reduction in structural strength
- Environmental and mechanical factors combine to produce the types of aircraft corrosion that usually lead to catastrophic in-flight failures. The tropical marine environment is one of the most severe that modern aircraft are exposed to. An example of wing strut deterioration that was produced by this highly corrosive environment is shown in Fig. 2. The corroded wing strut was fabricated from aluminum alloy 2024-T351 (QQ-A-200/3) extruded bar
- Some of the most critical types of aircraft corrosion than can result in fracture of components or airframe members are SCC, corrosion fatigue, and hydrogen embrittlement (Ref 3). Selected examples of these aircraft fracture failures are illustrated in Fig. 3, 4, 5, 6, 7, 8

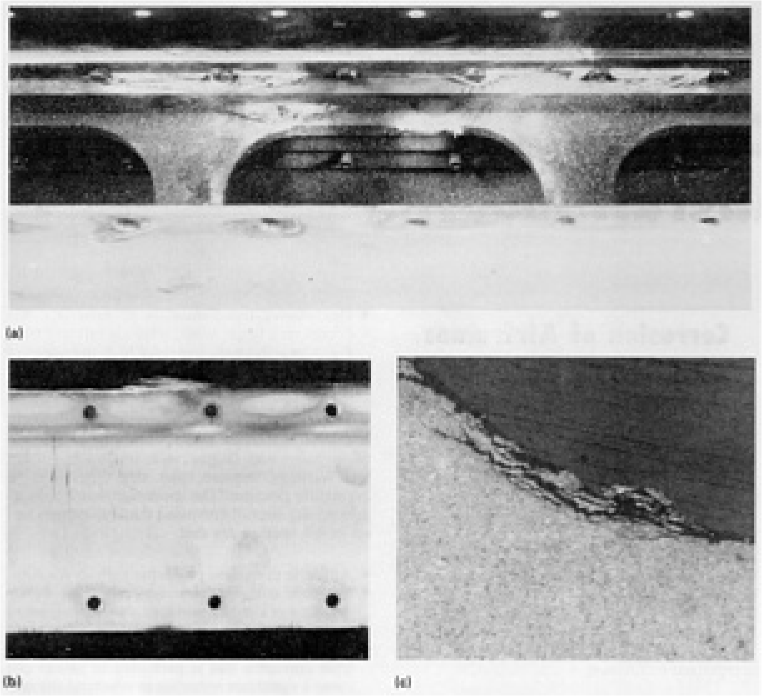

Fig. 2 Corroded aluminum alloy 2024-T351 wing strut (a) with attached leading edge. (b) Close-up of corrosion on the wing strut with the leading edge skin removed. (c) Corrosion on the wing strut. 25×

New Material and Process Solutions From Old Corrosion Problems

Of the numerous cases of aircraft corrosion that the author has reviewed, many have appeared in various forms in the past 30 years. However, those corrosion problems that have challenged aircraft materials and process engineers have usually led to positive developments, which have resulted in greater control of aircraft corrosion.

Some very recent corrosion cases have also led to significant new corrosion-preventive measures for aircraft applications. For example, in 1985, a C-5B military cargo aircraft was grounded so that about 11,000 aluminum nuts could be replaced by the specified cadmium-plated steel nuts (Ref 6). An additional 40,000 aluminum nuts are to be replaced on four other C-5B aircraft. The aluminum nuts, which were installed despite the engineering drawing requirement for cadmium-plated steel nuts, were discovered during an inspection by the manufacturer. The positive side of this story is that the C-5B manufacturer has developed and patented a magnesium chromate ($MgCrO_4$) sealant that can be used for corrosion prevention in structures that have mating surfaces of aluminum and steel (Ref 6). Aluminum nuts can be used for reduced weight, and steel is used for greater strength on the C-5B, which contains about 4,000,000 structural fasteners.

Other corrosion-related incidents that have been investigated by aerospace materials engineers have been reported many years ago and are still being studied today so that improved solutions can be obtained. One such case is concerned with the hydrogen embrittlement and SCC of high-strength steel aircraft components. A monograph on hydrogen stress cracking and hydrogen embrittlement of low-alloy aircraft steel was published in 1956 (Ref 7). The failure of 4140 steel nacelle eyebolts was reported in 1971 (Ref 7). This bolt failure was due to a baking time that was too short to provide the steel bolts with proper hydrogen embrittlement relief, which would have enhanced the mechanical strength of these fasteners. In-service failures due to hydrogen embrittlement and SCC have also occurred in chromium-plated landing gears and in cadmium-plated steel fasteners (Ref 7).

Approximately 14 years after the above case histories were published, a report confirmed that baking time is the only significant variable in determining the final hydrogen concentration in cadmium-plated high-strength steels (Ref 8). The importance of baking time for hydrogen embrittlement relief was recognized by several aerospace companies in the early 1960s. The process specifications that had been written by these companies were revised to require 23 h of baking at 190 °C (375 °F), instead of the 3-h baking time that was found in military specifications.

One approach that can be used to prevent hydrogen embrittlement is to avoid the processing of steel components in plating or pickling baths. Another technique is to apply iron vapor deposited (IVD) aluminum coatings. These coatings have recently been reported as an effective method for protection against hydrogen-induced embrittlement, as well as SCC, and can withstand service temperatures up to 495 °C (925 °F) (Ref 9).

Ion vapor deposited coatings must meet the requirements of military specification MIL-C-83488 (Ref 10). Aluminum IVD coatings have been applied to the following aircraft structures with favorable results in terms of improved corrosion resistance (Ref 9):

- Steel and titanium fasteners installed in aluminum aircraft structures
- A fatigue-critical aluminum alloy wing skin
- A DC-10 aft engine hanger
- A high-strength steel landing gear

Exfoliation corrosion, which has a long history in connection with airframe deterioration, was observed many years ago where cadmium-plated fasteners were installed in high-strength aluminum alloys. Exfoliation corrosion occurs in metallic materials that have a directionally oriented grain structure. Riveted aircraft structures have a high vulnerability to exfoliation corrosion because the rivet holes provide an unobstructed pathway for corrosive electrolytes to reach metallic airframe materials, especially aluminum, which is the material selected for many aircraft parts (Ref 11).

Exfoliation corrosion initiates between bimetallic couples and progresses along grain boundaries as an intergranular crack. This intergranular crack widens into a crack plane and enlarges into multiple crack planes. Corrosive oxides press outward against the adjacent metal, thus producing a pattern of delamination.

An illustration of this type of failure, originating at a fastener hole, is shown in Fig. 9. The best alternative available for preventing exfoliation corrosion is to select a corrosion-resistant alloy and heat treatment. Chromate-inhibited elastomeric sealants can also be applied to protect airframe fasteners against corrosion (Ref 12). These fasteners must be wet-installed with the chromated sealant material in order to obtain the highest degree of corrosion protection.

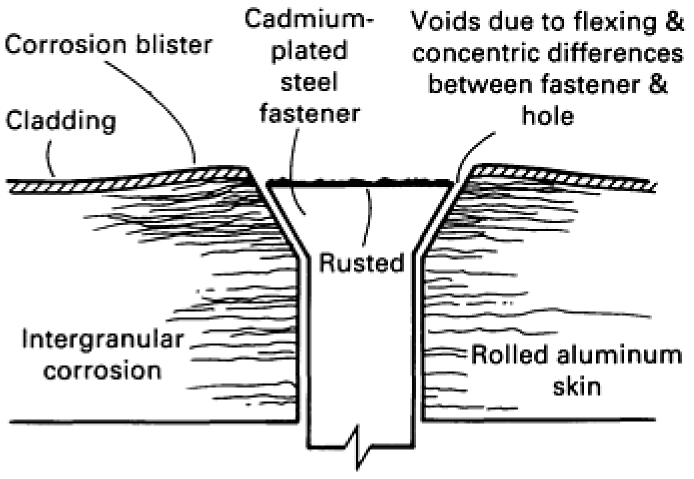

Fig. 9 Schematic of exfoliation in an aluminum aircraft panel. Source: Ref 12

Another example of exfoliation corrosion is illustrated in Fig. 10. The failed airframe structure shown was removed from an aircraft that operated primarily in a marine environment. The structure is a tail plane attachment fitting made of an aluminum alloy (2024-T4) that meets federal specification QQ-A-250/4. The arrow in Fig. 10(a) points to the corrosion. This corrosion problem was primarily caused by inadequate sealing of the bolt hole during installation of the cadmium-plated steel bolt; this allowed seawater to attack the aluminum alloy.

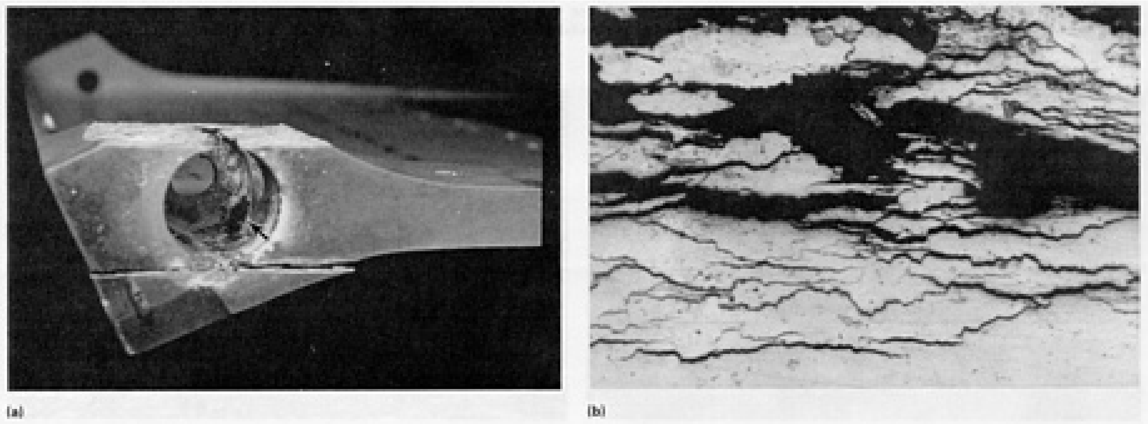

Fig. 10 Example of exfoliation corrosion. (a) Failed aluminum alloy 2024-T4 tail plane fitting. Arrow points to corrosion that was produced by direct contact between a cadmium-plated steel bolt and the aluminum fitting. (b) Exfoliation in the tail plane fitting. 55×

Additional Corrosion Cases

There are many more examples of how the scope of aircraft structural corrosion spans long periods of time between the origination of a specific problem and the development of an improved material or process, or both, for mitigating the corrosion problem. Aircraft corrosion cases are often solved within much shorter periods than those problems described above. However, the same immediate, or quick-fix, solutions will be reevaluated and modified over the years by aircraft manufacturers for:

- Increased reductions in the gross weight and cost of aircraft systems
- Materials and processes that will meet the increasingly stringent environmental and occupational safety regulations of state, local, and federal government agencies

Corrosion-preventive technology also requires continued study and modification. This is for the purpose of ensuring that corrosion-resistant materials and corrosion control techniques are effectively applied to the diverse variety of airframe components. For example, thick organic coatings usually cannot be used on mating parts that have close tolerances. These parts are often protected by inorganic coatings that are relatively thin (about 1 to 35 μm, or 0.04 to 1.4 mils), such as the wear-resistant chromium platings or anodized coatings on aluminum structures, the black oxide or phosphatized coatings on steel parts, and the dichromate and anodic (Dow 17) treatments used on magnesium alloy structures.

Some materials problems, such as microbial deterioration of integral wing fuel tanks, have plagued the aircraft industry since the beginning of the jet age (Ref 13). Such ongoing problems illustrate the need for continuing research and development of new materials and protection systems for corrosion control.

Aircraft materials that are resistant to corrosive deterioration should be selected during the design phase. This objective can be facilitated by following the general techniques and design rules for corrosion prevention and control presented in Table 1. When selecting aluminum alloys for SCC resistance, aircraft designers should consult Table 2. The process of selecting corrosion-resistant steels for aircraft systems can be facilitated by reference to Table 3, which provides the resistance to general corrosion and SCC of several classes of steel.

Table 1 General techniques and design considerations for minimizing corrosion

Item	Suggestions
Eliminate areas where trapped moisture is held in contact with metal	Avoid such features at the design stage by careful attention to design or structure details.
	Provide properly located drain holes. Minimum hole size should be 3.2 mm ($\frac{1}{8}$ in.) to prevent plugging.
Choose nonabsorbent, nonwicking materials	Determine water absorption qualities of materials to be used.
	Use epoxy and vinyl tapes and coatings, wax, or latex for protective barriers.
	Avoid, if possible, use of wood, paper, cardboard, open cell foams, and sponge rubbers.
Protect all faying surfaces	Use proper sealing materials (tapes, films, sealing compounds) on all faying surfaces. Use primers.
	Lengthen continuous liquid path to prevent formation of an electrolytic cell.
Use compatible metals	For magnesium-aluminum couples, 5000- and 6000-series aluminum alloys are the most compatible.
	For magnesium-steel couples, use tin or cadmium plated steel.
	For bimetallic couples use metals or alloys in the same group per MIL-STD-889, or as close as possible. Use tapes or primers on faying surfaces to prevent metallic or electrical contact.
Select proper finishing systems	Choose chemical treatments, paints, plating on basis of service requirements.
	Service test system before setting up production run.
	Use past experience in similar applications as guide to choice.

Aircraft Corrosion-Related Failures

The best way for professional engineers to grasp the extent of aircraft-related corrosion problems and solutions is to become familiar with many of the corrosion-related cases that have been documented. The following discussions in this section provide a comprehensive overview of many aircraft corrosion problems that have been described in the technical literature. For most of these corrosion cases, the successfully applied corrosion-preventive treatments, which were developed to avert future corrosion problems, are described. These airframe corrosion cases were selected because they can be of great assistance to design and corrosion engineers in alleviating possible airframe corrosion problems in the future.

Galvanic Corrosion. When dissimilar and unprotected structural materials with different electrochemical potentials are assembled and exposed to a corrosive environment, galvanic corrosion (dissimilar-metal corrosion) occurs. The more active (less noble) material of the galvanic couple becomes the anode and therefore undergoes dissolution and corrosion (Ref 16).

One of the best ways of identifying galvanic corrosion is to examine the severity of corrosion damage at the junction between the dissimilar metals. Galvanic corrosion usually predominates at the point of contact between the two materials. Several examples of galvanic corrosion, which have been described in the literature on aircraft structural corrosion, are provided below (Ref 16).

Cadmium-Plated Steel Fasteners. These fasteners were in contact with a 7075-T6 aluminum skin (Fig. 11). Severe corrosion damage occurred on the aluminum skin around the periphery of the fastener heads.

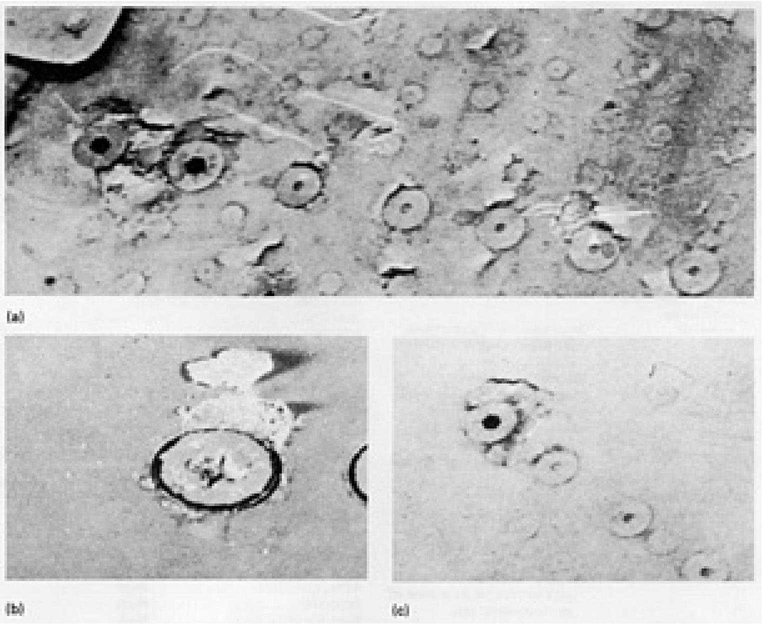

Fig. 11 Galvanic corrosion of aluminum alloy 7075-T6 aircraft skin around cadmium-plated steel fasteners. (a) General view. (b) and (c) Close-ups of individual fasteners. Source: Ref 16

Aluminum Alloy Skin. Galvanic corrosion in this aluminum alloy skin was caused by an electrically conductive adhesive compound. The corrosion occurred along the edges of an anti-icing boot that was bonded to the wing leading edges.

7075-T6 Kingpin Lug. Galvanic corrosion on this lug was caused by direct contact between this part and steel bushings. The bushings were used to protect the lug mounting holes from mechanical damage. This failure could have been prevented by the proper application (and continual inspection) of a protective coating on the aluminum alloy, such as a hard anodized coating.

Cast Magnesium Flap Control Lever Arm. The lever arm was manufactured from a magnesium casting alloy. A zinc-chromate primer and an epoxy topcoat had been applied to the lever arm structure for corrosion protection. Galvanic corrosion occurred in the sockets of the levers, where steel balls were located. The movement of these steel balls in the socket caused mechanical deterioration of the protective coating. The highly anodic magnesium, therefore, was in direct contact with the steel balls, causing the galvanic corrosion. Galvanic corrosion also was found around a press-fitted aluminum bushing in the lever arm. Current aircraft design requirements (in most cases) prohibit the use of magnesium castings, especially for components that will be in contact with moving parts. Application of the sealants and organic coating systems according to the guidelines in Ref 17 might have averted this corrosion problem.

In summary, galvanic corrosion can be prevented by avoiding dissimilar-metal contact. Whenever joints between dissimilar metals must be made, metals should be selected whose galvanic potentials in seawater (or salt water) are closest in order to minimize corrosion rates. Generally, potential differences of less than 0.25 V will be satisfactory without protection.

Where possible, a high ratio of anodic-to-cathodic area is desirable in designing to prevent galvanic corrosion. Therefore, the use of a fastener that is slightly cathodic to the base metal is often desirable. Furthermore, materials that naturally form protective oxides should be selected. These materials, including stainless steel and aluminum, often do not become active in galvanic cells. Other design approaches include eliminating the corrosive environment and providing an organic or inorganic barrier coating between the dissimilar metals. This involves the installation of steel fasteners into aluminum with a wet chromate primer or the use of an anodized aluminum structure in contact with a steel part. More information on galvanic corrosion is available in the section "Galvanic Corrosion" of the article "General Corrosion" in this Volume.

Uniform corrosion, or general corrosion, is a type of material deterioration that develops evenly over large areas of aircraft structures. Uniform corrosion is produced by many closely spaced anodic and cathodic sites on unprotected or partially protected surfaces (Ref 16).

Because large areas are affected in uniform corrosion, this type of damage can be recognized and remedied relatively easily as compared to other types of corrosion. The recognition of uniform corrosion is also enhanced by the unique characteristics of the corrosion products that are produced by various engineering materials (Ref 16). Typical problems and corrosion-preventive treatments pertaining to uniform corrosion that have been described in the technical literature include the following (Ref 16).

Adjuster and Eye of a Steel Track Rod. Rust occurred on these components after the cadmium plating on the threads became damaged during assembly or maintenance. This problem may have been prevented by the application of a protective coating, such as an organic paint primer, over the cadmium plating.

Aluminum Alloy Stringer. General corrosion was found on the surface of this component Deterioration occurred in areas where the chromate pretreatment and primer coating had flaked off of the stringer.

Magnesium Alloy Skin of a Helicopter. This case is similar to the previous example. The uniform corrosion on this component also developed from the failure of the chromate conversion coating that had been applied to the magnesium skin.

Aluminum-Honeycomb Structure on a Fighter Aircraft. Water penetrated the inner surface of the aluminum skin through small holes. A foam rubber filler between the skin and the honeycomb core possibly contributed to the uniform corrosion that was produced in this case.

Structural Steel Fasteners. The surfaces of the nuts had the greatest degree of corrosion damage. In some areas, the corrosion penetrated very close to the bolt surface.

In summary, uniform corrosion can be prevented by selecting proper protective coatings, by ensuring proper surface preparation and coating application, and by touching up deteriorated surfaces as soon as possible. Sacrificial coatings, such as alcladding on aluminum, spread corrosion over large areas and thus enable aluminum sheet metal products to retain their mechanical strength. Information on the mechanism of uniform corrosion can be obtained in the article "General Corrosion" in this Volume.

Pitting corrosion produces deterioration of airframe structures by forming cavities and oxidation products in small (localized) areas of the affected components. The severity of pitting corrosion is determined by:

- The susceptibility of the airframe material to pitting attack. Unprotected, active metals, such as magnesium, are most susceptible.
- The severity of the environments often cause pitting in airframe structures (Ref 16). This is because the chloride (Cl^-) ions in seawater promote the destruction of protective oxide films on the metallic materials that are used in airframes

Damage that as produced by pitting corrosion in airframe components has been documented for many cases that provide good examples of this type of aircraft degradation. Several of these incidents will be discussed for the following airframe structures.

Helicopter Structural Cleat (Ref 16). This magnesium alloy casting had been given the corrosion-preventive treatments of chromating and sealing (Ref 16). Pitting deterioration was enhanced by local damage in the protective coating. The alleged cause of this damage was impact from tools that were used for installing fasteners.

Stringer End Cap (Ref 16). This airframe structure was also made of magnesium, and it was chromated and primed. Moisture exposure contributed to the severe degree of pitting corrosion that occurred in this part.

Spring Wire. This hard-drawn high-carbon steel structure was observed to have been damaged by fatigue cracking in an area that had deteriorated by pitting corrosion (Fig. 12). Cyclic loading that is exerted on aircraft components during

takeoff and landing promotes this type of fatigue fracturing in airframes that deteriorate because of corrosion. This particular case can also be classified as an example of corrosion fatigue (see the discussion "Corrosion Fatigue" in this section).

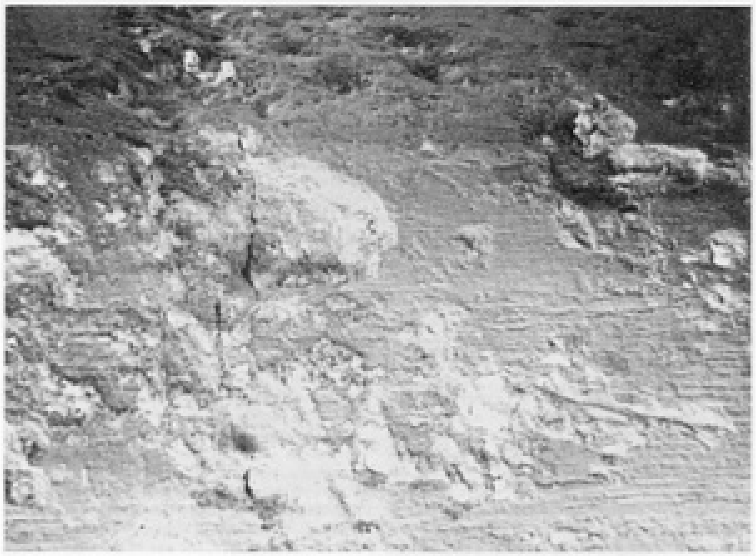

Fig. 12 Fatigue cracking of a hard-drawn carbon steel spring. Courtesy of Aeronautical Research Laboratories, Australia

Hydraulic Cylinders. An inner landing gear door actuator cylinder that failed on an F-101 aircraft is shown in Fig. 13. This part was fabricated from aluminum alloy 2024-T4. A close-up view of this failed component is shown is Fig. 13(b), which clearly indicates surface pitting corrosion. This pitting contributed to the fracture that is illustrated in Fig. 13(c). From Fig. 13(c), it was determined that exfoliation corrosion was involved in the initiation of the failure process.

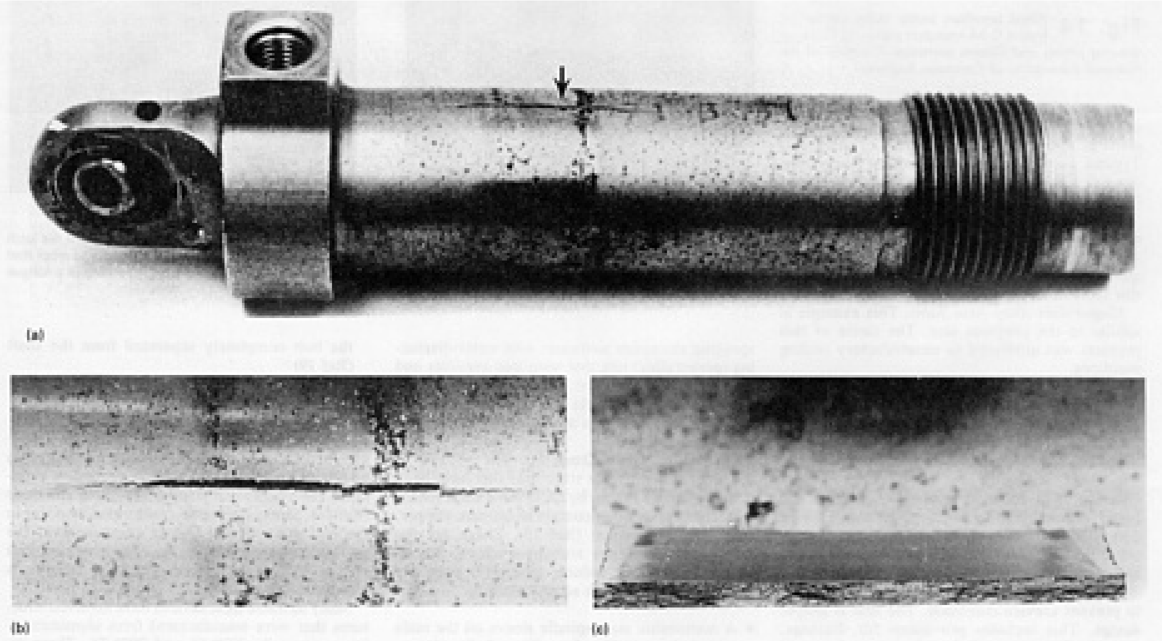

Fig. 13 Aluminum alloy 2024-T4 landing gear door actuator (a) that failed because of pitting corrosion. Arrow points to crack. (b) Close-up of crack in landing gear door actuator in (a). (c) SEM of the fracture surface of the door actuator. Source: Ref 5

Cargo Aircraft Brake Lining Carriers. Damage produced by pitting corrosion was observed in the brake lining carrier structure on the C-5A cargo aircraft (Ref 18). This brake lining carrier serves as a heat sink (for energy dissipation) during aircraft landings. Figure 14(a) shows the entire part, and Fig. 14(b) provides a magnified view of the component. Pitting deterioration was responsible for inducing filiform corrosion in the brake lining carrier, which consisted of the purest available beryllium material--approximately 99% Be. After this case was detected, a chromate conversion coating that conforms to MIL-C-5541C was applied to this part to minimize the probability of similar corrosion problems in the future. However, a 1985, the corrosion-prone beryllium was replaced by a carbon (graphite) composite material in the manufacturing of the later-model C-5B cargo aircraft (Ref 18). The carbon-composite material was selected by the C-5H manufacturer because it provided reduced weight (the new brake lining carriers saved up to 180 kg, or 400 lb, per aircraft in comparison to the beryllium structures), lower cost, and longer life, with better corrosion resistance and durability than the beryllium component.

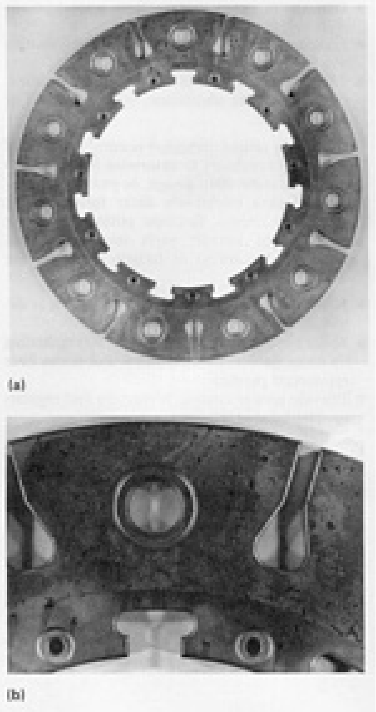

Fig. 14 Pitted beryllium brake lining carrier (a) from a C-5A transport plane. (b) Close-up showing pitting and filiform corrosion. Courtesy of the National Association of Corrosion Engineers

Tip Tank Latch Knob (Ref 16). Pitting corrosion and fatigue occurred on this AISI 4340 steel structure. Several failures were recorded for this component. Fractures occurred below the head of the latch knob at the curved surfaces (radii). The fracture surfaces are shown in Fig. 15 at magnifications of 2.5 and 5×. Pitting corrosion was determined to be the primary cause of the fatigue failures that occurred with this latch knob. A change of the 4340 steel material to 17-4PH stainless steel was recommended as the long-term solution to this problem. This is because 17-4PH steel has significantly greater corrosion resistance than 4340 steel. However, periodic inspections also were required for increased protection against pitting, crevice, and edge corrosion in a marine environment.

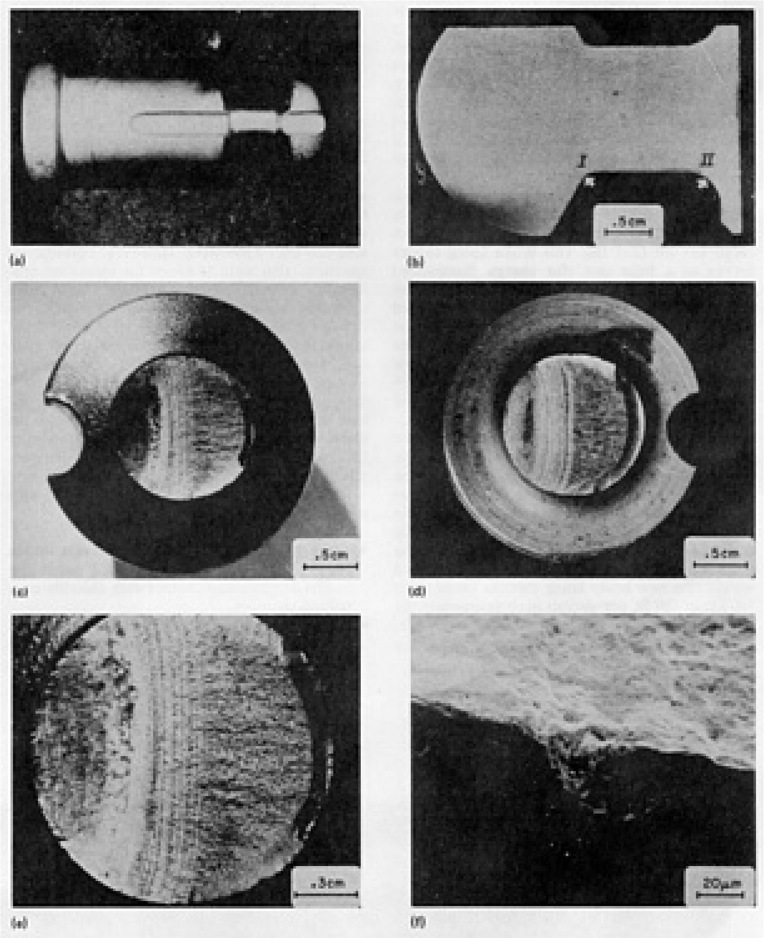

Fig. 15 Pitting corrosion and fatigue failure of a 4340 steel tip tank latch knob. (a) General view of the latch knob. (b) Cross section through the knob showing crack initiation sites. (c) Fracture surface of crack that initiated at site I. (d) Fracture surface of crack that initiated at site II. (e) Fracture surface at site I. (f) Pitting at a fatigue crack initiation site. Source: Ref 16

Wing Flap Hinge Bearings (Ref 16). These structures consisted of chromium-plated type 440C martensitic stainless steel. The inner diameter of the failed bearings had numerous corrosion pits. Fracture occurred intergranularly, either by SCC or by hydrogen embrittlement. An electroless nickel plating was used as a substitute for the chromium plating in order to alleviate this pitting corrosion problem.

In summary, pitting corrosion in aircraft systems is often caused by:

- Local breakdown in a protective film on an alloy. This is usually accelerated when the material comes into contact with chloride-containing solutions.
- Alloys susceptible to pitting because of localized impurities in the alloys. These impurities are either anodic or cathodic to the base metal
- Deposits of heavy metal (from water) on aircraft surfaces
- Localized damage (holidays) in applied protective coatings
- The accumulation of deposits, (dirt, dust, grease) on bare aluminum, stainless steel, or steel surfaces

Whenever pitting corrosion occurs, a review of its causes is necessary to determine if a change in material (or materials), design, or protective coatings will most effectively deter future pitting corrosion problems. Because pitting can cause perforation of aircraft parts (especially thin, sheetmetal structures) or fatigue failures, care must be taken to:

- Neutralize pitting corrosion whenever it is detected
- Make repairs and provide local strengthening by using doublers (small patches of boron fiber reinforced plastic)
- Provide proper coating protection and regularly scheduled maintenance inspection

More information on pitting corrosion is available in the section "Pitting" of the article "Localized Corrosion" in this Volume.

Crevice corrosion occurs on aircraft structures when a corrosive fluid, such as salt spray, enters crevices that are located in individual parts or in between different components of a structural assembly. An anodic region usually develops at the bottom of the crevice, producing corrosive attack on the structure. Differences in the concentrations of dissolved salts or dissolved oxygen in the corrosive fluid will produce concentration cells and thus promote the development of anodic sites in structural airframe crevices (Ref 16). Typical cases of crevice corrosion have been observed in the following aircraft components (Ref 16).

Magnesium Panel. Crevice corrosion perforated this structure, which was in a dismantled joint area from a transport aircraft structure. Inadequate sealing was determined to be the cause of this corrosion problem.

Magnesium Alloy Skin Joint. This example is similar to the previous one. The cause of this problem was attributed to unsatisfactory sealing practices.

Point of Contact Between a Magnesium Alloy Floor Panel and Aluminum Alloy Frames and Angle Plates. Both galvanic corrosion and crevice corrosion occurred in this case. Both of these forms of corrosion could have been prevented or minimized by a better protective coating, a more effective fluid removal (drainage) system, and better utilization of sealants (Ref 16). Crevice corrosion also occurs in many alloy systems other than magnesium, including stainless steels and aluminum alloys.

In summary, two methods are commonly used to prevent crevice corrosion. The first is proper design. This includes provisions for drainage, sealants that are applied to faying surfaces, or beads of sealant that cover crevices formed by mating surfaces. The second method consists of spraying aluminum airframes with water-displacing (penetrating) oils that seep into crevices and prevent water ingestion. The section "Crevice Corrosion" of the article "Localized Corrosion" in this Volume contains more information on this form of attack.

Stress-Corrosion Cracking. The majority of the aluminum airframe structures that have been documented as failing by SCC have been manufactured of alloys that contain aluminum, copper, zinc, and magnesium (Ref 19). These are the 2000- and 7000-series aluminum alloys. Stress-corrosion cracking failures have also been observed in high-strength steels, such as:

- A martensitic steel spindle sleeve on the main rotor hub assembly of a military helicopter
- Large (38-mm, 1.5-in., diam) high-strength steel bolts. When these parts failed, the head of the bolt completely separated from the shaft (Ref 19)
- A 300M steel landing gear drag strut on a military helicopter (Ref 20)

Stress-corrosion cracking is difficult to recognize in aluminum forgings because there is often no visual indication of surface corrosion products. The cracks can also be very long and deep (Ref 16). Stress-corrosion cracks usually occur in the end grain of the forged component at the parting plane of the forging. The cracking that occurs in airframe stress-corrosion failures is usually intergranular.

Many airframe SCC failures have involved structures that were manufactured from aluminum alloys, especially 7079-T6 and 7075-T6. These include the following airframe components that were fabricated from aluminum and that have been observed to fail by SCC (Ref 16) (the specific aluminum alloy is provided in parenthesis):

- A main landing gear locking cylinder (7079-T6)
- A main landing gear H-link structure (7079-T6). This damaged component is illustrated in Fig. 16. The

stress corrosion was induced by the precipitation of magnesium aluminide (Mg_2Al_3, which caused the grain boundaries in the aluminum forging to deteriorate anodically

- The front and rear spars of a vertical fin (7079-T6). As shown in Fig. 17, many of the cracks in this failure propagated from fastener holes. These spars has received corrosion-preventive surface treatment. However, some of this protection was inadvertently removed during the installation of bolts. Bare metal, therefore, was exposed to a high-humidity environment and sustained high tensile stresses that were produced by the installation of fasteners into these structure. This problem was remedied by the use of 7075-T73 aluminum forgings for the front and rear spars. The latter material provides greater resistance to SCC than 7079-T6
- The bearing housing of a vertical stabilizer beam (7079-T6)
- A main landing gear bogie, which has the appearance of a beam or strut-type structure (7075-T6)
- The hydraulic cylinders that serve as actuators for a main landing gear door (7075-T6). Views of the fracture surface, including the appearance of intergranular fracture, are shown in Fig. 18. This problem could have been alleviated by the application of a better corrosion-protective treatment in order to minimize the degree of pitting corrosion that occurred during the storage of these cylinders. The use of the more SCC-resistant aluminum alloy 7075-T73 also would have helped to prevent this failure
- The fork and strut components of a nose landing gear (7075-T6)
- A fuselage frame structure, in which SCC occurred in between fastener holes (7075-T6)
- A nose landing gear strut (7075-T6)

Stress-corrosion cracking has also been observed in an aircraft aluminum-copper main landing gear forging and in four main landing gear retraction cylinders that were made of 4340 steel (Ref 16). Several views of this main landing gear forging failure are shown in Fig. 19. Deep corrosion pits were observed in the area of stress-corrosion crack initiation (Fig. 19c and d). This main landing gear forging was manufactured from an alloy that contains aluminum, copper, silicon, and manganese. This alloy is similar to aluminum alloy 2017. Aircraft structures that are fabricated from the 2017-T4 and 2017-T451 alloys can fail by SCC when sustained tensile stresses are exerted in the transverse direction relative to the grain structure.

A representative example of SCC in an aircraft tubing structure is shown in Fig. 20. This part was fabricated from AM350 precipitation-hardened stainless steel. An intergranular type of cracking can be seen in the photomicrograph in Fig. 20(b). Fracture was intergranular (Fig. 20c).

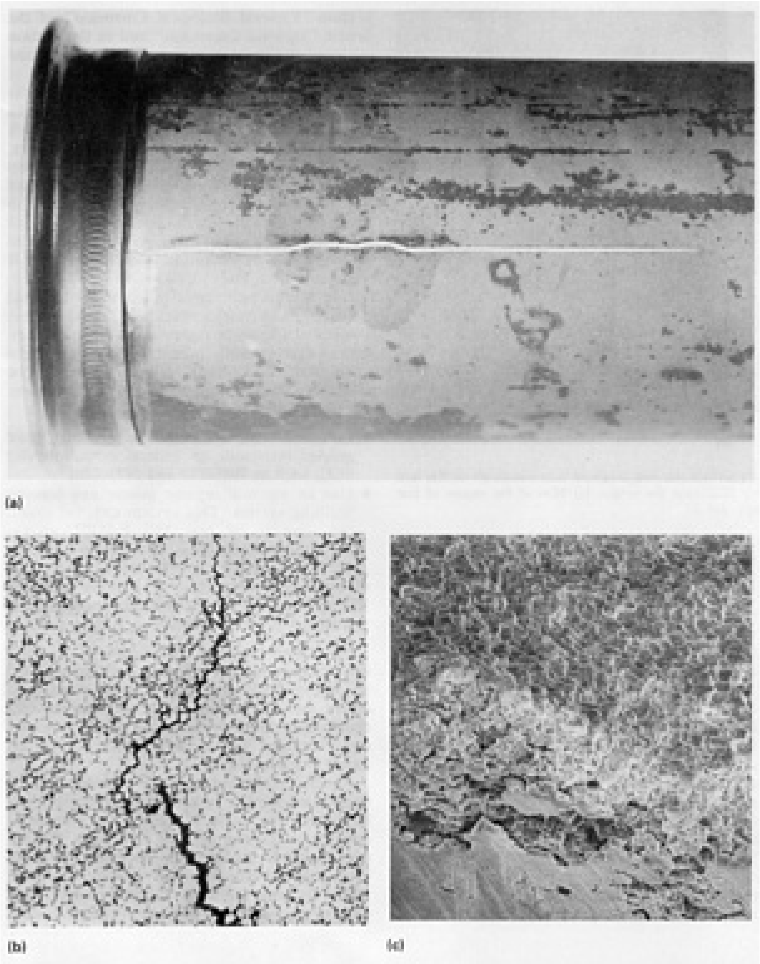

Fig. 20 Intergranular SCC in an aircraft pipe structure fabricated from AM-350 precipitation-hardened stainless steel. (a) Overall view of pipe. (b) Micrograph showing intergranular nature of cracking. (c) SEM of crack shown in (b). 400×

Good examples of SCC in airframe fasteners have been presented in the literature. Most of these fractured parts were H-11 steel bolts manufactured according to AMS 6487. The usual corrosion-protective treatment for these bolts was either:

- A coating of fluoborate cadmium that complies with NAS 672 (for fasteners that have minimum tensile strengths of 1517 MPa, or 220 ksi)
- A vacuum-deposited cadmium finish, as specified by MIL-C-8837 (for fasteners that have minimum tensile strengths of 1793 MPa, or 260 ksi)

As shown in Fig. 21, the initiation of SCC in a failed aircraft alloy steel bolt occurs at a surface corrosion pit. Propagation of this corrosion-induced crack gradually continues until the bolt fractures, because the stress-corrosion crack significantly reduces the amount of mechanical stress the bolt can sustain.

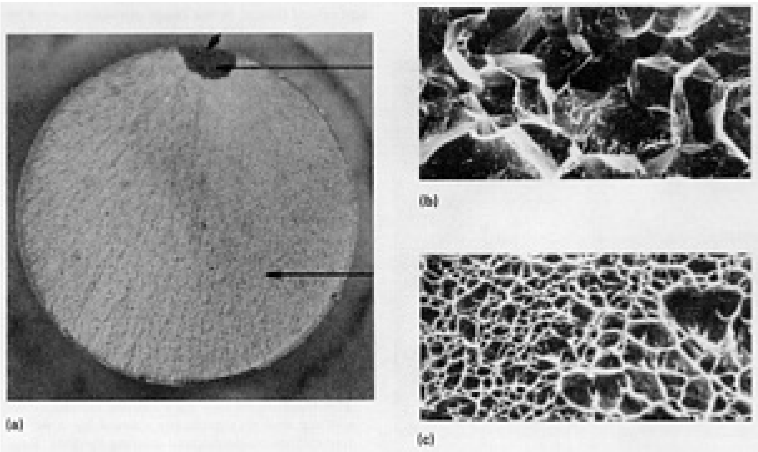

Fig. 21 SCC of an alloy steel aircraft bolt. (a) Fracture surface showing origin at a corrosion pit on the bolt surface. (b) SEM showing brittle, intergranular SCC near the origin. (c) SEM of the region of fast fracture showing ductile nature of fracture in this area. Source: Ref 21

Two SCC case histories involving H-11 alloy steel fasteners have resulted in beneficial airframe design improvements. These incidents, and the design solutions, are described below.

In the first case history, cadmium-plated H-11 fasteners became pitted and eventually failed by SCC on a widebody transport (cargo) aircraft. These fasteners were installed in the engine-to-pylon attachment structures. The cadmium-plated steel fasteners had been installed into a titanium airframe component. This coupling of dissimilar airframe materials produced galvanic corrosion, severe pitting, and the eventual failure of these fasteners by SCC (Ref 21).

As a result of this incident, all of the fasteners that were considered to be critical to the engine-to-pylon attachments were replaced by cold-worked and aged A286 stainless steel and cold-worked and aged Inconel alloy 718. Generally, neither cadmium- nor silver-plated parts should be used in contact with titanium under compressive loading. This condition causes the cadmium or silver to migrate into the intergranular structure of the titanium and induce cracking. This migration of cadmium or silver into the intergranular structure of titanium is commonly referred to as poisoning. Although suitable for installation into steel structures, cadmium- and silver-plated parts are to be avoided in titanium assemblies that will be subjected to high compressive loads, heat, or both.

In the second case history, SCC failures of 1517 MPa (220 ksi) H-11 fasteners occurred in the wing attachment area on several general-purpose aircraft. Alloy steel fasteners installed in this wing attachment structure also fractured. These alloy steel fasteners had maximum tensile strengths of 1103 and 1240 MPa (160 and 180 ksi). The design solution to this problem was to have all of the noncorrosion-resistant steel fasteners, including the alloy steel ones, replaced by 1240 MPa (180 ksi) and 1517 MPa (220 ksi) Inconel 718 fasteners (Ref 21).

There are a few important guidelines that can be followed in order to minimize the probability of fastener failure due to SCC or other types of corrosive deterioration (Ref 22). First, fasteners should not produce adverse effects on the structures that they are joining. These fasteners also should not be installed into certain materials that would make these fasteners susceptible to corrosion. Second, fasteners should be selected that are slightly cathodic to the parts they will join. This is especially advisable in aggressive environmental conditions, such as in tropical-marine areas. Materials that are susceptible to hydrogen embrittlement, such as high-strength steels, generally should not be used for fastening applications in aircraft structures. Finally, critical joints should not be connected with fastening materials that are susceptible to corrosive deterioration in the environment in which the actual aircraft system will be operating.

Aircraft service safety and airworthiness can be significantly improved by selecting airframe materials that are resistant to SCC and brittle fracture (Ref 23). Aircraft design engineers can minimize airframe failures due to SCC by ensuring that:

- Materials that are selected for aircraft applications have low rates of SCC (Ref 23). The T6-tempered 2000-series aluminum alloys (except for 2024 aluminum) should be avoided. The 7000-series aluminum

alloys should be in the T-73 or T-76 tempers. Similarly, stress-corrosion-resistant tempers of steel alloys should be used

- Cracks in selected airframe materials are detected prior to a significant reduction in the static strength of the airframe part (Ref 23)
- Tensile and residual stresses, which may become significant during fabrication and assembly, are minimized. This can be done by selecting stress-relieved tempers for specific alloys (Ref 24) and by minimizing assembly stresses by shimming, avoiding interference fits, and shot peening
- Compressive stresses are properly applied on machined surfaces by shot peening
- Organic coatings are used, whenever possible (Ref 24)
- Inorganic corrosion-protective methods are used, such as cladding on aluminum or electro-plating on steel, whenever possible (Ref 24)

More information on the mechanism of SCC is available in the section "Stress-Corrosion Cracking" in the article "Environmentally Induced Cracking" in this Volume.

Intergranular Corrosion. A severe case of intergranular corrosion was described in the beginning of this section (see Fig. 9 and 10). This discussion will provide some additional corrosion problems and solutions involving intergranular corrosion and the more damaging form of intergranular corrosion--exfoliation. The purpose of this discussion is to provide a more detailed explanation of how these forms of corrosion are interrelated.

In intergranular corrosion and in exfoliation corrosion, the grain boundaries of the corroded metal become anodic. The bulk material in between the grain boundaries is not affected and therefore is cathodic. Corrosion products and, occasionally, cracking are produced on the surface of materials that corrode intergranularly. This form of corrosion sometimes penetrates underneath the metal surface, making it difficult to detect the damage without the aid of a microscope (Ref 16). Intergranular corrosion can occur either alone, in conjunction with pitting corrosion, or with exfoliation corrosion.

When intergranular corrosion occurs along grain boundaries that are parallel to the plane of the material, such as in a flat plate, the corrosion proceeds in the short-transverse direction along these elongated grain boundaries. The combination of the corrosion and the entrapped corrosion products causes the plate to delaminate.

When intergranular corrosion occurs, a network of fine surface cracks can develop. This fine cracking pattern has been observed in an aircraft hydraulic valve made of a forged aluminum alloy that deteriorated by intergranular corrosion (Ref 16).

An example of exfoliation corrosion of an aluminum alloy stabilizer bracket from a light aircraft is shown in Fig. 22. This deterioration started as intergranular corrosion but gradually became more severe and propagated as exfoliation corrosion. The horizontal surface of the stabilizer bracket had been exposed to atmospheric moisture and contaminants, which collected at the interface between the bracket and a nylon bushing. No corrosion was found on bracket surfaces that were protected by a chemical conversion coating. This problem could have been prevented by effective sealing of the bracket-to-bushing interface, along with regular inspections (Ref 16). Some typical, documented examples of intergranular corrosion and exfoliation corrosion have also occurred on the following structures.

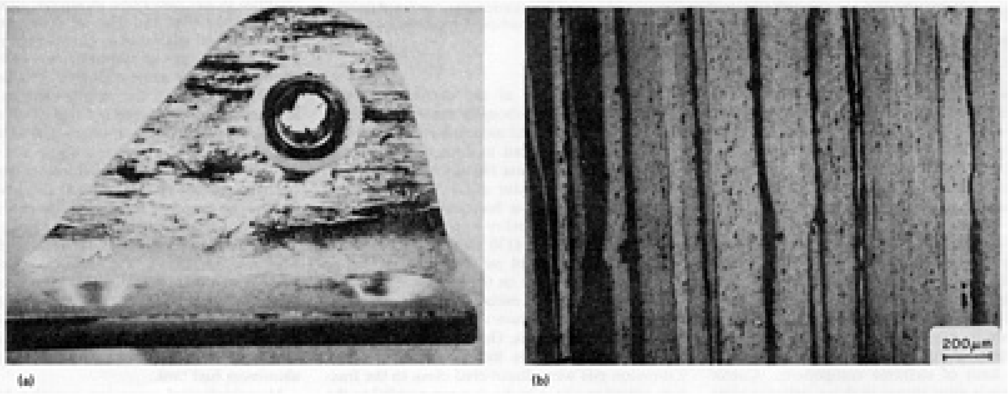

Fig. 22 Exfoliation corrosion of an aluminum alloy stabilizer bracket. (a) Heavy surface corrosion on the stabilizer bracket. (b) Cross section through the bracket showing corroded surface grains and corrosion at grain boundaries of elongated grains. Source: Ref 16

Wing Box Lower Panel of a Fighter Aircraft (Ref 16). This panel was made of aluminum alloy 7075-T6. Most of the corrosion occurred around fastener holes. Extensive intergranular cracking was observed. The report on this case also indicated that pitting occurred in the bores and countersinks of the fastener holes. Filiform corrosion was also detected in the fastener hole areas. This problem was solved by applying a conversion coating to the fastener hole bores and countersinks. Next, the fasteners were wet assembled using a strontium chromate primer and an acrylic topcoat. Another part of the solution in this case was the development of a new aluminum alloy, 7475-T761 (Ref 16). This material has a high level of resistance to exfoliation corrosion and therefore has been considered by aircraft designers as a favorable replacement for the 7075-T6 alloy.

Main Rotor Blade of a Helicopter (Fig. 23). Intergranular and exfoliation corrosion predominated in the area between the leading edge spar and the surface skin of the blade. Extensive corrosion accumulated at the leading edge, causing the skin of the blade to lift off of the spar. The leading edge spar was manufactured from aluminum alloy 2024. During a metallurgical examination, copper aluminide was found in the grain boundaries of this material. It was therefore determined that the 2024 aluminum structure was improperly heat treated. More information on this form of attack is available in the section "Intergranular Corrosion" of the article "Metallurgically Influenced Corrosion" in this Volume.

Filiform Corrosion. One of the more insidious types of electrochemical degradation in aircraft structures is filiform corrosion. This form of corrosion usually occurs beneath the cladding of clad aluminum alloys, under organic coatings applied to airframe surfaces, and at fastener holes (Ref 1, 16). Filiform corrosion has been described as a type of anodic undermining, with reference to its occurrence on metallic structures that are protected by organic primers and topcoats (Ref 1).

Filiform corrosion usually begins as a shallow corrosion pit, which continues its attack on the base metal by spreading laterally along the surface of the structure. This appears as an irregular pattern of thin filaments of corrosion products on the affected metallic material. A schematic illustration of filiform corrosion is presented in Fig. 24.

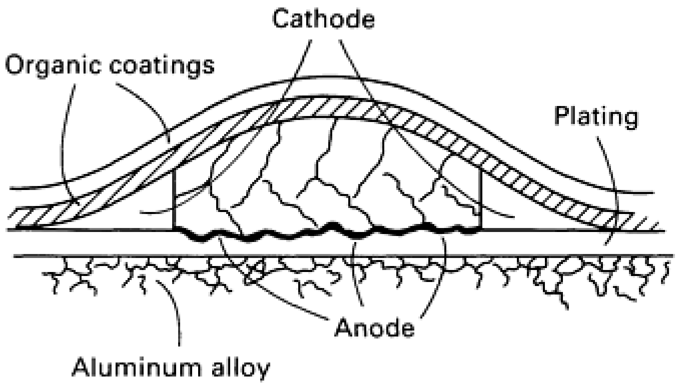

Fig. 24 Schematic of the development of filiform corrosion on an aluminum alloy. Source: Ref 25

One theory that is applicable to aircraft systems proposes the following series of events that promote filiform corrosion on coated metallic airframe parts (Ref 25):

- In-flight, minor relative motion (vibration) produces very thin discontinuities, which also have been called hair cracks, in the airframe paint coating. Salts that primarily consist of sodium and calcium are present in the areas where these small cracks originate
- These salts (inside the hair cracks) absorb moisture from the atmosphere by osmosis. High humidity accelerates the propagation of filiform corrosion (Ref 16). Chlorine also can activate this type of corrosion (Ref 25)
- Moisture absorption at the airframe structure produces an aqueous electrolyte, which causes anodic and cathodic reactions to take place
- The anodic reaction produces pitting that does not penetrate very deeply into the aluminum airframe material
- Aluminum hydroxide ($Al(OH)_3$) is precipitated because of the formation of hydroxyl (OH^-) groups
- The head and body of the corrosive filament develop and separate from the areas where the original cracks were formed
- The corrosive filamentary head continues to deposit corrosion products because water is replenished in the head by osmosis

Because filiform corrosion propagates on structural areas that are either clad or coated with organic paint, this type of material deterioration can spread extensively before it is detected by aircraft maintenance personnel. In typical cases, filiform corrosion develops around fastener holes on airframe sheet structures. Paint blistering around the rivet holes is a characteristic feature of this type of corrosion. Some of the materials that are known to have been affected by filiform corrosion are magnesium, aluminum, steel, and chromium-plated nickel. Documented case histories of filiform corrosion of various components include the following.

Fuselage Skins. On a Boeing 707 aircraft operated by a major commercial airline, filiform corrosion occurred on fuselage skins along rows of fasteners (Ref 26). Paint blistering is produced on airframe aluminum sheetmetal structures when this form of attack occurs (Ref 26).

Areas Around Steel Fasteners. Filiform corrosion was observed in the areas around steel fasteners, which originally were affected by intergranular corrosion. The corroding fasteners were installed in the lower wing skins of the Boeing 707. Figure 25(a) illustrates this deterioration prior to paint removal, while Fig. 25(b) shows the filiform corrosion damage after the paint coating was stripped from the airframe surface.

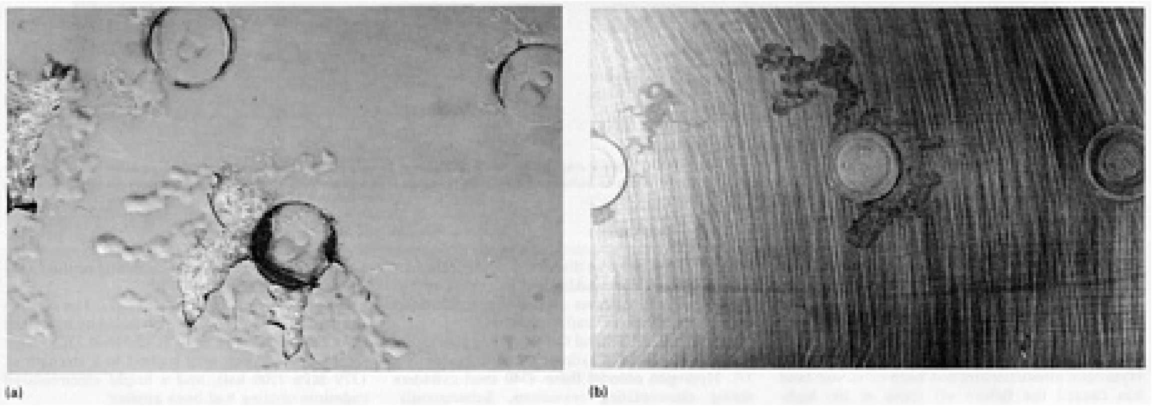

Fig. 25 Filiform corrosion of an aluminum aircraft skin around steel fasteners. (a) Before paint removal showing paint cracking and blistering. (b) After paint removal. Courtesy of Qantas Airways and the Society for the Advancement of Material and Process Engineering

Lower Wing Skin. When a Boeing 747 aircraft was first placed into service, filiform corrosion was detected on the lower wing skins of one of these aircraft (Ref 26). This corrosion developed from intergranular corrosion around titanium fasteners that were inserted into the airframe structure.

Pylon Tank. Filiform corrosion caused the perforation of one area of an aluminum alloy 6061-T6 pylon tank (Fig. 26). Pitting and intergranular corrosion were also detected on the pylon tank during the investigation of this problem (Fig. 26c). The aircraft that operated with this tank had been flying in the hot and humid Mediterranean environment. The proper application and maintenance of epoxy or polyurethane paint finishes would have minimized the amount of deterioration on this structure.

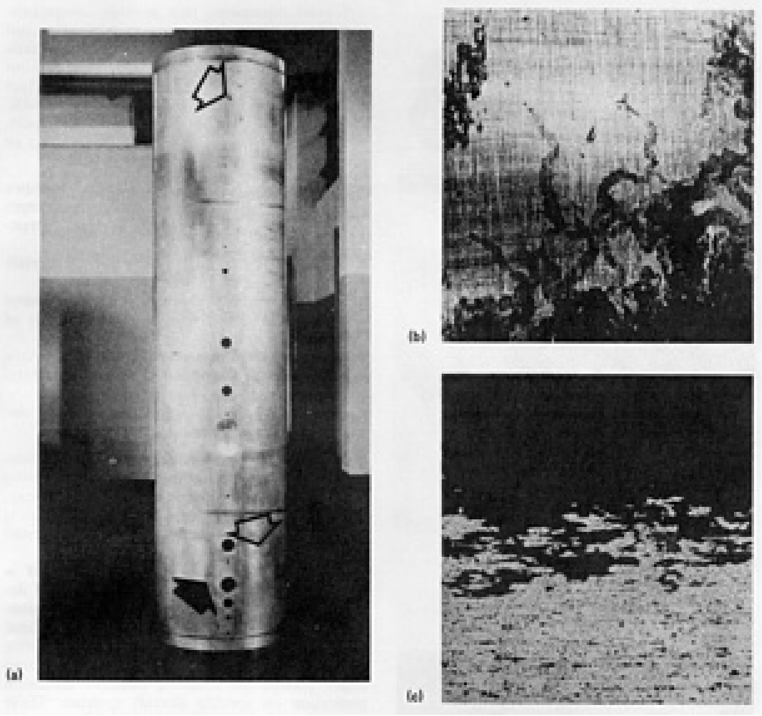

Fig. 26 Filiform corrosion of a fighter aircraft pylon tank. (a) Overall view of the tank showing uniform corrosion (open arrows) and penetration (solid arrows). (b) Indications of filiform corrosion. (c) Pitting and intergranular corrosion. Source: Ref 16

Other Components. A structural engineer for a commercial airline reported that filiform corrosion was detected on horizontal and vertical stabilizers, trailing edge flaps, and an aluminum metal sprayed surface on fiberglass wing-body fairing panels (Ref 26).

For the areas on the Boeing 707 that were affected by filiform corrosion, a corrosion-inhibiting compound called LPS-3 was found to be a successful treatment for the prevention and control of corrosive (filiform) growth. This compound is a greasy hydrocarbon-base preservative that minimizes oxidation by displacing water away from the head of the corrosive filament (Ref 26).

The following sequential treatment has been determined to be effective in alleviating filiform corrosion of airframes:

- Glass bead blasting to remove observable corrosion products
- Chemical conversion coatings
- Boeing Material Specification (BMS) 10-79 strontium chromate epoxy primer
- BMS 10-60II flexible polyurethane enamel

The commercial airline engineer that reported the above airframe treatment for filiform corrosion stated that this treatment provides 5 years of service life with only minor maintenance (Ref 26).

A polysulfide-calcium-strontium rubber primer covered with polyurethane paint, which has been used for corrosion protection on military aircraft, has also been found to be effective in deterring filiform corrosion (Ref 26). In one case, for example, filiform corrosion was observed on some aluminum alloy 2024 aircraft ailerons and flaps (Ref 16). This largely superficial corrosion initiated at the surfaces around fastener holes. The recommended solution was to replace the nitro-alkyd resin paint coating with a finishing system that consisted of an epoxy primer and a polyurethane topcoating. The section "Filiform Corrosion" of the article "Localized Corrosion" in this Volume provides more information on filiform corrosion.

Fretting corrosion occurs on airframe structural surfaces that move against each other in an environment that is conducive to corrosion. Often, the relative movement is barely discernible, but results in significant deterioration. This type of corrosion is very significant in operational aircraft systems because airframes are subject to high vibration levels and because airframe components must also endure various types of mechanical stress other than vibration, resulting in small relative movement between parts (Ref 27).

Some of the airframe parts that have been documented as being susceptible to fretting corrosion are (Ref 27):

- Hinge point bearings on ailerons, elevators, rudders, and flap structures
- Control pulley bearings
- Universal joint bearings
- Propeller and propeller control bearings, housings, and shafts
- Instrument bearings
- Spline connections
- Pin joints
- Clamps
- Riveted lap joints

Fretting actually appears as a combination of wear and corrosive deterioration. Fretting corrosion occurs in the presence of oxygen, which oxidizes the small wear particles that form in structural contact areas. These small particles develop because of the oscillatory motion that exists in contacting metallic materials. The hard oxides then become trapped in the point of contact and further promote intense wear on the two rubbing surfaces (Ref 28).

Concerning the development of aluminum helicopter rotor blades, it has been noted that fretting produces a significant reduction in the fatigue strength of the root retention area of the blade (Ref 28). With little or no fretting, the maximum allowable alternating stress, at 10^7 cycles, is about 21 MPa (3000 psi). Fretting causes the maximum allowable stress to

drop to between 8 and 10 MPa (1200 and 1500 psi) in joints where there will be high stress concentrations (Ref 28). Representative descriptions of documented cases of fretting corrosion in aircraft structures include the following.

Flying Control Hinge Pins. Fretting deterioration on these cylindrical structures appeared as broad bands of accumulated corrosion products. Severe (deep) pitting corrosion was also observed in this case (Ref 16). This damage possibly occured as a result of both wear (due to large and small amplitude displacements) and fretting corrosion (resulting from oxidation).

Propeller Shaft Ball Bearings. Fretting corrosion was observed in the inner and outer races of these propeller aircraft bearings. The bearings were manufactured from 51100 bearing steel, and they were heat treated to produced a fine tempered martensite (hardness 63 HRC). The locations on the outer bearing race at which fretting corrosion occurred appeared to be slightly brighter than the unaffected regions of the structure. The fretted areas were also damage by pitting corrosion (Ref 16).

Lower Boom of the Wing Forward Spar. This structure was fabricated from an aluminum alloy 2014 forging (Ref 23). A fatigue crack started at the edge of a bolt hole in this bomber aircraft component. This crack extended to only 0.5% of the total cross-sectional area of this part. The initiation of this fatigue crack, which eventually caused the in-flight failure of the aircraft, was attributed to fretting (Ref 23).

Engine Fuel Tanks. Failures in these components occurred because of fretting that caused poorly soldered lap joints to separate (Ref 29). Mechanically locked joints were the recommended solution for alleviation of this problem. The redesign of these fuel tanks also included use of a thicker terne (lead-tin) plate on tank inner surfaces (Ref 29).

One of the most widely used techniques for averting fretting corrosion is to apply a continuous film of lubrication between the contacting surfaces (Ref 28). A second method consists of increasing the load (pressure) at the point of surface contact. This will reduce the amount of slip (relative, oscillatory motion) at the contact point.

Yet another method involves selecting materials with a high resistance to fretting corrosion. Metallic combinations that have high, medium, and low resistances to fretting corrosion are presented in Table 4. There results are from a study on fretting wear and corrosion that was conducted by the Massachusetts Institute of Technology. Fretting tests were performed under dry conditions both in air and in a vacuum. In this investigation, low fretting corrosion resistance was attributed to the high hardness of metal oxides that were formed when certain pairs of metals were moved against each other. For example, the low resistance to fretting corrosion of the aluminum-to-aluminum combination was probably a result of the high hardness of aluminum oxide, which is formed during fretting and has a Moh's hardness of 9 (the maximum Moh's hardness value is 10) (Ref 28). Preloading assembled joints and the use of sealants can reduce this problem in aluminum-to-aluminum joints. Anodizing of mating parts is also effective because a continuous, hard aluminum oxide is produced on the mating surfaces.

Table 4 Resistance to fretting corrosion of various material couples under dry conditions

Couple	Resistance to fretting
Steel on steel	Low
Nickel on steel	Low
Aluminum on steel	Low
Antimony plate on steel	Low
Tin on steel	Low
Aluminum on aluminum	Low
Zinc-plated steel on aluminum	Low
Iron-plated steel on aluminum	Low
Cadmium on steel	Medium
Zinc on steel	Medium
Copper alloys on steel	Medium
Zinc on aluminum	Medium
Copper plate on aluminum	Medium
Nickel plate on aluminum	Medium
Iron plate on aluminum	Medium
Silver plate on aluminum	Medium
Lead on steel	High

Silver plate on steel	High
Silver plate on aluminum plate	High
Steel with conversion coating on steel	High

Corrosion Fatigue. Aircraft structures are subjected to in-flight mechanical stresses as well as to corrosive environments. The mechanical stresses are cyclic in nature; that is, periods of high stress, or loading, are followed by relatively lower stresses, or unloading (Ref 1). This cyclic stress results in fatigue of airframe structures.

When airframe structures are adversely affected by the combined effects of corrosion and fatigue, th accelerated deterioration that occurs is referred to as corrosion fatigue. Airframe structures fracture in a shorter time because of fatigue that occurs in combination with corrosion (Ref 16). Further, corrosion reduces the fatigue (endurance) limit of airframe components. Corrosion fatigue is most severe in those airframe parts that are most vulnerable to both fatigue and corrosion, such as fastener holes (Ref 30).

A typical example of the corrosion fatigue failure of a military helicopter rotor assembly is discussed in Ref 16, and more information on this failure is also provided in Example 16 in the section "Appendix: Case Histories and Failures" in this article. This rotor assembly consisted of several components--a horizontal hinge pin, a nut, and a locking washer--that were manufactured from 4340 and 4130 steels (Fig. 27a to c). Fracture was observed on the horizontal hinge pi. A flat beach mark on the hinge pin indicated the location of crack initiation in the structure. Figures 27(d) and 27(e) show the respective fracture surface and beach mark. One side of the threaded area of the hinge pin had a dent (Fig. 27f). Corrosion pits were discovered close to the fracture initiation site. Cracks that ran parallel to the primary fracture surface appeared to be emanating from small pits in the hinge pin (Fig. 27g). An embedded thread in the hinge pin was formed by contact of the 4130 low-alloy steel nut with the 4340 pin (Fig. 27h).

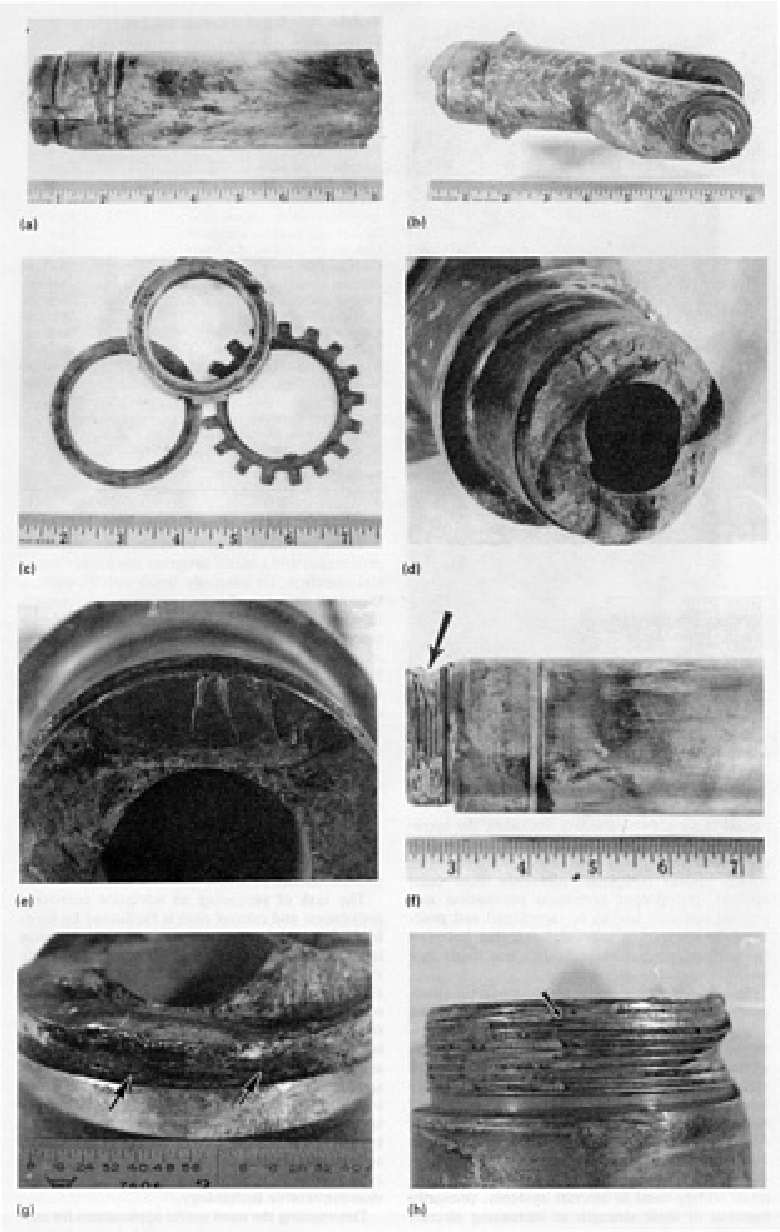

Fig. 27 Corrosion fatigue of a 4340 steel helicopter rotor assembly. (a) Horizontal hinge pin. (b) Nut. (c) Locking washers. (d) and (e) Views of the hinge pin fracture surface. A beach mark is visible in (e). (f) Dent on one of the threaded surfaces of the horizontal hinge pin. (g) Corrosion pits and cracks that emanated from pits in the hinge pin. (h) Embedded thread from the nut in the hinge pin threads. Source: Ref 16

The failed hinge pin had been cadmium plated. Pitting corrosion in the hinge pin promoted the deterioration of the cadmium plating and the exposure of the 4340 steel base material.

This corrosion fatigue failure led to a complete inspection and overhaul of all components in this fleet of helicopters. The inspected (undamaged) hinge pins were stripped of the cadmium plating, shot peened, and replated to a minimum thickness of 12.5 μm (0.5 mil) (Ref 16).

Other typical corrosion fatigue failures have been documented, including the following(Ref 16):

- A main landing gear wheel, made of magnesium alloy AZ91C
- A main landing gear wheel manufactured from magnesium alloy QE22A. Figure 28 illustrates the deterioration that occured in this case. The fracture of this part started on the outer surface and was probably caused by a defective corrosion-protective coating system. Regular inspection and repair of the

paint system that was applied to this structure could have prevented this damage

- Rivets fabricated from aluminum alloy 5052. These rivets were used for the installation of a helicopter filter housing. The damaged rivets are shown in Fig. 29. Figure 29 also presents views of the fracture surface and the grain structure of the rivet material

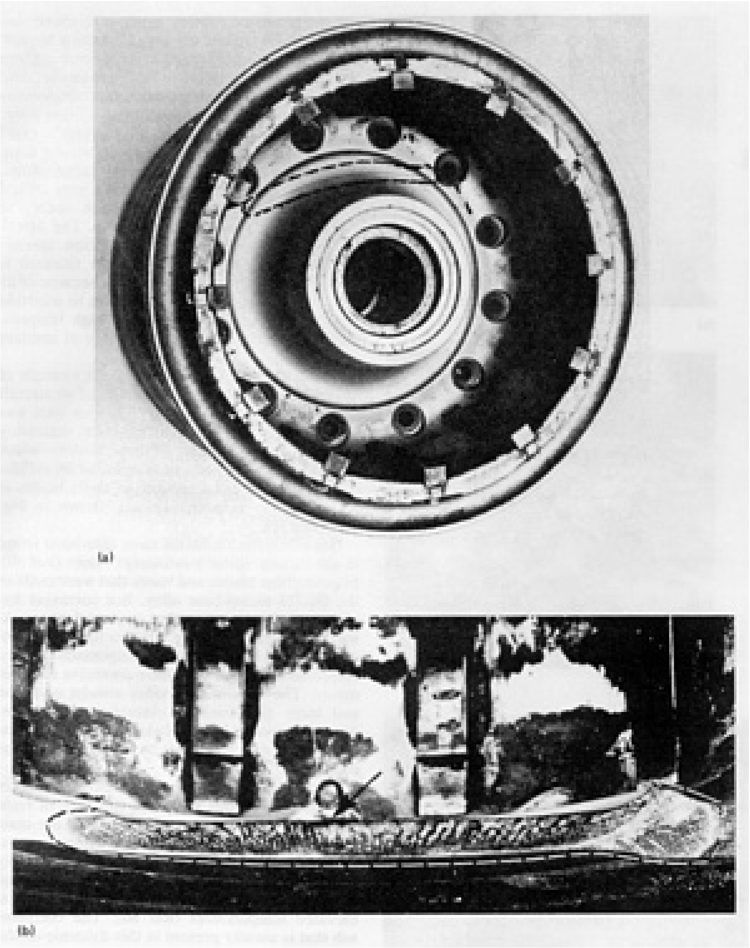

Fig. 28 Corrosion fatigue failure of a magnesium alloy QE-22A main landing gear wheel. (a) General view of wheel. Crack is shown by the dashed line. (b) Fracture surface. Origin is indicated by the arrow. Source: Ref 16

The deformation is caused by tearing in an overload region. 500×. Source: Ref 16

In summary, special corrosion prevention and control treatments must be provided to aircraft that operate in environments conducive to corrosion fatigue. Fatigue resistance can be enhanced in critical areas by designing parts with generous corner radii and by shot peening. Adequate corrosion protection must be used and then followed up by continuous in-service inspections. Pitting must be removed from critical parts because corrosion fatigue often nucleates in corrosion pits. More information on corrosion fatigue is available in the section "Corrosion Fatigue" of the article "Mechanically Assisted Degradation" in this Volume.

Microbiological Corrosion. This type of airframe corrosion is also called biological corrosion (Ref 31). Microbiological corrosion was discovered in the mid-1950s in aircraft integral fuel (wing) tanks (Ref 13). The microbes used kerosene fuels and salt water as growth media (Ref 16, 31). Certain types of synthetic rubber have also been found to promote microbial growth (Ref 14, 32). This support of microbial growth by synthetic rubber was discovered in cases of microbiological corrosion on the military C-130 transport aircraft (Ref 32).

Most of the observed airframe corrosion has been produced by a group of microbes called fungi. The greatest number of cases of aircraft integral fuel tank corrosion have been attributed to the fungus *Cladosporium Resinae* (Ref 16). This microorganism was recently identified by some Argentinian investigators in an integral fuel tank corrosion incident (Ref 33). The fuel tank material was aluminum alloy 2024. The fungus was most active (and, therefore, most corrosive) at the fuel/water interface inside of the 2024 aluminum fuel tank.

Microbiological corrosion can also be caused by bacteria and yeasts (Ref 16). The bacterium *Pseudomonas aeruginosa* has been observed in aircraft fuel tank corrosion cases, but much less frequently than *Cladosporium resinae.*

Aircraft that operate in tropical environments appear to be most vulnerable to microbiological corrosion (Ref 16). Pitting corrosion is often present in microbiological corrosion cases, with pit depths ranging from 1.5 to 3.2 mm (0.06 to 0.125 in.) (Ref 13). One report on microbial corrosion, involving commercial transportation aircraft, indicated that the structural fastener areas had the highest level of deterioration, based on the severity and frequency of corrosive attack (Ref 13).

Microbiological corrosion problems have been observed both in military and commercial aircraft (Ref 34). One case that involved a DC-9 wing fuel tank led to the conclusion that microbiological corrosion can develop on airframes protected by the polyurethane coating that conforms to military specification MIL-C-27725 (Ref 34). One researcher confirmed that microorganisms can penetrate polyurethane coatings in a report on C-130 integral wing tank corrosion problems (Ref 32). The remedy that was selected for prevention and control of C-130 microbiological corrosion was to remove the synthetic rubber lining and to substitute it with a polyurethane coating that contains a biocidal green dye (Ref 32).

A commercial airline system that started a fuel quality improvement program in the early 1970s has reported that microbiological corrosion problems in its fleet of aircraft have been almost completely eliminated. Therefore, it can be concluded that two actions are necessary for the prevention and control of airframe microbiological corrosion problems. These are the selection of the proper structural materials, including biocidal protective coatings, and the implementation of stringent controls on the quality of fuel that is used in aircraft systems. More information on attack by microorganisms is available in the section "General Biological Corrosion" of the article "General Corrosion" and in the section "Biological Corrosion" of the article "Localized Corrosion" in this Volume.

Corrosion in Aircraft Bilges. Corrosion often occurs in aircraft bilge areas, which are sinks (or sumps) into which waste fluids and solids collect. These materials--especially oil, water, and dissimilar metallic drill chips--can set up electrochemical (galvanic) cells in the bilge (Ref 35). Because these corrosion reactions occur in areas that normally are not accessible to aircraft maintenance personnel, the potential for extensive airframe deterioration due to corrosion is significant (Ref 36).

One of the best ways to control bilge area corrosion in aircraft systems is to provide access through stairways or rampways so that mechanics can conveniently inspect and maintain these areas (Ref 36). Additional measures that can be taken, especially during the aircraft design phase, are to (Ref 36):

- Consider using aluminum alloys that have greater resistance to general corrosion and SCC, such as 7075-T73 and 7475-T761
- Use an external organic primer and topcoat finishing system. This system can, for example, consist of the MIL-P-23377 epoxy-polyamide primer (one coat) and the MIL-C-83286 polyurethane topcoat (two coats)
- Seal all faying surfaces of the airframe structure. A sealant meeting MIL-S-81733, which contains corrosion-inhibitive chromates, is often used

Hydrogen-induced failures of aircraft equipment result from a chemical and mechanical interaction with hydrogen. The hydrogen that enters metallic airframe structures causes mechanically induced deterioration by applying very high pressures within small cavities in the affected airframe structure.

Another term that is used for hydrogen-induced fracture is hydrogen embrittlement. Hydrogen embrittlement can cause dangerous and sometimes catastrophic failures in some steel parts that are used in aircraft. Two possible processing sources of hydrogen embrittlement are pickling solutions, which are used for scale and rust removal, and electroplating solutions (Ref 16). Hydrogen embrittlement may also result in areas where steel acts as the cathode during galvanic (dissimilar metal) corrosion.

Hydrogen-induced cracking is one of the more severe forms of deterioration because it can result in delayed fracture under sustained stress. Hydrogen embrittlement has been observed (and has caused the failure of) some of the high-strength steel alloys used in aircraft landing gears (Fig. 30). Representative cases involving this type of corrosion were discussed in the introduction to this section. Additional examples of hydrogen-induced airframe corrosion are discussed below for various aircraft structures.

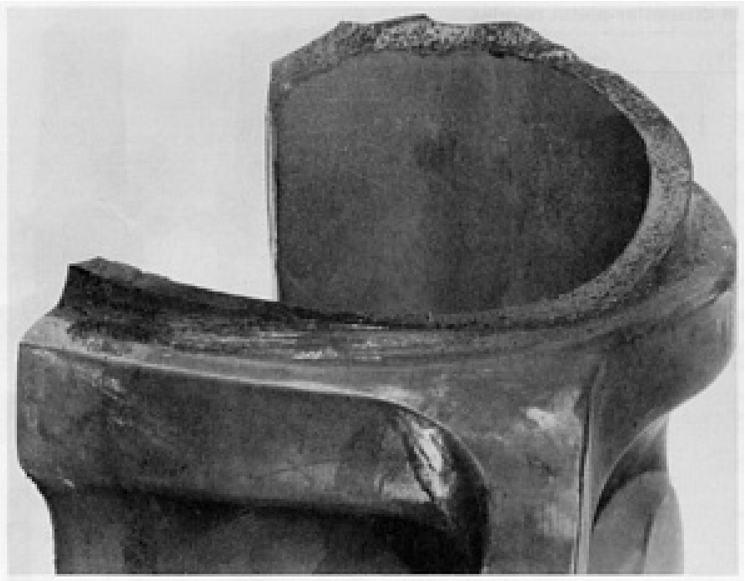

Fig. 30 Hydrogen embrittlement failure of a high-strength steel aircraft landing gear component

Landing Gear. Several C-141 landing gear cylinders failed because of hydrogen embrittlement (Ref 37). Hydrogen entered these 4340 steel cylinders during electroplating operations. Subsequently, 300M steel cylinders, coated on the interior surfaces with a hard chromium plating, have been used as a result of a redesign and retrofitting of the C-141 landing gear cylinders (Ref 37).

Propeller Retaining Bolt (Fig. 31). The composition of this steel part--which failed by hydrogen embrittlement--was Fe-0.5C-2.5Ni-0.75Cr. This steel bolt had been heat treated to a strength of 1379 MPa (200 ksi), and a bright electroplated cadmium coating had been applied.

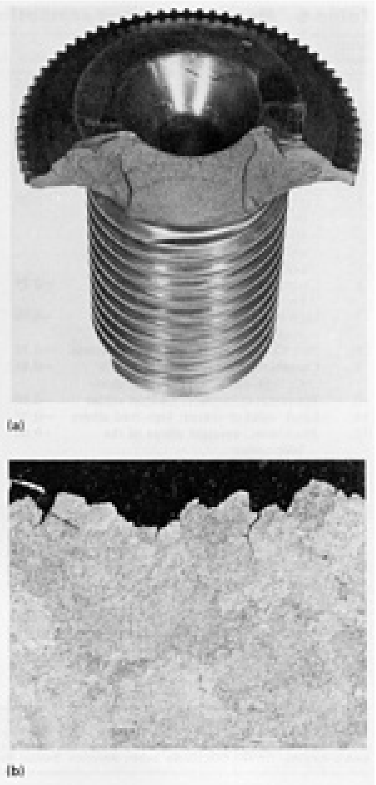

Fig. 31 Hydrogen embrittlement of a high-strength steel propeller retaining bolt. (a) Overall view of bolt. (b) Cross section on the bolt. 215×. Courtesy of Aeronautical Research Laboratories, Australia

Nose Gear Strut. Hydrogen embrittlement was the primary cause of the failure of this steel aircraft component (Ref 38). The strut separated during the taxiing of a small bomber. The severely corrosive Southeast Asian environment probably abetted the ultimate failure of this structure.

Flap Control Return Spring (Ref 16). The internal crack in this carbon steel part indicated that the failure resulted from hydrogen embrittlement. This flap control return spring was cadmium plated, but there was no evidence that the part had been baked to remove hydrogen. Precautions were subsequently taken to ensure that proper baking is performed.

Main Landing Gear Pivot Pins (Ref 16). The intergranular fracture of these 4340 steel components was caused by hydrogen penetration into the metallic structures. Sustained loads were a major contributing factor in this failure. The pivot pins were chromium plated, and it was determined that the hydrogen came from the plating process. Therefore, the baking procedure, which is performed after electroplating, was modified to enhance the degree of hydrogen removal.

Main Landing Gear Drag Link Bolt (Ref 16). This 4340 steel part had been cadmium plated. Fracture occurred in the threaded region of the bolt.

Hydrogen tolerance for steels is inversely proportional to their strength levels. Hydrogen embrittlement can be avoided by using lower-strength steels, by limiting immersion times in acid or plating baths, and by in-process (intermediate) baking. Plated parts are usually baked at 190 °C (375 °F) to provide hydrogen embrittlement relief. A safer baking duration for high-strength steels (>1100 MPa, or 160 ksi) is 23 h. Longer baking times may be required for parts that have large cross sections, bright cadmium treatments, or very high strength. More information on hydrogen-induced failures is available in the section "Hydrogen Damage" of the article "Environmentally Induced Cracking" in this Volume.

Corrosion of Bonded Airframe Structures. Adhesive-bonded airframe structures can deteriorate by delamination and electrochemical corrosion of one or both of the metallic structural face sheets that eventually separate from the bondline. The long-term environment susceptibility of bonded structures to this type of corrosion is known to be primarily caused by (Ref 39):

- Water or moisture intrusion into the adhesive bondline. Perforated honeycomb core sections of these bonded parts promote the collection of moisture (Ref 40). This leads to deterioration of the honeycomb core due to freezing-thawing cycles, corrosion, or both (Ref 41)
- Deficient surface preparation of face sheet and core materials that are used in the complete adhesive-bonded part

Improper surface preparation was the documented cause of the failure of a C-141A wing trailing edge upper surface panel. This was caused by a separation of the outer face sheet because of poor adhesion to a corner section of the wing upper surface. Corrosion of the aluminum face sheet started after the face sheet separated from the bonded structure. The disbonded aluminum face sheet had been prepared by using the sodium dichromate-sulfuric acid etch process, which is also called the Forest Products Laboratory (FPL) etch. The failure of the C-141A outer wing panel was attributed to inadequate process control while the FPL etching process was being accomplished (Ref 39).

Another reported adhesive bonding failure occurred on the C-141A petal door inner skin assembly. This delamination and corrosion also occurred because of poor surface preparation and moisture penetration between the bonded structural panels. Extensive corrosion was noted near the hinge fitting of this skin assembly (Ref 39).

Delamination and corrosion of adhesive-bonded airframe components have also been reported on the C-141 main landing gear doors (Ref 41) and on the more highly stressed aircraft control surfaces, such as spoilers, on one fleet of commercial airliners (Ref 42). These latter parts consisted of alclad aluminum alloy 7075 bonded to aluminum honeycomb with an adhesive that cured at 120 °C (250 °F).

A significant contribution to the engineering effort to mitigate these delamination and corrosion problems has been the development of the phosphoric acid anodizing process (Ref 39, 40, 41, 42). This solution to adhesive structural disbonding resulted from 10 years of research at the Boeing and Douglas aircraft companies. Phosphoric acid (H_3PO_4) anodizing enhances the durability of adhesive-bonded structures by improving the resistance of the bondline too hydration and by reducing the extent of corrosion of exposed alclad aluminum surfaces (Ref 42).

In addition to H_3PO_4 anodizing, the following techniques have helped to reduce delamination and corrosion of bonded airframe structures:

- Curing the film adhesive at 175 °C (350 °F) instead of at 120 °C (250 °F) (Ref 42)
- Coating the surfaces with a corrosion-inhibiting primer that cures at 120 °C (250 °F) (Ref 42)
- Better-quality adhesive bonding through the use of adhesives that have greater long-term resistance to plastic deformation. This increased toughness is obtained by the crosslinking of these two-part 100% solids paste adhesives during room-temperature curing (Ref 40)

Because corrosion of alclad aluminum spreads in the plane of the sheet, corrosion of alclad airframe parts results in the delamination of bonded honeycomb panels. Therefore, alclad sheet is often avoided for honeycomb facesheets.

Another effective corrosion control approach is to apply only nonperforated honeycomb core. This prevents the moisture penetration that can occur in cellular honeycomb parts. Sealing is performed on the edges of honeycomb panels to protect the core from moisture ingestion.

Erosion-corrosion is corrosion that is accelerated by the impingement of moving fluids, which may contain solid particles, onto the surfaces of materials. Erosion-corrosion in aircraft is most severe when the fluid impinges upon the aircraft surface at a high velocity and when the moving fluid contains abrasive solid matter, especially sand. High temperatures also accelerate the deterioration process when erosion-corrosion occurs.

One reported case in which erosion-corrosion was recorded in aircraft structures involved damage to the undercarriage parts of a transport aircraft. This large air vehicle had been operating on a desert landing strip. The erosion-corrosion damage on this structure, therefore, was accelerated by extremely high temperatures and impact by sand (Ref 16).

Prevention and Control of Airframe Corrosion

The cost escalation attributed to corrosion problems in the United States has been significant--from $5.5 billion in 1947 to $167 billion in 1985 (Table 5). Therefore, it is important that the manufacturers and users of aircraft systems implement an effective corrosion prevention and control program.

Table 5 Cost escalation for corrosion in the U.S. from 1947 to 1985

Year	Cost, billions of dollars
1947	5.5
1965	>6
1967	>10
1975	70
1982	126
1985	167

Source: Ref 43

There are many techniques that are available for preventing and controlling airframe corrosion. Some of these corrosion control methods have been used for many years, such as the application of greases to bearings in aircraft control mechanisms, wheels, rudder posts, and other components (Ref 44). Other relatively new approaches have been utilized, including the application of advanced composite materials to secondary airframe structures (Ref 45). In cases in which carbon composite materials have been applied, the proper corrosion prevention and control methods had to be developed and practiced for preventing galvanic corrosion between the carbon composites and other less noble materials, especially aluminum.

In addition to noncritical (secondary) structures, airframe manufacturers have also applied reinforced plastic and carbon composites to primary structures, such as the fuselage, wings, and empennage, which have a greater degree of safety-of-flight importance than secondary structures. On the C-130, for example, the wing contains about 80% advanced composite materials (Ref 45). Advanced composites are also used in 71% of the structure of one business aircraft (Ref 45). Advanced composite materials are being more widely used in aircraft systems, primarily because of their strength at increasing aircraft velocities (Ref 46).

Corrosion-preventive technology must be properly and regularly applied to airframe components to ensure that the airworthiness and flight safety of operational aircraft are not jeopardized. The corrosion cases that have been presented in this section demonstrate that the objectives of airframe corrosion prevention and control can be attained by implementing new and improved engineering design solutions.

The essential elements of an airframe corrosion prevention and control program are proper material selection, an adequate finish specification, a thorough plan for effective maintenance, inspection, and repair (Ref 47). During the material selection phase, considerable trouble can be avoided if aluminum alloys and tempers are selected based on SCC resistance, exfoliation corrosion resistance, fracture toughness, and mechanical strength properties. Tempered steel having a yield strength below 1379 MPa (200 ksi) should be selected whenever possible in order to avoid hydrogen embrittlement and SCC problems. The corrosion prevention and control specification must ensure that these materials receive satisfactory hydrogen embrittlement relief during processing. Precipitation-hardening steels that have been heat treated for maximum resistance to SCC should be used.

The task of preparing and adequate corrosion prevention and control plan is facilitated by feed-back from aircraft operators and maintenance technicians. The engineers and other specialists who provide feedback to corrosion engineers and designers should be thoroughly familiar with the operational profile of the aircraft system for which the specific corrosion prevention and control plan is being written (Ref 48). Feedback will not only assist airframe designers in writing a plan and specifications for corrosion prevention and control but will also enable these professionals to understand how and where corrosion problems tend to occur in particular airframe structures and to determine the most useful (and most cost-effective) applications for airframe corrosion-preventive technology.

Determining the most useful applications for corrosion-preventive technology will help to minimize repeated occurrences of airframe corrosion problems. An example of this is a significant metallurgical contribution to the C-130 airframe

corrosion prevention and control program--the use of aluminum alloy 7075-T73 (instead of the less corrosion resistant 7075-T6 aluminum alloy) in the upper-center wing and other components of the C-130 (Ref 32). The main structural (aluminum) parts of the C-130 are provided with additional corrosion protection by anodizing and then coating them with a polysulfide primer (Ref 32).

An adequate finish specification must be prepared and enforced in the early stages of aircraft design. During the design period, qualified corrosion engineers should review the initial drawings; this would prevent potential corrosion problems from occurring.

Several documents that provide comprehensive requirements for corrosion prevention and control have been published. These standards were written for military airframe systems, but they can also be applied to corrosion protection on commercial airframes with little or no modification. The following United States DOD specifications can be used as a guide in selecting or preparing an adequate finish specification:

- Military Specification MIL-F-7179: "Finishes and Coatings: General Specification for Protection of Aerospace Weapons Systems, Structures, and Parts"
- Military Standard MIL-STD-1568: "Materials and Processes for Corrosion Control"
- Standardization Document SD-24: "General Specification for Design and Construction of Weapon Systems"
- Military Specification MIL-S-5002: "Surface Treatments and Inorganic Coatings for Metal Surfaces"
- Aeronautical Design Standard-13: "Air Vehicle Materials and Processes"

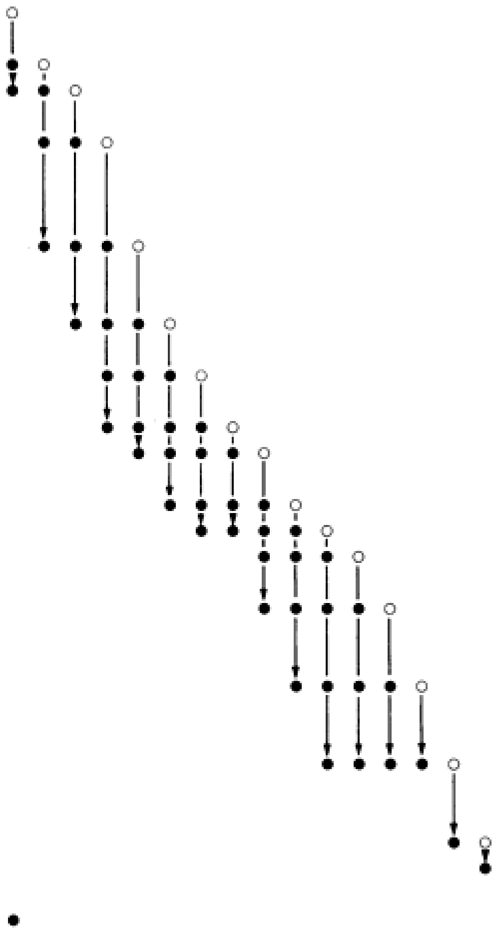
The corrosion prevention and control guidelines include in the above specifications have been widely used by government and industry. One of the most significant of these guidelines is the use of compatible materials in dissimilar metal couples, as summarized in Table 6.

Table 6 Metals and alloys compatible in dissimilar-metal couples

Source: Ref 17

Group number	Metallurgical category	emf, V	Anodic index(a), V
1	Gold, solid and plated; gold-platinum alloys; wrought platinum	+0.15	0
2	Rhodium plated on silver-plated copper	+0.05	0.10
3	Silver, solid or plated; high-silver alloys	0	0.15
4	Nickel, solid or plated; monel metal, high-nickel-copper alloys	−0.15	0.30
5	Copper, solid or plated; low brasses or bronzes; silver solder; German silvery high copper-nickel alloys; nickel-chromium alloys; austenitic corrosion-resistant steels	−0.20	0.35
6	Commercial yellow brasses and bronzes	−0.25	0.40
7	High brasses and bronzes; naval brass; Muntz metal	−0.30	0.45
8	18% Cr type corrosion-resistant steels	−0.35	0.50
9	Chromium plated; tin plated; 12% Cr type corrosion-resistant steels	−0.45	0.60
10	Tin-plate; terneplate; tin-lead solder	−0.50	0.65
11	Lead, solid or plated; high-lead alloys	−0.55	0.70
12	Aluminum, wrought alloys of the 2000 series	−0.60	0.75
13	Iron, wrought, gray or malleable; plain carbon and low-alloy steels, armco iron	−0.70	0.85
14	Aluminum, wrought alloys other than 2000 series aluminum, cast alloys of the silicon type	−0.75	0.90
15	Aluminum, cast alloys other than silicon type; cadmium, plated and chromated	−0.80	0.95
16	Hot-dip zinc plate; galvanized steel	−1.05	1.20
17	Zinc, wrought; zinc-base die-casting alloys; zinc plated	−1.10	1.25
18	Magnesium and magnesium-base alloys, cast or wrought	−1.60	1.75

Compatible couples(b)



(a) Anodic index is the absolute value of the potential difference between the most noble (cathodic) metals listed and the metal or alloy in question. For example, the emf of gold (group 1) is +0.15 V, and the emf of wrought 2000-series aluminum alloys (group 12) is −0.60 V. Thus, the anodic index of wrought 2000-series aluminum alloys is 0.75 V. (b) "Compatible" means the potential difference of the metals in question is not more than 0.25 V. An open circle indicates the most cathodic members of a series; a closed circle indicates an anodic member. Arrows indicate the anodic direction. Source: Ref 17

In addition to having a written plan, it is important to have designated corrosion and design engineers that are appointed to corrosion prevention teams or advisory boards. These groups have the responsibility of establishing materials and process requirements and design improvements for ensuring effective corrosion protection on specific aircraft systems. These requirements are generated from documented cases in which corrosion has been observed on airframe components, especially those parts that have deteriorated on earlier models of the same or similar aircraft systems.

Airframe maintenance and repair should be performed to alleviate airframe corrosion. Examples of these actions include:

- The application of corrosion-preventive (water-displacing) compounds to airframe surfaces (Ref 49)
- Use of corrosion-inhibitive elastomeric sealants (Ref 50)
- Repair of stress-corrosion cracks on internal aluminum wing structures by applying bonded doublers consisting of boron fiber reinforced plastic (Ref 51)

Another important step in the corrosion control effort is the drafting of a preventive maintenance and inspection plan (Ref 47). This plan provides an outline of corrosion maintenance, inspection, and repair requirements that include the locations and frequencies of inspections and the corrosion-contributing factors that should be considered by professionals who

inspect aircraft structures for deterioration. Some of the factors that can induce the corrosion of airframes include the environmental conditions to which the airframe is (or will be) exposed and corrosive spillage (usually alkaline or acidic chemicals) from galleys and toilets.

The inspection and maintenance plan must be defined and administered as early as possible. This is very significant because early corrosion control actions are crucial for the avoidance of costly aircraft damage or failures.

Corrosion of Powerplants

Michael L. Bauccio, The Boeing Company

Aircraft powerplants have the important function of providing thrust, or propulsion, to enable aircraft to take off and remain in flight. Powerplant systems also provide reverse thrust to enable aircraft to land safely. The development and proper utilization of corrosion-preventive technology has enabled aircraft powerplants to fulfill these significant functions.

In aircraft powerplant systems, including engine and hydraulic power units, several types of corrosion have been observed. Among these types of powerplant corrosion (but not the only kinds) are:

- High-temperature corrosion. This has also been referred to as sulfidation, or hot corrosion. High-temperature corrosion of powerplant components is also manifested as hot-salt-induced SCC and as very rapid oxidation (fire). Both of the latter forms of high-temperature corrosion have been observed primarily in titanium structures
- Cold corrosion. This type of powerplant corrosion originally referred to all types of corrosion other than hot corrosion, which primarily includes pitting and fretting corrosion of aircraft powerplant components. The cold form of pitting and fretting corrosion develops at considerably lower temperatures than those attained under hot corrosion conditions
- Chemical corrosion
- Erosion corrosion

The objective of this section is to focus on the above generic of aircraft powerplant corrosion. The problems and corrosion-preventive solutions that have proved to be significant developments for minimizing future occurrences of these corrosion problems will also be discussed. The thesis of this section is that powerplant corrosion problems can be minimized by regularly scheduled maintenance inspections and by effective applications of corrosion-preventive treatments to powerplant components.

Most of the literature on the corrosion of aircraft powerplants is concerned with high-temperature corrosion, which occurs above approximately 315 °C (600 °F). This is because aircraft powerplants operate at extremely high temperatures. Some aircraft powerplant sections--such as the turbine rotor inlet--reach temperatures of about 1240 °C (2260 °F) (Ref 52). These high-temperature operating cycles have produced hot corrosion in powerplant components that did not have adequate corrosion protection. Some reciprocating parts, such as exhaust valves, are protected against high-temperature corrosion by coatings of high-temperature alloys (Ref 2). These metallic coatings are welded onto the valve faces and then machined to the required angle of either 30 or 45° (Ref 53).

Corrosion of powerplants has also been found in many cases at much lower temperatures than those attained in hot corrosion. One of the most cold corrosion prone areas of the aircraft--the engine air inlet, or frontal, area and the cooling air vents--has experienced corrosive deterioration at relatively low temperatures. The frontal areas are vulnerable to erosion that is caused by airborne particulate matter, such as dirt, sand, and gravel. This abrasive action removes protective treatments and coatings from the frontal engine structures. This is eventually followed by corrosive deterioration in and around the areas that had been mechanically damaged by airborne solids (Ref 54). Certain engine parts, including reciprocating engine cylinder fins and accessory mounting bases, have small, unpainted areas that are susceptible to corrosion by airborne salts and moisture (Ref 54). The most effective technique for preventing and controlling corrosion in engine intake areas is to clean, examine, and refurbish these areas regularly, especially when the aircraft system must operate under aggressive conditions, such as in a tropical marine environment (Ref 55).

The materials that are usually affected by the highly corrosive powerplant environment are metal alloys that are designed for long-term service at high temperatures. These alloys consist primarily of nickel, cobalt, and titanium. Some of the older nickel-base superalloy materials, such as Udimet alloy 700, have a low resistance to fatigue, which compromises the high-temperature static strength of these alloys (Ref 56). Therefore, powerplant corrosion can be minimized by the

increased use of materials that have the best combination of fatigue strength and corrosion resistance at elevated temperatures.

Case Histories

Many typical case histories, or lessons learned, have been described in the literature of powerplant corrosion. Discussions of the actual forms of deterioration, as well as the corrosion-protective measures that were implemented to control or avert future problems, are presented below. These corrosion problems have led to significant improvements in the materials and processes used for the protection of aircraft powerplant components and for the assurance of aircraft flight safety

High-Temperature Corrosion

There are three predominant types of high-temperature corrosion that have caused mechanical failures of aircraft powerplant components. These are sulfidation, hot-salt SCC, and fires.

Sulfidation has occurred in gas turbine parts that were made of nickel and cobalt alloys. Hot corrosion was observed in the 1960s on gas turbine blades that were manufactured from Nimonic 105 (Ni-20Co-15Cr-5Mo-4.5Al-1.4Ti) and GMR-235 (Ni-15.5Cr-10Fe-5.2Mo-3Al-2Ti). This corrosive deterioration was called black plague (Ref 57). Some of the cobalt-base superalloys, which are also used in gas turbine powerplants, have also required advanced protective coatings for the mitigation of hot corrosion (Ref 58). The nature of these coatings will be discussed later in this section.

Hot-salt SCC has been found primarily in titanium-alloy powerplant parts, such as the compressor blades of military supersonic trainer engines (Ref 59). A case history concerning hot-salt SCC in a titanium powerplant component is given in the discussion "Hot-Salt SCC" in this section.

Fires have occured in powerplant components that are fabricated from titanium and other materials. This phenomenon is an extremely rapid form of oxidation that can cause extensive damage within a brief period in aircraft powerplant. In the case of titanium fires, this is a very critical problem because titanium oxidation occurs so quickly that is produces combustion. The deterioration that is caused by combustion spreads throughout the powerplant because titanium is widely used in aircraft powerplants because of its high strength-to-weight ratio, ability to maintain adequate strength a moderately high temperatures, and good corrosion resistance at ambient temperatures.

Hot Corrosion (Sulfidation). An example of hot corrosion in the rotating blades of an aircraft powerplant is shown in Fig. 32. This part was manufactured from the nickel-base superalloy 1N-738. The creep failure of these blades--which also are called buckets--was initiated sulfidation. Magnified cross sections of these blades at 75 and 130×, respectively, are shown in Fig. 32(b) and 32(c).

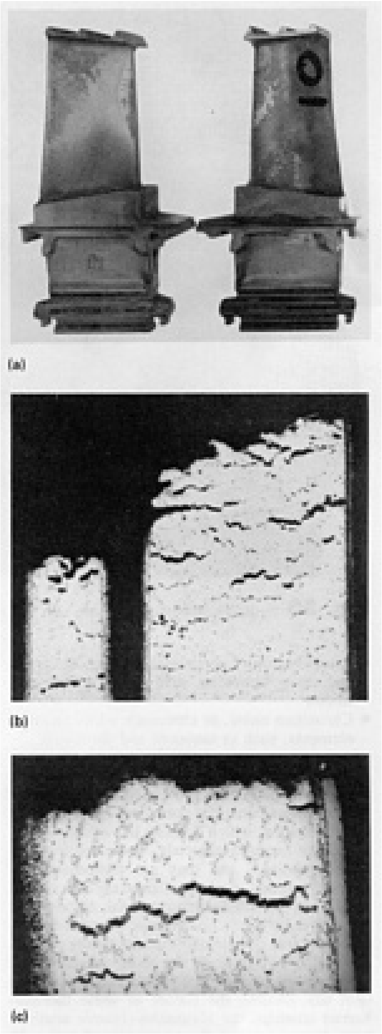


Fig. 32 Aircraft powerplant turbine blades (a) that were damaged by hot corrosion. (b) Higher-magnification view of corrosion. 35×. (c) Corroded turbine blade. 55×

Hot corrosion problems have also been found in gas turbine stator (stationary) vanes (Ref 59). In gas turbine blades and vanes that were made of the IN-724 nickel-base alloy, hot corrosion has produced deterioration that appeared as cracking, swelling, or spalling. Oxides have been observed below the surface of components that are subjected to high-temperature corrosive environments. The subsurface oxides consist of nickel and large quantities of chromium, aluminum, titanium, and niobium. Nickel-rich metallic material has been found to lie adjacent to these oxides (Ref 59).

The dynamic nature of the environment in aircraft powerplants promotes this type of high-temperature oxidation (sulfidation) of the main burner components and of downstream parts, such as turbine blades, vanes, and seals. Very high thermal and mechanical strains are produced on these parts because of powerplant operation at elevated temperatures (Ref 60). The corrosive ash that is usually present in this dynamic-oxidation environment is sodium sulfate (Na_2SO_4), which reacts with powerplant materials and causes a depletion of the alloying elements required to form a protective oxide film on the surfaces of these parts. The formation of a protective film can also be inhibited by consumption of the alloying elements by means of either acidic or basic oxide fluxing reactions (Ref 52, 60).

Hot corrosion protection has been obtained primarily by the use of advanced-technology coatings and materials that are specifically designed for long-term endurance in dynamic corrosion environments. One such coating is a proprietary mixture of cobalt, chromium, aluminum, and yttrium (CoCrAlY). Aluminum is the most significant element in this coating because it reacts with oxygen to form a thin layer of corrosion-resistant aluminum oxide on the surface of the powerplant parts (Ref 61). Coatings of this type have been applied by electron beam plasma vapor deposition techniques.

Hot corrosion problems in aircraft powerplants have also been alleviated by the application of pack cementation type coatings (Ref 58). These coatings consist of either of the following elements:

- Aluminum only, or a combination of aluminum and other elements, such as chromium and silicon
- Chromium alone, or chromium added to other elements, such as tantalum and aluminum

Another type of advanced coating that has been investigated for protection of powerplant components against hot corrosion is the thermal-barrier coating, which consists of various combinations of ceramic materials. These coatings are plasma sprayed, and they are composed of a specific ceramic material that applied over a layer of an oxidation-resistant metal. Accelerated hot corrosion tests on ceramic thermal-barrier coatings have determined that the failure mechanism of these coatings involves delamination, which occurs prior to surface cracking or spalling (Ref 62). Despite the failure of some thermal-barrier coatings, the aluminum-ceramic coatings have been successfully applied in the last 20 years to various gas turbine components, including blades and vanes for corrosion protection to temperatures of about 650 °C (1200 °F) (Ref 63).

Other materials have been developed and used for improving the resistance of powerplant components to hot corrosion, such as oxide dispersion-strengthened alloys (Ref 64), which include the following materials:

- Inconel alloy MA-754, which was developed for use in gas turbine vanes
- Incoloy alloy MA-956, which was developed for powerplant combustion chamber burner cans
- Alloy MA-6000E, which was designed and produced for application in gas turbine blades

In addition to the above oxide dispersion-strengthened materials, the following materials have been designed for mitigating high-temperature corrosion in powerplant systems:

- Nickel-, cobalt-, and iron-base superalloys that contain platinum and platinum-group metals. Alloying with platinum group metals provides a great improvement in overall hot corrosion resistance (Ref 65)
- Directional solidified alloys. These materials include columnar-grained and single crystal forms (Ref 56). In addition to having a significantly higher resistance to hot corrosion, these materials (such as the directional solidified MAR-M200 nickel-base alloy) have up to 100 times the high-temperature fatigue life of the polycrystalline forms of the same alloy (Ref 56)

Hot-salt SCC has been produced in the laboratory in titanium alloys that are susceptible to embrittlement and fracture. The conditions required to induce this type of failure are a combination of the following (Ref 66, 67, 68):

- High Stress
- High temperature (approximately 345 °C, or 650 °F)
- Exposure to a high concentration of chloride salts, which is anticipated in a marine environment

Hot-salt SCC usually produces intergranular-type corrosion in titanium alloys. In cases in which hot-salt SCC occurs because of the exposure of titanium powerplant parts to solid chloride salts, the minimum temperature at which hot-salt SCC develops is approximately 290 °C (550 °F) (Ref 68).

Hot-salt SCC of titanium powerplant components has been reported as the cause of powerplant deterioration in one incident that occured during ground testing. In this case, a compressor rotor assembly in a turbine engine failed during an overspeed acceleration test. Two compressor disks, manufactured from titanium alloy Ti-7Al-4Mo, fractured in several locations. Cracking occured at the bolt holes, where dissimilar-metal (A-286) bolts were in contact with the titanium disk. This failure is illustrated in Fig. 33. The two failed disks had large silver deposits in the tie bolt holes, which was indicated by surface attack at the crack initiation sites. Silver chloride was formed during the test cycle by a chemical reaction between silver and chlorine, which were present in the high-temperature environment. Silver had been used as an

antifretting coating on the tie bolts. As a consequence of this failure, the silver coating was replaced by a molybdenum disulfide dry-film lubricant (Ref 67, 69).

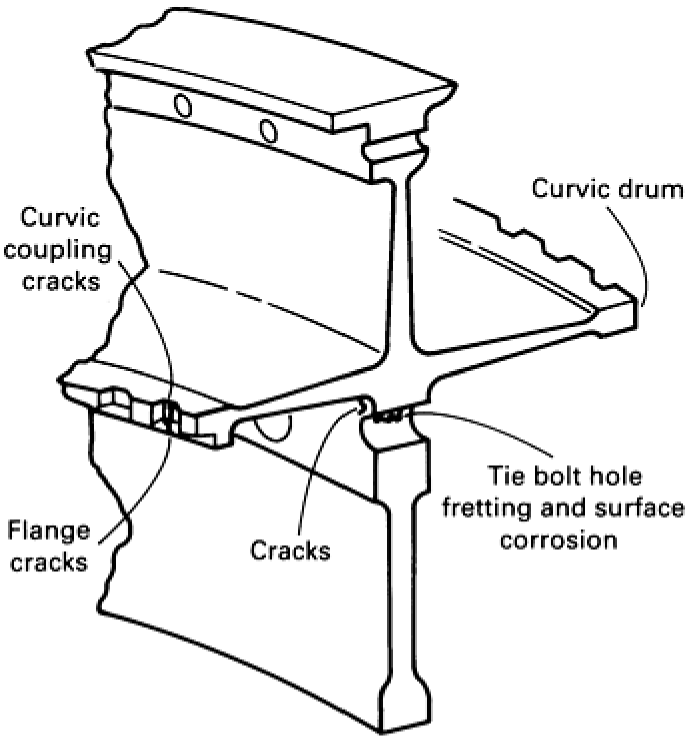

Fig. 33 Cracking of a Ti-7Al-4Mo aircraft powerplant compressor disk

Rapid Oxidation. Corrosion problems produced by rapid oxidation (combustion) in aircraft powerplants have predominantly involved titanium. In some isolated cases of rapid oxidation, the damaged parts were fabricated from steel. The total number of known occurrences of titanium combustion in powerplants has been reported to be 144. In 85 of these incidents, the combustion did not penetrate the case, or skin, of the powerplant. Details of the deterioration that occurred in the 144 documented cases of titanium combustion are available for only two of these incidents (Ref 70).

The ignition temperature of titanium in air is approximately 1625 °C (2960 °F). This is significantly higher than the maximum service temperature for titanium. Therefore, either a mechanical or aerodynamic upset of the operation of the powerplant must occur in order to raise the temperature of titanium components to the ignition point. Several events can cause mechanical rubbing or jamming in powerplant structures, including (Ref 70):

- Interference by loose solid particles with rotating and static structures. These particles can bend blades, causing the blades and vanes to rub against each other continuously.
- Rotor imbalance, which can cause severe rubbing. This develops from the failure of rotating disks, spools, or blades
- Radial or axial displacement of the rotor, which can be caused by a failed bearing
- Displacement of the rotating powerplant blades into stationary parts, which produces compressor stall

The most significant of these causes of powerplant titanium combustion are trapped blades and radial displacement of the rotor (Ref 71). Only a small number of titanium combustion incidents have occurred because of aerodynamic heating, stall, or surge (Ref 71).

Powerplant case penetration has been observed in 57% of the titanium combustion incidents involving high-bypass ratio turbofan powerplants. Case penetration is illustrated in Fig. 34. In most of the case penetration incidents, small holes were

observed in various locations on the case. Some incidents of case penetration have been characterized by complete deterioration of the case that covers the compressor section of the powerplant (Ref 71).

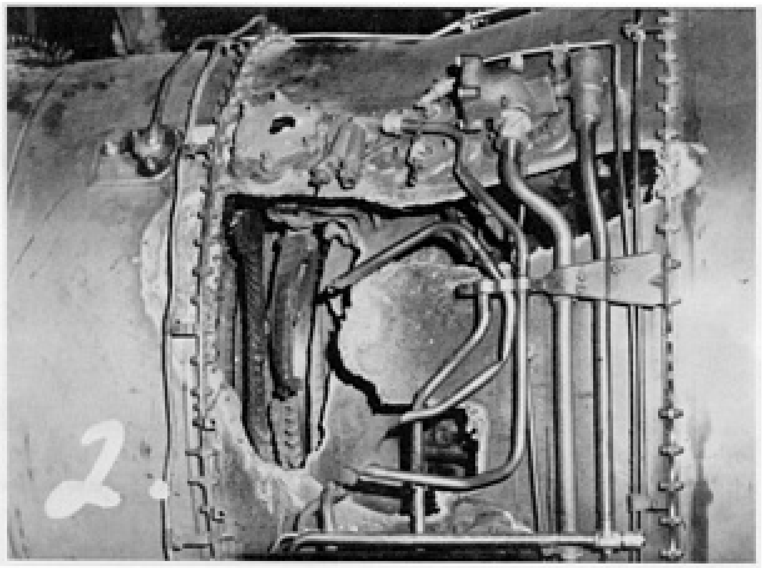

Fig. 34 Case penetration produced by titanium combustion in a high-bypass turbofan aircraft powerplant. Courtesy of C.W. Elrod, Wright-Patterson Air Force Base

Titanium fires that are caused by blade tip rubbing can be prevented by (Ref 71):

- Increasing the clearances (tolerances) between the powerplant blade tips and case interior surfaces, although this is in opposition to the current trend toward tighter tolerances for improved performance
- Applying blade-tip materials that are resistant to wear. Abrasion-resistant materials have been investigated for this purpose. A plasma-sprayed Co-30WC tip treatment compound provided the best results in one study (Ref 72)
- Protecting the entrance edges of bleed air manifolds with steel grommets (Ref 70)

As previously mentioned, steel components have also failed by rapid oxidation in aircraft powerplants. These powerplant corrosion problems are described as breech chamber failures. Breech chambers are used in various types of aircraft engines. These chambers are part of the cartridge, or pneumatic, starters (Ref 5). Combustion products from the breech chambers are exhausted toward the turbine blades to start the engine rapidly. Typical breech chamber failures are shown in Fig. 35. These components were fabricated from 4340 steel heat treated to between 40 and 45 HRC. As indicated in Fig. 35, the breech chamber dome bursts at a point that is opposite to the hot gas discharge nozzle. These failures occur where stress concentrations are the highest, which is where the dome contacts the breech chamber body (Ref 5).

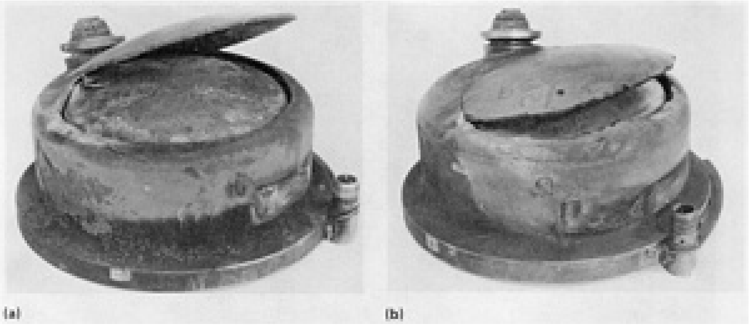

Fig. 35 Typical failures of 4340 steel aircraft powerplant breech chambers. Source: Ref 5

A fracture at the hot gas nozzle of the breech chamber is shown in Fig. 36. At the base of the nozzle (beyond the location of the fracture), a pattern of trenches was observed on the external chamber surface (Fig. 36b). The most probable explanation for these breech chamber failures is a defective coating system. There was no finish on the internal surfaces of these failed chambers. The domes were coated with electroless nickel, which caused galvanic corrosion on the more active (anodic) steel chambers (Ref 5). Future breech chamber failures can be avoided by coating the entire chamber with one of the high-temperature resistant coatings mentioned in the discussion "Hot Corrosion (Sulfidation)" in this section. The electroless nickel finish, applied directly to the steel chamber dome, should not be used, because of the possibility of galvanic corrosion at the nickel and steel contacting surfaces.

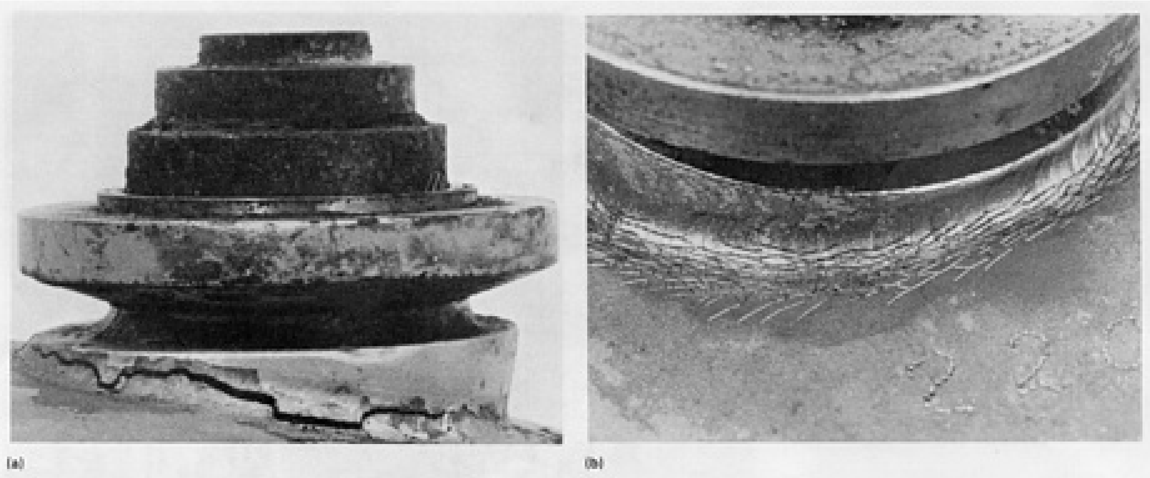

Fig. 36 Fracture in the hot gas nozzle (a) of a powerplant breech chamber. (b) Trench pattern at the base of the breech chamber hot gas nozzle shown in (a). Source: Ref 5

Cold Corrosion

Fretting corrosion is a very important design consideration for titanium parts in aircraft powerplants. This is because fretting corrosion can significantly reduce the fatigue strength of titanium alloy Ti-6Al-4V (Ref 73). Fatigue strength reductions of greater than 50% have been documented (Ref 67).

Fretting-induced deterioration has occurred in aircraft powerplant control bearings (Ref 67). The components that are most susceptible to significant fretting deterioration are the fan roller bearings on aircraft turbofan engines (Ref 74).

Fretting is also a significant factor in the design of powerplant compressor blades fabricated from titanium. Fretting corrosion can occur on the root and midspan shroud of these blades unless adequate design precautions are taken to minimize the potential for fretting to occur (Ref 67).

In addition to powerplant bearings and compressor blades, the following components of aircraft engines are known to be susceptible to fretting corrosion (Ref 74):

- Airfoil roots in rotors and stators
- Stator vanes and shroud interfaces
- Splines and root assembly stackup interfaces
- Piston ring secondary seals
- Torque pins for seal mountings
- Fasteners, including threads, the surfaces of bolted joints, and disconnect rings
- Metal static seals
- Engine mounts and thrust links
- Slip joints, which are used in burners and tubing assemblies
- Disk spacers
- Planetary gear shafts (Fig. 37). These parts have incurred fretting damage primarily in the gear bore. A smaller amount of fretting deterioration has also been observed in the bearing bore
- Clutches
- Joints and interfaces between titanium, aluminum, and austenitic stainless steel parts

The most significant fretting problems in aircraft powerplants have occurred in seals, splines, blade mountings, and blade dampers (Ref 74).

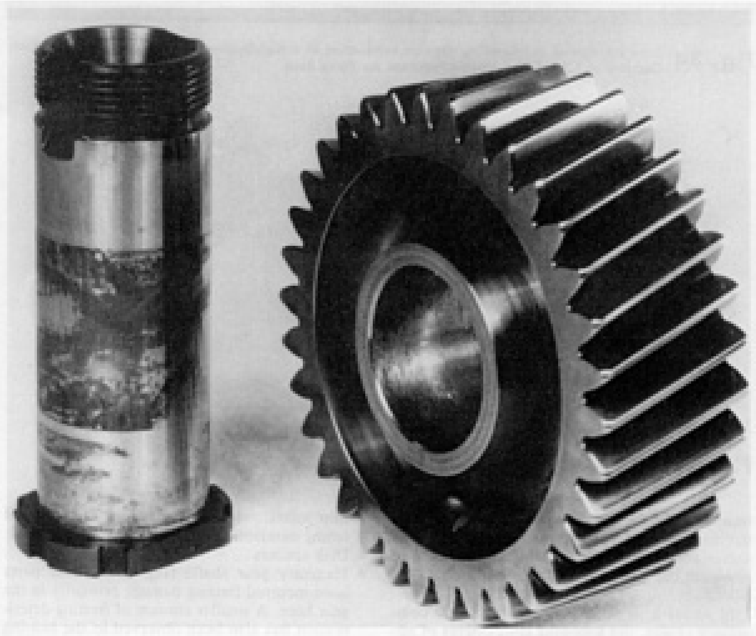

Fig. 37 Fretting corrosion of a planetary gear shaft from an aircraft powerplant. Courtesy of the Advisory Group for Aerospace Research and Development

The damage produced by fretting corrosion usually appears as pitting, polishing, or both. Galling is produced in powerplant structures when fretting continues over relatively long periods of time (Ref 74). Both galling and fretting have been observed on oil-film dampers that are coupled with thrust washers. Additional powerplant components that have been subject to fretting are discussed below.

Over-Running Clutches. These components are used in helicopter drive trains (Ref 74). Figure 38 shows the fretting damage that has been observed in the powerplant components. This problem is caused by vibration (and rubbing) of the balls in the inner and outer races of bearings that support the rotor shaft. These inner and outer bearing races rotate at the same speed when the over-running clutches are engaged (Ref 74).

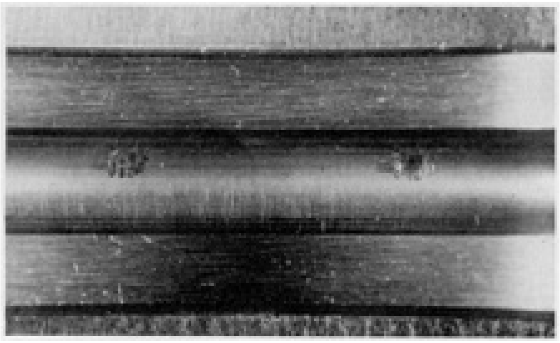

Fig. 38 Fretting corrosion of the bearing race of an aircraft powerplant over-running clutch. Courtesy of the Advisory Group for Aerospace Research and Development

Splines. In one case involving fretting on a compressor-turbine shaft spline, the spline failed and resulted in an engine fire, which caused the aircraft to crash. A spline structure surface that suffered fretting corrosion damage is shown in Fig. 39.

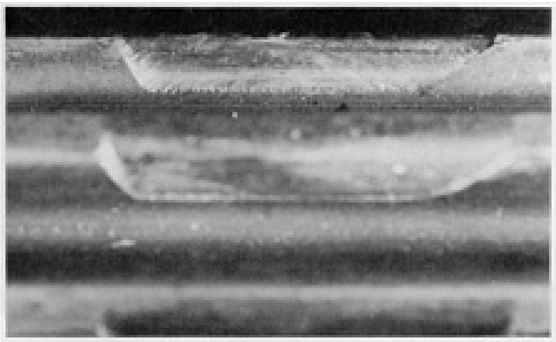

Fig. 39 Fretting corrosion on an aircraft powerplant spline structure. Courtesy of the Advisory Group for Aerospace Research and Development

Fretting of splines is inhibited by maintaining a lubricating oil film on the surfaces of these parts. Solid film lubrication has proved to be an effective antifretting treatment for splines. The use of beryllium-copper material instead of SAE 4140 steel has also enhanced the fretting resistance of powerplant spline structures (Ref 74). Applications of vacuum coatings, such as by sputtering or ion plating, have also proved to be effective in alleviating spline fretting corrosion problems (Ref 74). Components that have been subject to fretting corrosion are discussed below.

Powerplant Rotor Blade Root Mounting Surfaces. An illustration of this fretting corrosion problem is provided in Fig. 40. Fatigue cracks can propagate as a result of this fretting damage, leading to eventual failure of these blades. Plasma-sprayed coatings, which have good adherence and friction-reducing properties, can be applied to blade surfaces in order to minimize the deterioration and subsequent mechanical failures caused by fretting.

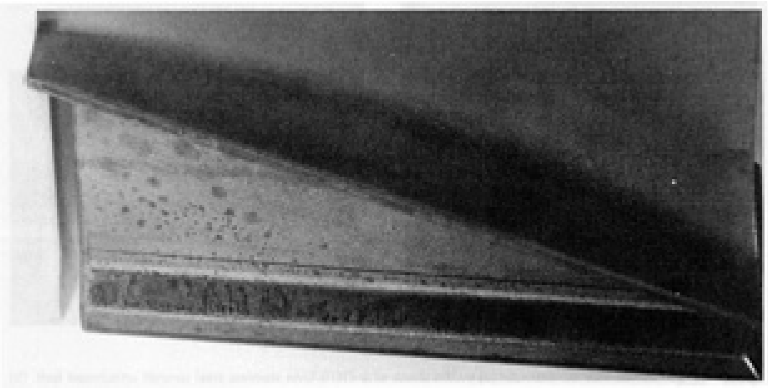

Fig. 40 Fretting corrosion on the root surface of an aircraft powerplant compressor blade. Courtesy of the Advisory Group for Aerospace Research and Development

Helicopter Reciprocating Engine Connecting Rod. This component failed in flight by fatigue that was caused by fretting corrosion on a small area on the bore of the connecting rod (Ref 55). Fretting corrosion developed in this connecting rod because the shell bearing, inside of the large-end bore of the rod, moved in a rapid rotational-oscillatory manner. The design solution to this problem was to increase the circumference of the shell bearings and to apply greater torquing force onto the bolts. This sufficiently reduced the rotational-oscillatory movement that had caused this problem, and further fretting corrosion was prevented (Ref 55).

Low-Pressure Compressor Casing. This part was made from magnesium alloy EZ33. Fretting corrosion occurred on this component because of mechanical rubbing action by a row of steel stator vanes on an annular ring. Because this fretting damage resulted from contact between dissimilar metals (steel against magnesium), this incident is an example of fretting corrosion that occurred in a dissimilar-metal couple (Ref 55). The softer metal in the couple (EZ33 magnesium) was damaged more severely than the harder metal (steel). This problem can be alleviated by changing the EZ33 magnesium casing material to a harder, more wear-resistant alloy or by applying a wear-resistant (hard-facing) coating to the areas of the EZ33 magnesium casing that will come into contact with the steel stator vanes.

Stress-corrosion cracking has been reported as the dominant type of deterioration in the following failures of aircraft powerplant components.

Engine Exhaust Tailcone Assembly (Ref 5). A large section (about one-third) of this component fell away from an A-7D aircraft during flight. Circumferential resistance-welded stiffeners (Fig. 41) were used for stabilizing the tailcone structure on the outer surface of the assembly. The material used in the manufacture of this powerplant assembly was corrosion-resistant steel. In addition to SCC, intergranular degradation was observed where the tailcone was welded to the circumferential stiffener. During the analysis of this failure, the A-286 alloy was found to be prone to intergranular corrosion due to the formation of precipitates in the grain boundaries of the A-286 material.

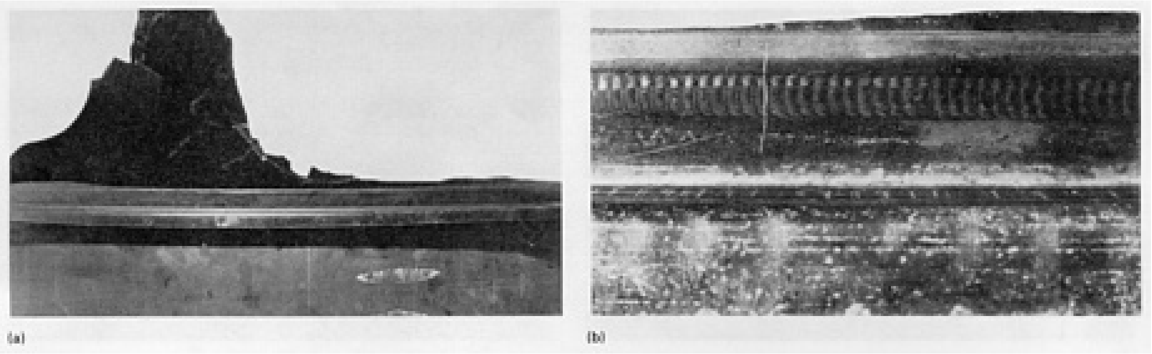

Fig. 41 Circumferential stiffener (a) from a tailcone assembly that fell off an aircraft during flight. (b) Resistance weld on the stiffener in (a). Source: Ref 5

High-Pressure Powerplant Compressor Vane (Ref 39). This failure occurred on a military fighter aircraft. The SCC originated at a point on the vane where pitting corrosion had developed. Several actions have been taken to prevent future powerplant vane failures, including changing the vane material, coating the vanes (nickel plating was one of the evaluated coatings), and periodically washing the compressor with water.

Pitting Corrosion. Cases involving pitting corrosion in powerplant components have developed over a relatively long period of time as compared to other types of ambient-temperature corrosion. The pitting corrosion of rotor and stator blades made of low-alloy steels and martensitic stainless steels is a significant powerplant deterioration problem that has produced fatigue failures and compressor stalls (Ref 75). The severity of these pitting problems was reduced by using better coatings and by applying improved corrosion control procedures, such as washing of the unprotected parts with water and inhibitors (Ref 76). Several types of coatings have been applied for the alleviation of pitting corrosion in these steel parts, including (Ref 77, 78):

- Paint
- Overlay coatings
- Metal-ceramic barrier coatings
- Nickel-cadmium diffusion coatings

A proposed solution to this problem was to change the blade material from steel to a nickel-base superalloy, IN-718 (Ref 77). The cost of this material change, however, would be significantly greater than the alternative of applying a specific coating to these parts. Powerplant blades and vanes can be coated with aluminum for pitting corrosion protection. Aluminum coatings can be applied by using the following techniques:

- The slurry method (Ref 79)
- Pack diffusion (Ref 79)
- Hot dipping and diffusion treatments (Ref 79)
- Ion vapor deposition (Ref 80)

Pitting corrosion has occurred in powerplant compressor stator vanes despite the use of a ceramic barrier coating material (Ref 81). Severe pitting was noted in this case. Some of the pits developed at critical locations, where the strength of the stator vane could be adversely affected. Inadequate process controls during the application of the ceramic slurry (bisque) to the stator vanes contributed to the rapid acceleration of the pitting corrosion that occurred in this case (Ref 81). Additional incidents involving pitting corrosion in powerplant components are discussed below.

AM-355 Stainless Steel Compressor Blades (Ref 81). Severe pitting corrosion was observed in the dovetail section, which is where the blade meets the compressor wheel. This problem was solved by replacing the pitted blades

and by applying corrosion inhibitors to the newly installed parts. Pitting corrosion was prevented by the application of two different corrosion-preventive compounds (Ref 81).

Thrust Reverser Doors (Ref 55). Pitting corrosion caused the in-flight detachment of the thrust reverser doors of a commercial aircraft. One of the thrust reverser door driver links fractured because of fatigue. The fatigue crack started where pitting corrosion developed on the surface of the driver link, which was fabricated from type 422 stainless steel. The driver link had been coated with a dry-film lubricant consisting of molybdenum disulfide. Pitting damage in the stainless steel part was caused by the accumulation of fuel combustion by-products and moisture in localized areas where the coating was defective. Preventive measures that can be taken to eliminate this problem and similar problems consist of: (1) reducing the high stress level in the thrust reverser door drive link (this is a longer-term solution because it would require a redesign of the drive link); (2) recoating the links with a more protective material, which will prevent the future development of pitting corrosion; and (3) establishing a continuous inspection program to ensure that corrosion is identified early, if it occurs.

Engine Exhaust Valve (Ref 55). This fatigue failure occurred during the flight of a single-engine aircraft. The fatigue-induced fracture started at a local area on the valve stem that was severely damage by pitting corrosion. Pitting reduced the section diameter of the exhaust valve (near the location of the fracture) by about 0.25 mm (0.01 in.). This pitting deterioration was produced by acidic compounds in old engine oil that had not been drained and replaced with new oil. Timely draining and replacement of engine oil is required to maintain the required concentration of corrosion inhibitors in the oil for preservation of the engine components.

Erosion-Corrosion and Cavitation. Erosion-corrosion occurs when solid particles collide at high velocities with powerplant components. This action removes the protective coatings and oxide films, resulting in corrosion of the unprotected metallic parts.

Cavitation produces deterioration of power-plant components by the high-velocity impingement of water droplets on these parts. Titanium is one of the best materials to use in turbine blades for resistance to cavitation (Ref 67).

Severe erosion problems have developed in magnesium splitter vanes (Ref 75). The Naval Air Development Center has studied the use of explosively welded aluminum claddings as a possible solution to this problem. Aluminum alloy substitutions have also been considered as a solution to erosion-corrosion problems in magnesium air inlet housing (Ref 76). Erosion attack has been especially noted in the air stream where protective coatings had worn away (Ref 76).

Hot desert climates can cause very severe erosion-corrosion problems in aircraft that operate in this type of environment (Ref 55). Dust and sand, with high salt concentrations, can erode surface finishes on powerplant components. Corrosion is accelerated by the extremely high temperatures that are reached in desert areas.

Erosion-corrosion has a high probability of occurring on various powerplant parts, including the following:

- Impellers
- Compressor blades
- Turbine blades
- Turbine nozzles
- Turbine guide vanes

These powerplant components are vulnerable to erosion-corrosion that is caused by solid particles that impact these parts in the air intake area or in the hot gas stream. Powerplant components can be protected from erosion-corrosion by coatings that consist of hard, erosion-resistant materials. Many new erosion-resistant coatings are currently being evaluated (Ref 55).

Miscellaneous Types of Powerplant Corrosion

This discussion will cover various case histories regarding powerplant corrosion. The types of deterioration that caused these corrosion incidents are general corrosion; chemical corrosion, which is produced by chemical spills; intergranular corrosion; and corrosion fatigue.

General corrosion was found on aluminum-brazed titanium tailpipe extensions that were attached to the engine of a commercial aircraft (Ref 82). This deterioration was observed at the conclusion of a 3-year in-service evaluation of these tailpipe extensions. Among the factors that contributed to this corrosion problem were operation of the aircraft in rainy and humid conditions and a hydrophilic and sooty coating on the inner surfaces of the tailpipes.

The skins, or outer surfaces, of the tailpipe extension surrounded a honeycomb core. The skins were perforated for sound attenuation. The perforation resulted in atmospheric exposure and subsequent corrosion of the aluminum-brazed titanium component.

The hydrophilic (sooty) coating and the general corrosion are illustrated in Fig. 42. As a result of this case, it was concluded that aluminum-brazed titanium is not a suitable material for jet engine tailpipes that have perforated skins and honeycomb cores.

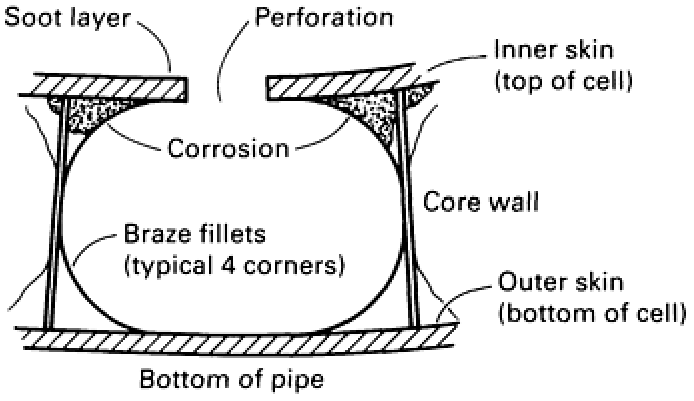

Fig. 42 Schematic showing an individual cell of a honeycomb sandwich engine tailpipe that failed because of corrosion

Chemical corrosion has been documented for components of the F-14 aircraft radar antenna hydraulic drive system (Ref 83). Corrosion on the internal surfaces of these parts was produced by contamination of the hydraulic fluid by water and halogenated solvents, primarily trichlorotrifluoroethane. The concentrations of these liquid contaminants exceeded the limits of the hydraulic oil specification (MIL-H-5606). These limits were 25 ppm for halogenated solvents and 150 ppm for water (Ref 83). The parts that were damaged consisted of 4130, nitralloy, and tool steels.

This corrosion did not lead to a failure of the hydraulic drive system. However, the long-term effect would have been a reduction in the reliability of the system. This problem was eliminated by ensuring that periodic draining and refilling with fresh hydraulic fluid was performed. This use of vacuum degassing procedures and desiccant filters also helped to alleviate this deterioration problem (Ref 83).

The emergency power unit of the F-16 military aircraft contains mixed hydrazine fuel consisting of 70% hydrazine and 30% water (Ref 84). Although this fuel can cause serious corrosion problems, no such cases have been published. Hydrazine-induced deterioration has been prevented on the F-16 emergency power unit by the development and application of an epoxy-type sealant that is resistant to hydrazine (Ref 84).

Intergranular corrosion was found to be the cause of a failure of a light aircraft engine exhaust pipe (Ref 55). The exhaust pipe separated from the aircraft engine during flight. The fracturing of the austenitic stainless steel pipe had occurred near its flange support. Intergranular corrosion cracks produced stress concentration sites. These stress raisers initiated fatigue due to vibration of the exhaust pipe and a muffler that was attached to the pipe. The muffler was cantilevered and unsupported--a design that produced high cyclic stresses, which was a major cause of the exhaust pipe failure.

The severely corrosive environment produced by exposure of the pipe to combustion by-products and condensates at high and low temperatures also played a major role in initiating the fracture of the exhaust pipe. It is possible that the exposure of the austenitic stainless steel to hot exhaust gases caused the sensitization of the steel. When sensitization occurs, the

grain boundaries become susceptible to intergranular corrosion. A greater degree of microstructural stability can be achieved in austenitic steels by reducing the carbon content of these materials (see the article "Corrosion of Stainless Steels" in this Volume). This intergranular corrosion problem was solved by adding a structural support for the muffler in order to minimize the level of cyclic stress that this component would have to endure.

Corrosion fatigue has been reported as the cause of failure of an aircraft powerplant rocker-arm journal bearing. The bearing surface was examined, and deep pits and score marks were found (Ref 55). Fatigue cracks were observed to propagate radially from cavities along the surface of this part. This journal bearing was determined to be cast aluminum alloy 242. It was determined that there was gross porosity in the bearing casting. The material was therefore unsatisfactory for fatigue-critical applications. Proper quality control during the metallurgical processing of the casting to prevent porosity would have helped to produce a stronger, more fatigue-resistant part. General corrosion abetted the failure process.

Corrosion fatigue has also been reported to be the cause of steel engine shaft failures. These failures can originate at bolt holes or at the roots of gear teeth. The original corrosion damage then propagates by fatigue (Ref 85).

The Air Force Wright Aeronautical Laboratories' Materials Laboratory Structural Failure Analysis Group is responsible for performing metallurgical failure analyses on a variety of aircraft structural components. This includes airframes, propulsion and missile systems, and ground support equipment. Some of these analyses concern failures that occurred by corrosion mechanisms. This number has averaged approximately 15% of the total analyzed failures for the last several years. Most of these incidences are either manufacturing/quality control related or involve materials and/or heat treatments used in older systems. The following discussions represent a number of case histories of failures associated with corrosion and the recommended corrective actions to preclude repetitive occurrences.

Examples of Aircraft Structural Corrosion Failures

Example 1: Aircraft Attachment Bolt Failure.

During a routine inspection on an aircraft assembly line, an airframe attachment bolt was found to be broken. The bolt was one of 12 that attach the lower outboard longeron to the wing carry through structure. Failure occurred on the right-hand forward bolt in this longeron splice attachment. The bolt was fabricated from PH13-8Mo stainless steel heat treated to have an ultimate tensile strength of 1517 to 1655 MPa (220 to 240 ksi). A water-soluble coolant was used in drilling the bolt hole where this fastener was inserted.

Investigation. Figure 43(a) shows a bolt shank with corrosion evident on surfaces in contact with the splice joint, while Fig. 43(b) shows the fracture and initiation site of the bolt failure. Surface pitting on the bolt shank and subsequent corrosion cracking are shown. Scanning electron microscopy (SEM) examination of the fracture revealed the topography to be intergranular at the initiation site and to a depth of 8.4 mm (0.33 in.) (Fig. 43c). The remainder of the fracture showed a mixed topography of cleavage and ductile dimples (Fig. 43d).

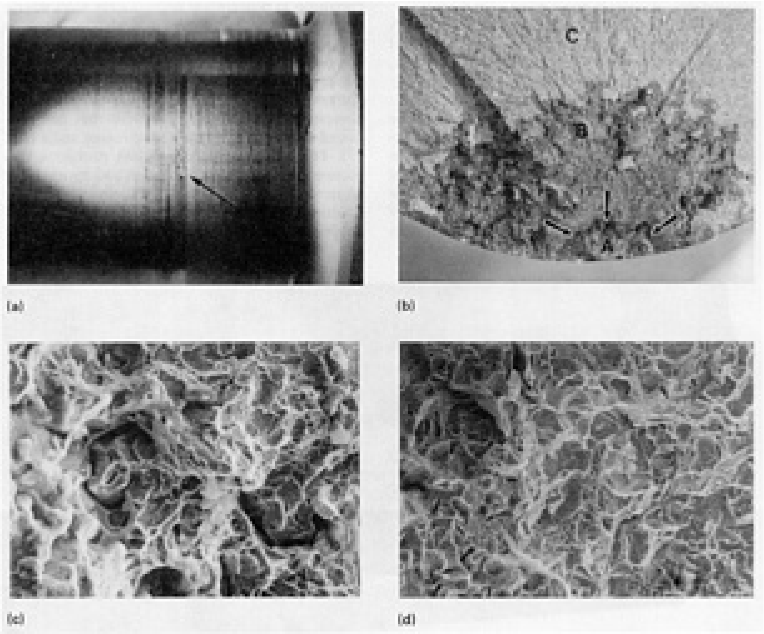

Fig. 43 Parallel lines of corrosion (a) on the shank of a PH13-8Mo stainless steel aircraft attachment bolt. (b) Close-up of fracture surface of bolt showing corroded area. Arrows point to one possible crack arrest line. (c) SEM fractograph of area in B in Fig. 2. Note corrosion product (left) and ductile dimples in the center. 265×. (d) SEM fractograph of area C in (b). Area of fast fracture shows cleavage and dimples. 265×

Examination of corrosion products on the fracture by Auger emission spectroscopy and secondary imaging spectroscopy showed the presence of elements typically found in tap water. Chemical analysis of the bolt material showed the composition to be within specification limits for PH13-8Mo stainless steel. Rockwell C hardness measurements taken on the bolt produced values ranging from 47 to 48 HRC, which would correspond to the specified ultimate tensile strength of 1517 to 1655 MPa (220 to 240 ksi).

Conclusion. It was concluded from the study that failure of the attachment bolt was caused by stress corrosion. The source of the corrosive media was the water-soluble coolant used in boring the bolt holes.

Recommendations consisted of inspecting for corrosion all the bolts that were installed using the water-soluble coolant at the spliced joint areas, rinsing all machined bolt holes with a noncorrosive agent, and installing new PH13-8Mo stainless steel bolts with a polysulfide wet sealant.

Example 2: Failure by SCC of an Ejection Seat Swivel.

A routine examination on a seat ejection system found that the catapult attachment swivel contained cracks on opposite sides of the part. This swivel, or bath tub, does not experience any extreme loads prior to activation of the catapult system. Some loads could be absorbed, however, when the aircraft is subjected to G loads. The bath tub is fabricated from aluminum alloy 7075-T651 plate.

Investigation. Visual examination of the part revealed that cracks were positioned near the base of the bath tub configuration and extended through the wall thickness. One of the cracks was opened (Fig. 44a); this indicated that the fractures initiated on the inner walls of the fixture.

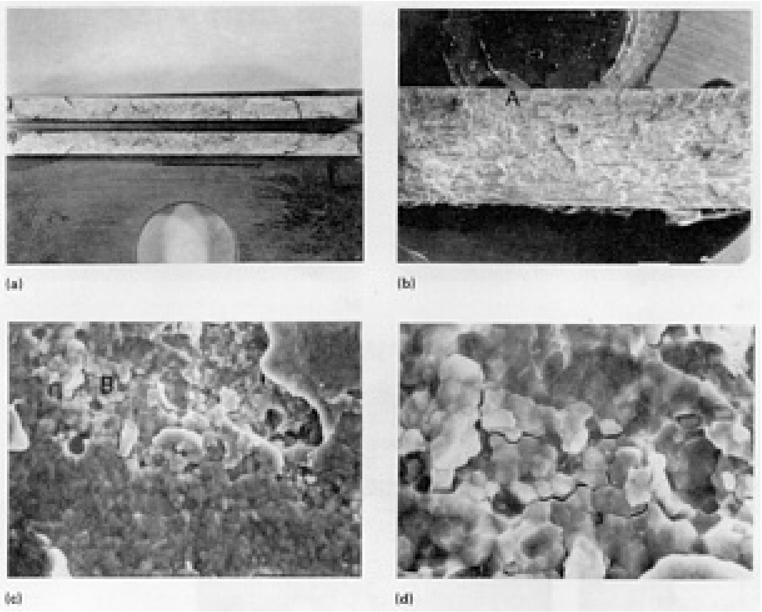

Fig. 44 Opened crack (a) in aluminum alloy 7075-T651 ejection seat swivel fixture that failed by SCC. Note crack propagation markings that suggest the crack initiated on the inside wall of the fixture and woody appearance of the fracture. (b) Higher-magnification view of fracture surface from (a). Note woody appearance, which indicates a precrack mechanism. The inner wall of the fixture is at the top. 5×. (c) SEM fractograph of area A from (b). Note slight intergranular appearance of structure. 425×. (d) SEM fractograph of area B from (c) showing intergranular facets on the fracture surface. 1060×

Electron optical examination of the fracture at low magnifications revealed a woody appearing topography (Fig. 44b). Further electron optical examination of the fracture at 800 and 2000× (Fig. 44c and d) showed that the cracking pattern initiated and progressed by an intergranular failure mechanism. This fracture topography indicated that cracking was due to stress corrosion.

Examination of the microstructure near the fracture revealed that the crack was progressing parallel to the transverse grain flow direction and further suggested SCC. Chemical analysis and hardness tests conducted on the submitted material showed it to be within specification requirements for 7075-T651 aluminum base material.

Conclusion and Recommendation. It was concluded that failure of the catapult attachment swivel fixture occurred by SCC, and it was recommended that the 7075 aluminum ejection seat fixture be supplied in the T-73 temper to minimize susceptibility to SCC.

Example 3: Cracking of an Aircraft Wing Bracket.

During an inspection cycle, cracking was detected in a wing fillet flap bracket. The cracking was located on the end of the bracket, as shown in Fig. 45(a). The configuration of the end of the bracket suggested that a bushing and rod were integral working components to the bracket hardware.

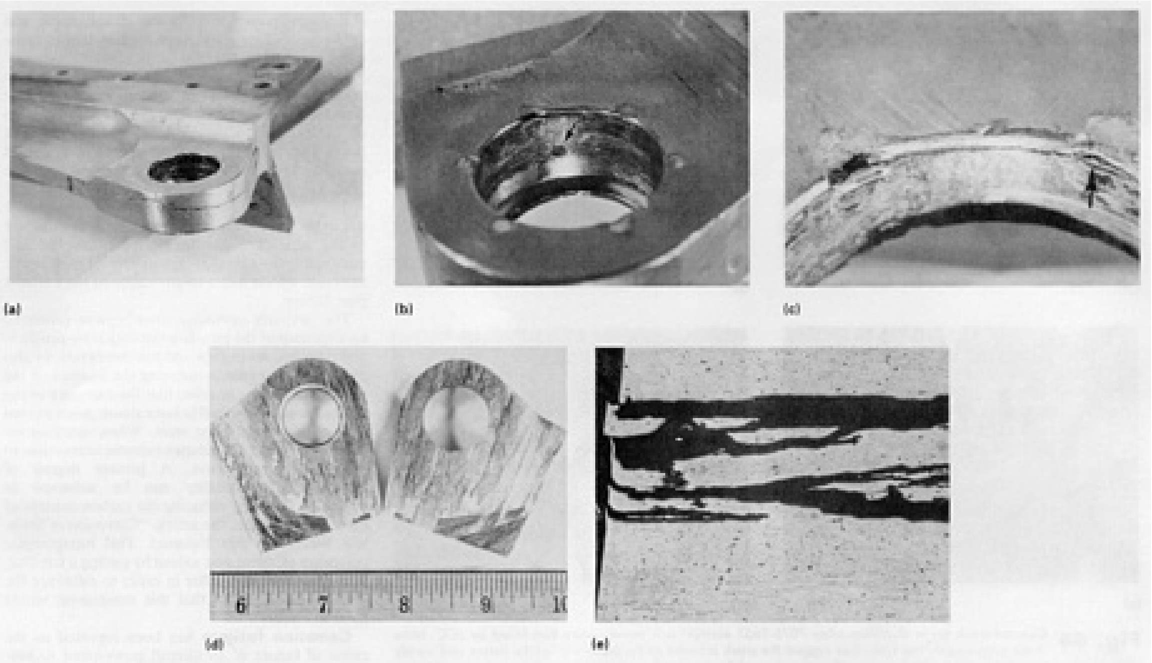

Fig. 45 End of aluminum alloy 7178-T6 aircraft wing bracket (a) showing cracking. (b) View of bracket showing symmetrical indentations on the top surface. Arrow shows a pit on the inner wall. 1×. (c) Close-up of indentations showing deformed surface (arrow) indicating directional movement of the bushing. 4×. (d) Failed fracture surfaces of bracket showing the woody fracture appearance characteristic of exfoliation. (e) Cross section of bracket showing delamination caused by exfoliation. 105×

Investigation. Visual examination of the bushing seat are showed the presence of surface corrosion pits (Fig. 45b). Also shown are six symmetrical indentations that were produced during staking to prevent shifting of the bushing. Further visual examination revealed deformation adjacent to the indentations (Fig. 45c), indicating that the bushing had deformed the material.

Optical examination of the opened fracture showed a woody, delaminated, fibrous-textured fractured surface (Fig. 45d). These fracture characteristics indicated that failure progressed by exfoliation corrosion. A cross section taken through the fracture surface revealed the presence of delamination due to exfoliation, as shown in Fig. 45(e).

A chemical analysis of the material revealed it to be within specification for the required aluminum alloy 7178 except for a slightly lower than required zinc percentage. A hardness survey taken on the hardware found the values to range from 85 to 87 HRB and suggested that the material was in the T-6 condition.

Conclusions. From this analysis, it was concluded that failure of the wing fillet flap bracket was due to surface corrosion pits on the extrusion bracket hole wall surface. Crack progression occurred by exfoliation corrosion and was aided by a contributing stress introduced by movement of the bushing.

Recommendations. It was recommended that a material substitution be made of the 7178-T6 material because of its susceptibility to exfoliation corrosion. Candidate replacements included aluminum alloys 7175, 7050, or 7049.

Example 4: Failure of an Aircraft Controller Diaphragm.

The diaphragm from a side controller was found during a preflight inspection to be broken. The controller diaphragm was fabricated from 17-7PH stainless steel in the RH 950 heat treatment condition. Failure occurred by cracking of the base of the flangelike diaphragm. The crack traveled 360° around the diaphragm.

Investigation. Examination of the submitted piece by SEM revealed that the failure occurred by a brittle intergranular mechanism and indicated a failure mode of selective grain-boundary separation (Fig. 46a and b). The diaphragms are heat treated in batches of 25. An improper heat treatment could have resulted in the formation of grain-boundary precipitates.

These grain-boundary precipitates would include chromium carbides. A loss of chromium from the matrix adjacent to the grain boundaries increases the susceptibility of this material to grain-boundary attack by oxidizing media. This action could result in intergranular corrosion and/or SCC if the part was placed under load in an oxidizing medium.

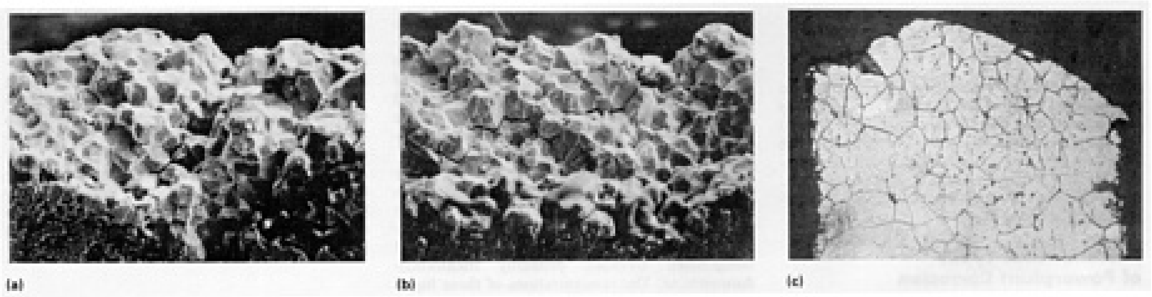

Fig. 46 SEM of fracture surface (a) from a failed 17-7PH stainless steel aircraft controller diaphragm showing intergranular fracture indicative of SCC. 170×. (b) SEM fractograph of area adjacent to that shown in (a) showing intergranular fracture, secondary cracking, and little or no evidence of ductility; this suggested a brittle fracture mechanism. 170×. (c) Microstructure of diaphragm taken perpendicular to the fracture face. The carbide network at the grain boundaries is evident. 210×

Metallographic examination of a section taken perpendicular to the fracture revealed a martensitic structure with grain-boundary attack on the outer surfaces. The grain-boundary attack most probably occurred during heat treatment. Figure 46(c) shows a microstructure that was etched to reveal the presence of carbide precipitates. The grain-boundary network of carbides strongly suggested that the material was exposed to an adverse heat treatment with chromium depletion of the matrix adjacent to the grain boundaries.

Conclusions. It was concluded that failure of the diaphragm was due to a combination of sensitization caused by improper heat treatment and subsequent SCC.

Recommendations. It was recommended that the remaining 24 sensor diaphragms from the affected batch be removed from service. In addition, it was recommended that a sample from each heat treat batch be submitted to the Strauss test (ASTM A 262, practice E) to determine susceptibility to intergranular corrosion. It was also recommended that a stress analysis be performed on the system to determine whether or not a different heat treatment (which would offer lower strength but higher toughness) could be used for this part.

Example 5: Fuel Line Corrosion.

Inspections revealed fuel line corrosion beneath ferrules (Fig. 47). The cause of the corrosion was traced to the fuel line marking process, which involved electrolytic labeling of ferruled aluminum alloy 6061-T6 tubes. Although subsequent rinsing of the fuel lines washed off most of the electrolyte, some was trapped between the 6061-T6 tubing and the ferrule. This condition made corrosion of the fuel lines inevitable.

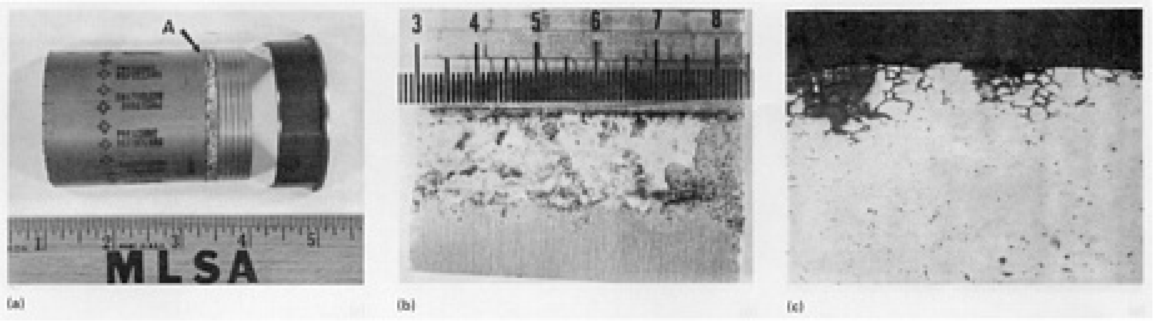

Fig. 47 Corrosion (a) of aluminum alloy 6061-T6 aircraft fuel line (arrow). (b) Close-up of corrosion on fuel line. Note pitting and corrosion products. (c) Intergranular corrosion of the fuel line at area A from (a)

Investigation. Microstructural analysis revealed extensive intergranular corrosion of the 6061-T6 tubing beneath the ferrule (Fig. 47c). This attack caused grains to become dislodged, giving the appearance of pitting. Corrosion penetrated approximately 0.13 mm (0.005 in.) into the tubing.

In an attempt to determine if the corrosion products were active, two specimens from the corroded fuel lines with corrosion products were mounted and soaked in distilled water at room temperature for 2 and 4 days. The 2-day exposure resulted in a localized intergranular corrosion on the inside diameter of the tubing, while the 4-day exposure resulted in extensive intergranular corrosion of the tube cross section from the inside diameter to the outside diameter.

Corrosion products from beneath the ferrules were placed on a piece of uncorroded 6061-T6 tubing in an attempt to substantiate further whether or not the corrosion products were active. Electrical tape loosely applied to the specimen held the products in place while the test specimens were submersed in distilled water for 5 days. Subsequent inspection of the specimen revealed that corrosion did not occur during the 5 days.

Emission spectroscopy of the corrosion products showed that small amounts of aluminum (4%), sodium (3%), cobalt (2%), chromium (0.35%), boron (0.25%), and iron (0.05%) were present. The remaining 90% of the material analyzed was nonmetallic.

Conclusions. It was concluded that the marking electrolyte used for labeling was trapped between the 6061-T6 tubing and the ferrule. This fostered intergranular corrosion. Experiments indicated that the corrosion products were inactive.

Recommendations. It was recommended that another marking process be used that does not involve corrosive materials. The prevention of electrolyte from being trapped between the tubing and ferrules by using a MIL-S-8802 sealant was recommended.

Example 6: Corrosion of Aluminum Alloy 7075-T6 Wing Panel.

New aircraft wing panels extruded from 7075-T6 aluminum were reported to be discolored, exhibiting an unusual pattern of circular black interrupted lines (Fig. 48a). The black marks were coherent with the metal and could not be removed by scouring or light sanding. The panels, subsequent to profiling and machining, were required to be penetrated inspected, shotpeened. H_2SO_4 anodized, and coated with MIL-C-27725 integral fuel tank coating on the rib side.

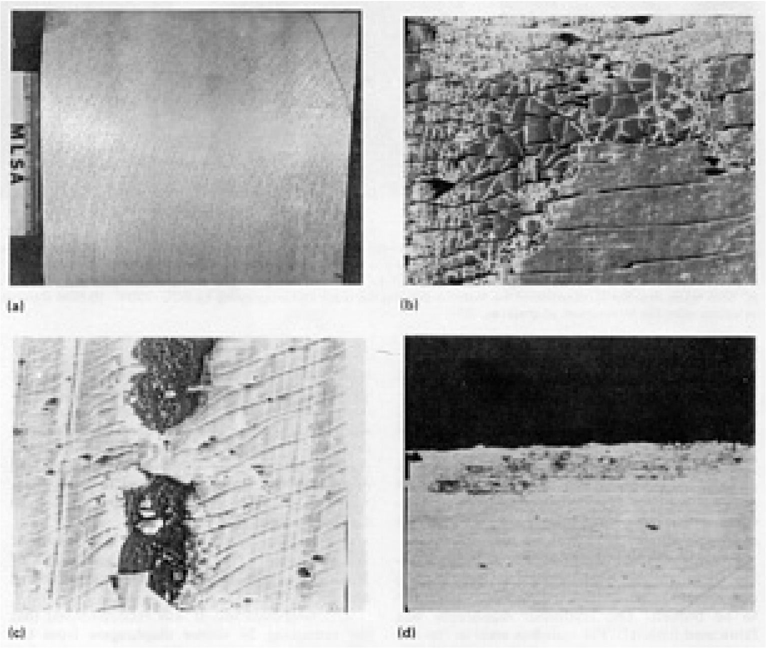

Fig. 48 Aluminum alloy 7075-T6 aircraft wing panel (a) showing unusual surface appearance. (b) SEM of the panel surface showing cracked anodized coating. 160×. (c) SEM showing the anodized coating flaking away and corrosion deposit under the coating. 85×. (d) Cross section of corrosion site on panel showing depth of intergranular attack. 265×

During processing, the extrusions are machined on the flat side, oiled, deburred, hot formed, cleaned, penetrant inspected, covered with oil, and then shotpeened. They are then recoated with oil, shipped to a second vendor, handwiped with a solvent, alkaline cleaned, acid desmutted, sulfuric acid anodized, and hot water sealed.

Investigation. The panels were studied using the scanning electron microscope and microprobe analysis. Both conventional energy-dispersive and Auger analyzers were employed. Figures 48(b) and 48(c) illustrate the contention that the anodic coating was applied over an improperly cleaned and contaminated surface. It was evident that the expanding corrosion product had cracked and in some places had flaked away the anodized coating. The corrodent had penetrated the base aluminum in the form of subsurface intergranular attack (Fig. 48d). The depth of attack was measured to be 0.035 mm (0.0014 in.).

Microprobe analysis of the corrosion product did not reveal any clues concerning the reason or origin of the corrodent. A high sulfur concentration was found associated with the corrosion product and on surface areas away from the products. It was suspected that the origin of the sulfur was the hydrocarbon oil. When the anodized layer was stripped from the panels using a phosphoric-chromic acid solution, the evidence of sulfur disappeared. This same stripping procedure did not remove the black corrosion product.

Energy-dispersive analysis of the corrosion product revealed the presence of iron, calcium, phosphorus, and chromium in excess. No chlorides were detected. Auger spectroscopy revealed the presence of large amounts of carbon and nitrogen. The MIL-C-27725 coating was removed from a portion of the rib side by using a paint stripper. No corrosion or discoloration of the aluminum was observed.

Conclusions. It was concluded that the corrosion of the anodized panel most probably resulted from improper and insufficient cleaning prior to anodizing. The preservation oils used during the various steps of manufacture and their incomplete removal prior to anodizing were highly suspect.

Recommendations. It was recommended that a vapor degreaser be used during cleaning prior to anodizing. A hot inhibited alkaline cleaner was also recommended during cleaning prior to anodizing. The panels should be dichromate sealed after anodizing. The use of deionized water was also recommended during the dichromate sealing operation. In addition, the use of an epoxy primer prior to shipment of the panels was endorsed. Most importantly, surveillance of the

anodizing process itself was emphasized, including continual monitoring of bath acid concentration, solution cleanliness, temperature control, and voltage/amperage control.

Example 7: Cracked Aircraft Wing Spar.

A crack (Fig. 49) was found in an aircraft main wing spar flange fabricated from aluminum alloy 7079-T6 during a routine nondestructive x-ray inspection after the craft had logged 300 h.

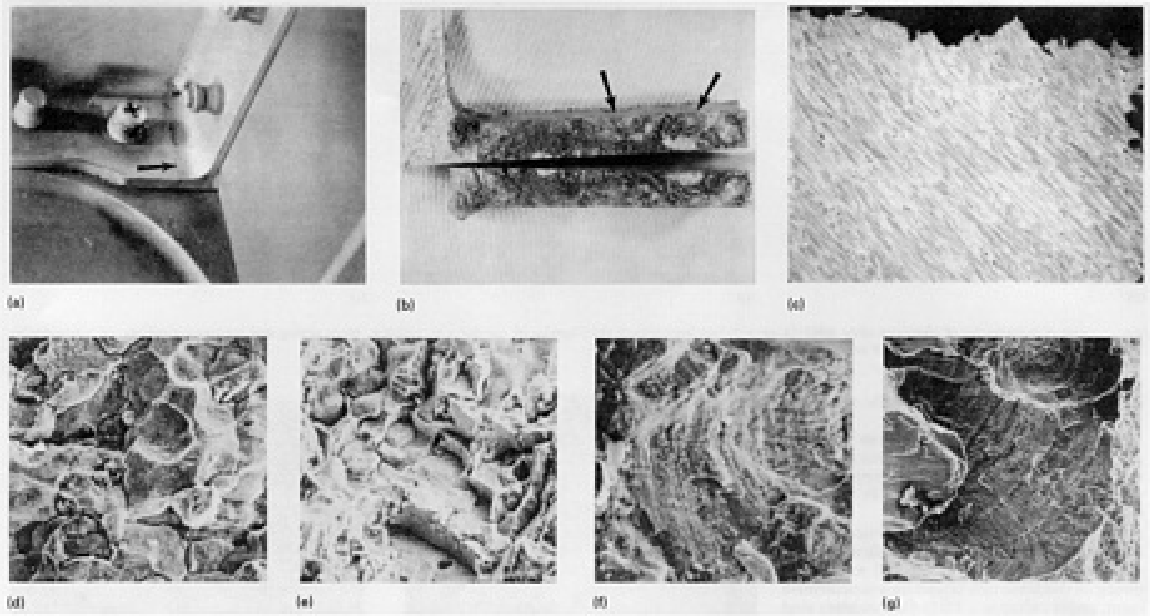

Fig. 49 Aluminum alloy 7079-T6 aircraft wing spar (a) showing crack (arrow). (b) Fracture surfaces of opened spar crack. Note clamshell marks at termination of the crack (left). Suspected multiple initiation sites are located between arrows. 1.5×. (c) Section of flange with surface at right. Grain flow in this area was at an angle to applied stress, which resulted in end grain exposure. 105×. (d) SEM fractograph taken between the arrows in (b). Note intergranular fracture pattern indicative of SCC. 95×. (e) SEM taken near the termination of the fracture showing the crack still progressing by SCC. 190×. (f) SEM showing fatigue striations near the crack origin. 235×. (g) Fatigue striations near the termination of cracking. 30×

Investigation. Visual examination of the crack edge shown in Fig. 49(a) revealed that the installation of the fasteners produced a fit up stress, as indicated by the approximate 0.75-mm (0.03-in.) springback of the flange after the crack propagated through the hardware. Further inspection of the opened fracture (Fig. 49b) showed that the crack had been present for some time because a heavy buildup of corrosion products was seen on the fractured surface. The fracture initiated at multiple origins between the arrows shown in Fig. 49(b). Metallographic examination of the flange in the area of fracture initiation showed the presence of end grain exposure (Fig. 49c), which would promote SCC.

Electron optical examination of the fracture shown in Fig. 49(b) produced the scanning electron fractographs shown in Fig. 49(d) to (g). Figures 49(d) and 49(e) show an intergranular topography, while the fractographs in Fig. 49(f) and 49(g) reveal fatigue striations. This clearly shows the flange was cracking by a mixed mode of stress corrosion and fatigue.

Chemical analysis of the flange showed that the material met compositional requirements for 7079 aluminum base material. Hardness measurement of 85 HRB showed the material was in the T-6 heat treat condition.

Conclusions. It was concluded that the cracking of the flange occurred by a combination of stress corrosion and fatigue. The cracking was accelerated because of an inadvertent fit up stress during installation. The age of the crack could not be established. However, a reevaluation of prior x-ray inspections in this area would result in some close estimate of the age of the crack. End grain exposure further promoted SCC.

Example 8: SCC of Pitostatic System Connectors.

Pitostatic system connectors were being found cracked on several aircraft. The cracks were not restricted to any particular group of aircraft. Two of the cracked connectors were submitted for failure analysis. Both were reportedly made of 2024-T351 aluminum. The connectors had cut pipelike threads that are sealed with teflon-type tape when installed.

Investigation. Longitudinal cracks were located near the opening of the female ends of each connector (Fig. 50a). Both connectors had the same size female end but different size male ends. The connector with the large diameter and longer male end had two cracks, while the connector with the small diameter and shorter male end had only one crack. This size difference was believed to have had no bearing on the cracking.

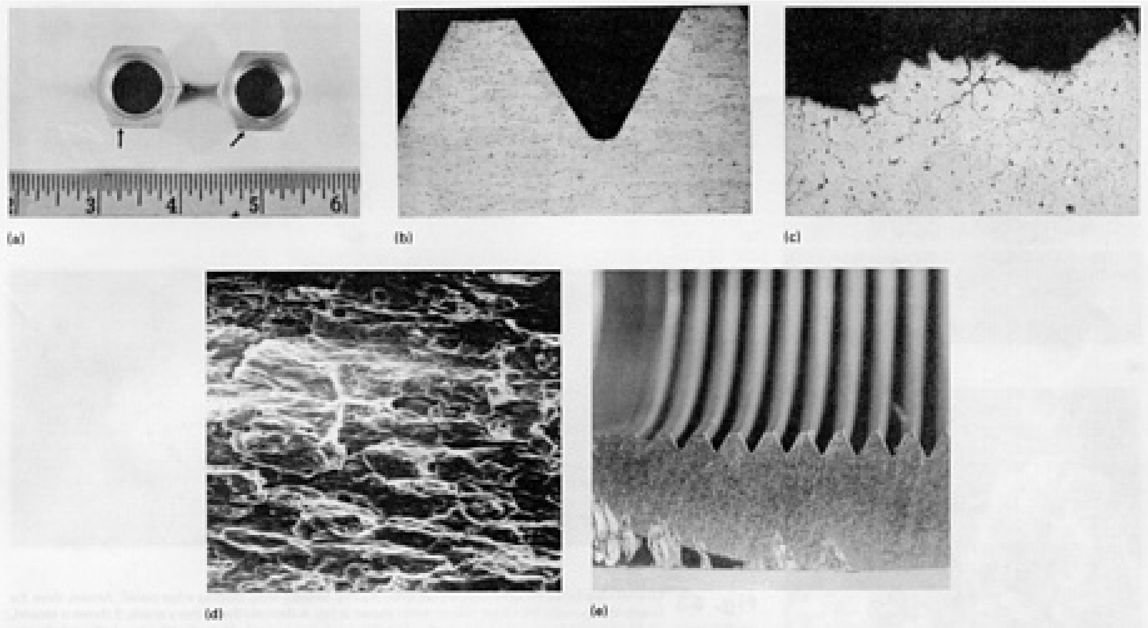

Fig. 50 Top view (a) of cracked aluminum alloy 2024-T351 pitostatic connectors. Arrows indicate cracks. (b) Cross section of one connector showing elongated grains that were cut to form connector threads. 25× (c) Cross section showing intergranular cracking with multiple branching in one connector. 105×. (d) SEM fractograph showing intergranular cracking and separation of elongated grains. 130×. (e) Cross section of connector threads showing incomplete thread form resulting from improper tapping

The connector with the large male end was sectioned, and part of the fracture was metallographically examined. The connector exhibited an elongated recrystallized grain structure with cut threads (Fig. 50b). A cross section through the fracture showed intergranular cracking and branching of the crack (Fig. 50c), characteristic of SCC.

Corrosion deposits were chemically removed from one section of the fracture surface, and the surface was examined in the scanning electron microscope. The fracture surface exhibited intergranular cracking of elongated grains (Fig. 50d).

A section of the connector with the large male end and some thin transparent film found on the threads of the connector were chemically analyzed. The connector was determined to be either 2014 or 2017 aluminum alloy, and the film was determined to be fluorinated hydrocarbon teflon-type tape.

Hardness checks on both connectors showed the large male end connector to be 75 HRB and the small male end connector to be 77 HRB. Electrical conductivity checks on both connectors showed the large male end connector to have a conductivity of 31% IACS (International Annealed Copper Standard) and the small male end connector to have a conductivity of 27.5% IACS.

The threads of all connector components were incompletely formed with a bottom tap and therefore produced a tapered or pipe-type thread. The large male end connector had only one to two threads cut full depth (Fig. 50e).

Conclusions. It was concluded that the pitostatic system connectors failed by SCC. The corrodent involved could not be conclusively determined. The stress was caused by forcing the improperly threaded female nut over its fully threaded

male counterpart to effect a seal. The pipelike, incomplete threads produced high hoop stresses when torqued down over a fully formed thread. The one connector tested for chemical composition was not made of 2024 aluminum alloy as reported but of 2017 aluminum. Hardness and conductivity data on both connectors were compatible with a T351 condition for a 2024 alloy.

Recommendations. It was recommended that the pitostatic system connector manufacturing process be revised to produce full-depth threads rather than pseudo pipe threads. It was also recommended that the wall thickness be increased to increase the hoop stress bearing area if pipe threads were to be used. A determination of proper torque values for tightening the connectors was also suggested.

Example 9: Cracking of Aircraft Pylon Strut.

A pylon strut was submitted for failure analysis. Cracks were found in two locations on the ears of the strut (Fig. 51a). Because the part was still intact, the cracks had to be forced open so that the fractures could be examined.

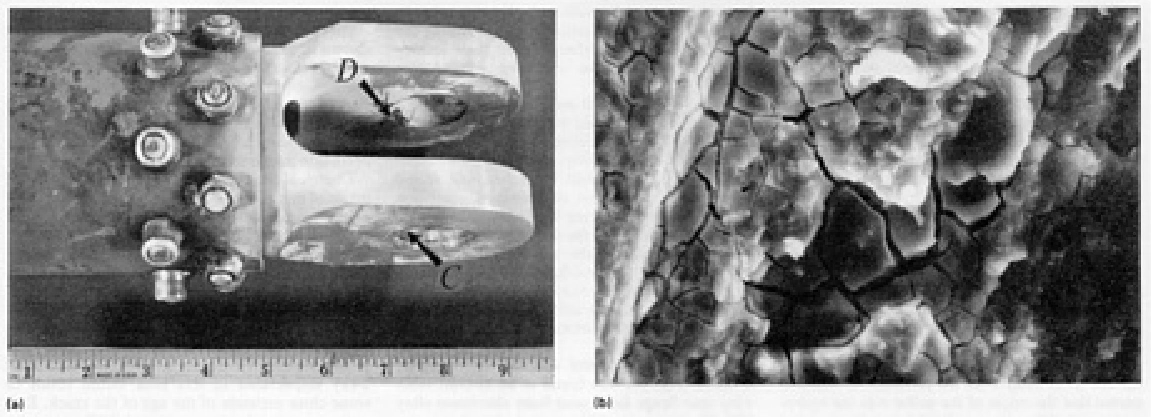

Fig. 51 Cracked aluminum alloy 7075-T6 aircraft pylon strut (a) with arrows indicating cracks. (b) SEM of crack C from (a) showing the mud crack pattern indicative of a corrosion mechanism. 820×

Investigation. Chemical analysis and hardness measurements indicated that the strut was 7075-T6 aluminum. Scanning electron microscopy of the opened cracks showed that the crack surfaces were covered with a mud crack pattern suggestive of SCC (Fig. 51b). The T6 temper is susceptible to SCC.

Conclusions. It was concluded that cracking of the strut could have been aggravated by the hard landing experienced by the aircraft. The strut, however, contained stress-corrosion cracks which were present before the landing.

Recommendation. It was recommended that an inspection for SCC be made of all pylon struts with a similar service life.

Example 10: Corrosion of a Ballast Gas Elbow Assembly.

A cadmium-plated 4340 steel ballast elbow assembly (Fig. 52) was submitted to the laboratory for failure analysis. It was requested that a determination be made regarding the element or radical present in an oxidation product found inside the elbow assembly.

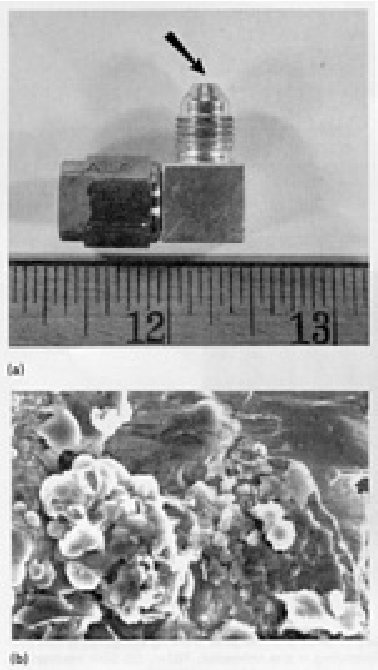

Fig. 52 Cadmium-plated 4340 steel ballast gas elbow assembly (a) with arrow showing hole where corrosion was found. (b) SEM of corrosion products on inside hole surface. 430×

Investigation. It was determined by energy-dispersive x-ray analysis in the SEM that iron was the predominant species, presumably in an oxide form. No cadmium was present inside the hole where oxidation occurred. However, there was cadmium on the outer surface. The inside surface had the appearance of typical corrosion products (Fig. 52b). Hardness measurements indicated that the 4340 steel was heat treated to a strength of approximately 862 MPa (125 ksi).

Conclusions. From these analyses, it was concluded that the oxide detected on the ballast elbow was iron oxide. The possibility that the corrosion products would eventually create a blockage of the affected hole was great considering the small hole diameter (4.2 mm, or $\frac{1}{6}$ in.). It was recommended that a quick fix to stop the corrosion would be to apply a corrosion inhibitor inside the hole. This, however, would cause the possibility of inhibitor buildup and the eventual clogging of the hole.

Recommendations. A change in the manufacturing process to include a cadmium plating on the hole inside surface was recommended. This was to be accomplished in accordance with MIL specification QQ-P-416, Type II, Class 1.

A material change to 300-series stainless steel was also recommended. Its strength is slightly lower than that of the 4340 material, but its corrosion resistance is superior, and no surface treatment would be required.

Example 11: Failure of Aircraft Wing Leading Edge Panel.

Cracks were found on the wing leading edge of a test aircraft. The cracks were located on the inboard side of the No. 2 and No. 3 engines. Crack lengths were approximately 230 mm (9 in.) long on the left side and approximately 130 mm (5 in.) long on the right side. The cracks ran parallel to the leading edge. The 230-mm (9-in.) crack was received for examination.

Investigation. Visual examination of the submitted panel revealed two cracks. One crack ran through six adjacent fastener holes (Fig. 53a and b). A close-up of the fastener holes shown in Fig. 53(c) and (d) revealed that sections of the beveled edges of the holes were missing; corrosion was evident. Further visual examination of the fastener holes after separation of the crack showed that the fracture faces were corroded.

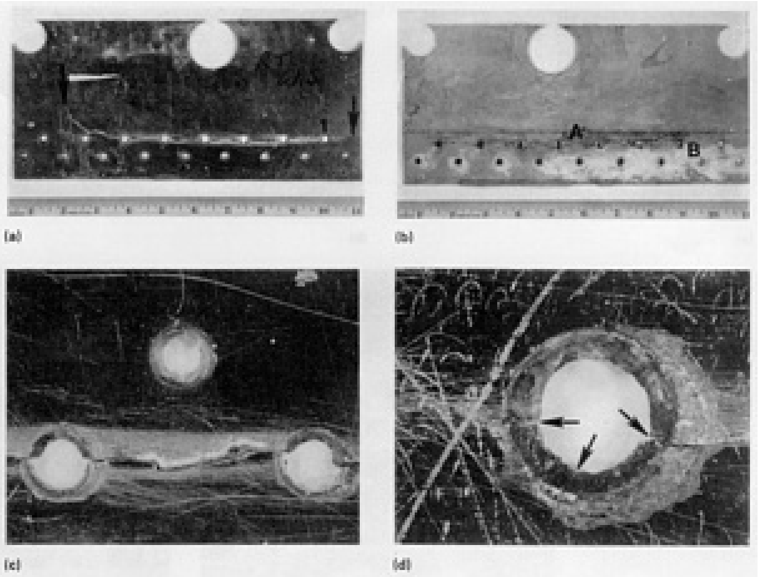

Fig. 53 Overall view (a) of cracked magnesium alloy AZ31B aircraft wing leading edge panel. Arrows show the length of the crack. (b) Other side of panel shown in (a). A denotes the primary crack; B shows a second, smaller crack. (c) Close-up of fastener holes through which the crack progressed. Note that the two bottom holes are not beveled. (d) Close-up of fastener hole showing cracking at three sites (arrows)

Optical examination of either side of the middle group of fastener holes showed that the area of suspected crack initiation had suffered excessive corrosion. Although a slight beach mark appearance was seen adjacent to the holes, a definite cause for the cracking could not be established. Examination of the holes on the end of the crack showed fracture characteristics typical of fatigue and/or corrosion fatigue.

A chemical analysis of the plate material showed the composition to be an AZ31B magnesium alloy.

Conclusion and Recommendation. It was concluded that crack propagation of the fracture in the wing panel occurred by a combination of corrosion and high-cycle fatigue in the end fastener holes. Conclusive proof of the cause of failure initiation in the middle fastener holes was masked by excessive corrosion. It was recommended that future panels be manufactured of 2024 aluminum.

Example 12: Failure of an External Tank Pressure/Vent Valve.

The pressure/vent valve shown in Fig. 54(a) was submitted for laboratory analysis. The external tank pressure/vent valve regulates the external tank fuel feed system, which transfers fuel under pressure to the internal tanks of the aircraft. It is stated in the technical order that when the solenoid of the pressure/vent valve (part A, Fig. 54b) is energized, service air at 448 kPa (65 psig) shifts the dual-position valve (part B, Fig. 54b).

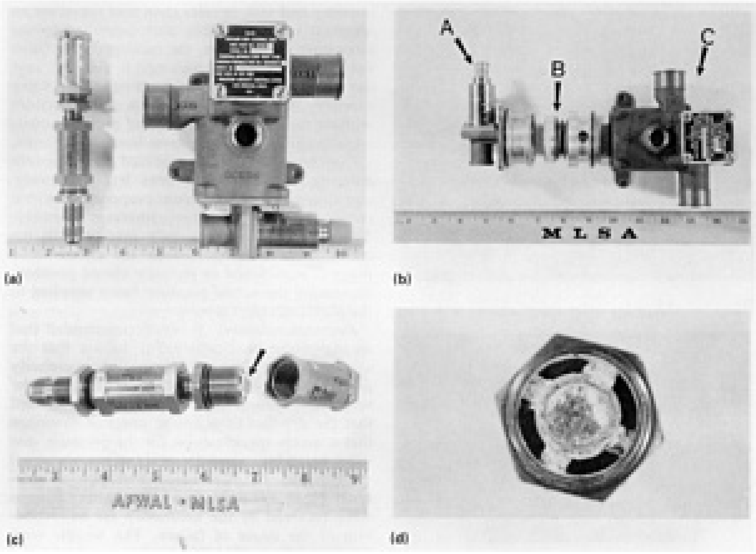

Fig. 54 Overall view (a) of external tank pressure/vent valve. (b) Partially disassembled valve. A, solenoid switch; B, dual-position valve; C, valve housing. (c) Segment of air line showing residue on check valve poppet (arrow). (d) Close-up view of check valve poppet

It was reported that the dual-position valve was found to be sticking at the intermediate positions. In addition, it was found that service air check valves located on the incoming lines contained poppets that were being stuck in a closed or partially closed position because of suspected corrosion product (Fig. 54c and d). These two factors prevented full pressurization of the external tank and caused a subsequent degradation in fuel flow to the internal tanks.

Investigation. Residue taken from the check valve poppet and from the dual-position valve was chemically analyzed. Only small samples (103 mg) of residue could be obtained from the parts for analysis. For this reason, each of the samples could be analyzed only for a single element. Chloride was selected for the analysis and was present in both samples. The residue found inside the check valve had a reddish color, indicating that the chloride-containing compound reacted with the anodized, dichromate sealed check valve housing.

It was noted that the dry-film lubricant applied to the dual-position valve was of different consistency and was heavier than that found on an identical valve assembly also submitted to the laboratory. In addition, the coating of the failed valve was flaking off. Although it did not cause the initial malfunction of the pressure/vent valve assembly, subsequent application of the lubricant without the complete removal of previous coats was a potential for longer-term binding problems.

Conclusions. It was suspected that moisture entering the service air lines left a chloride-containing compound upon evaporation within the air check valves and pressure/vent assembly. This compound subsequently reacted with the check valve housing to lock the check valve poppets in a closed or partially closed position, decreasing the actual pressure being supplied to the pressure/vent valve.

Recommendations. It was recommended that an inspection be conducted to ensure that the service air check valves are operating properly prior to removal and servicing of the pressure/vent valve assembly. It was also recommended that the dry-film lubricant be checked to ensure that it meets specifications for the pressure/vent valve assembly.

Example 13: Corrosion Fatigue of Aircraft Nose Wheels.

Four nose wheel failures were received by the laboratory for determination of the cause of failure. The wheels were fabricated from 2014-T6 aluminum material and were cold worked at the flange.

Investigation. Visual examination showed that the failure started in the tube well area on the wheel with serial number 31. The failure initiated in the flange fillet on wheels with serial numbers 67, 217, and 250. Figure 55(a) shows a typical example of these failures. Further visual examination of the wheel fractures indicated that failure progressed because of

fatigue (Fig. 55b and c). There was a superficial indentation adjacent to the origin on wheel 31 (Fig. 55d), and there were superficial periodic blemishes on the fillet of nose wheels 67, 217, and 250 (Fig. 55e). The indentation on wheel 31 could have contributed to the cracking found in the tube well; however, the blemishes at the fillet of wheels 67, 217, and 250 were merely superficial and were not thought to be deleterious.

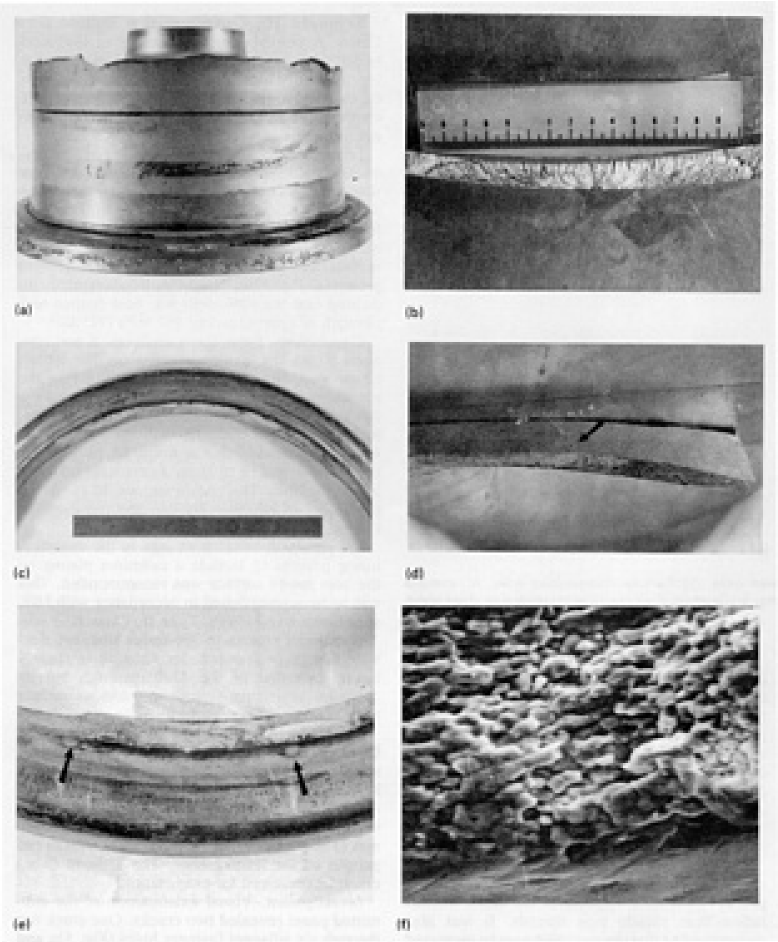

Fig. 55 Aluminum alloy 2014-T6 aircraft nose wheel (a) that failed at the flange. (b) Close-up of tube well on wheel 31. (c) Appearance of flange failure on wheel 67. The topography is typical of other flange failures. (d) Close-up of wheel 31; note indentation (arrow). (e) Close-up of wheel shown in (a); note surface blemishes (arrow). (f) SEM of typical initiation site showing an angular, blocky structure indicative of a corrosion-related failure mechanism. 780×

Scanning electron microscopy examination of the fractures showed that failure initiated by SCC or a corrosion pit on all failures examined. Figure 55(f) shows a typical example. The failures then progressed by fatigue.

A chemical analysis conducted on the submitted wheels showed that the wheels met the composition requirements for 2014 aluminum base material. A hardness survey indicated the wheels were in the T-6 tempered condition.

The wheels were examined by dye penetrant to determine if the remaining sections contained additional flaws. No additional flaws were seen on the wheels that had failed in the flange area. There was, however, one flaw area in the flange of the wheel that failed in the tube well. This flaw resembled a corrosion pit.

Conclusions. It was concluded that failure of nose wheels 67, 217, and 250 was caused by cracking due to SCC or pitting. The failures progressed by fatigue. Because failure occurred in the same general area on all three wheels, these locations are suspect as being underdesigned.

Recommendations. It was recommended that consideration be given to redesign of the nose wheel and that additional service data be accumulated in order to understand the contributing factors that result in failure of the wheel.

Example 14: Failure of Nose Gear Door Bolts.

Nose gear door securing bolts were reported to be failing; three separate incidents were cited. One of those bolts, measuring 25 × 32 mm (1 × 1 $\frac{1}{4}$ in.), was submitted for analysis. The bolt was a cadmium-plated, countersunk head type with a common screwdriver slot.

Investigation. Figure 56(a) shows the fracture face of the submitted bolt with the nut still attached. The fracture originated at a thread root and propagated across the cross section. An arrest pattern characteristic of fatigue that terminates at the smooth, featureless final overload area can be seen. The topography of the fracture was excessively rough and more granular than would be expected from pure mechanical fatigue; this indicated an allied corrosion mechanism.

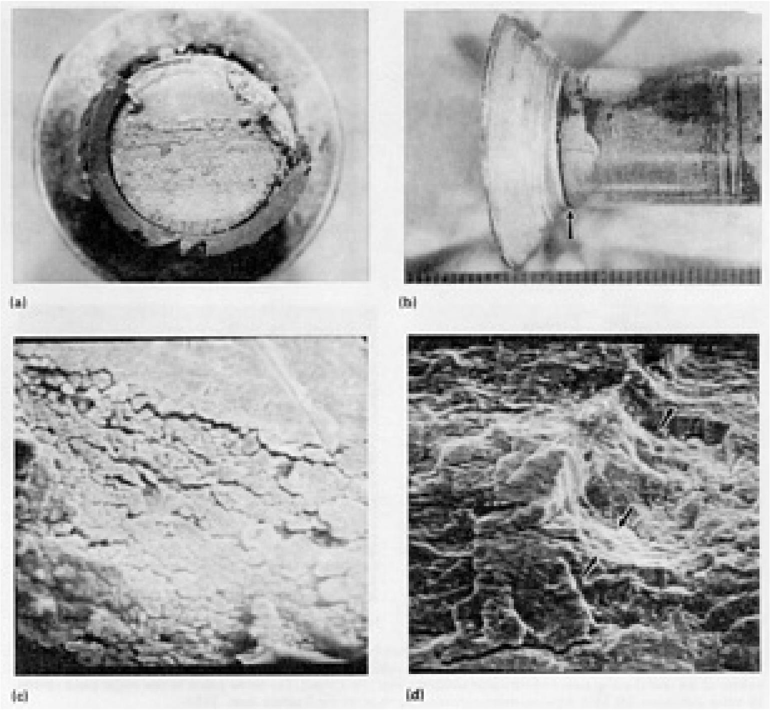

Fig. 56 Fracture surface (a) of failed cadmium-plated 1040 steel nose gear door bolt. The crack propagation pattern (arrow indicates the origin) and topography suggest both fatigue and corrosion. (b) Head of bolt showing cracking (arrow) that would lead to separation in a short time. 3×. (c) SEM of bolt surface showing extensive intergranular SCC. 650×. (d) SEM fractograph showing fatigue striations (arrow) interspersed with secondary cracking and evidence of SCC. 650×

Cracks other than the one leading of failure were observed in the bolt. The large crack at the bolt head shown in Fig. 56(b) was near separation. Metallographic examination of the bolt cross section showed many cracks typical of stress-corrosion damage. The scanning electron micrograph (Fig. 56c) of the bolt surface clearly showed extensive intergranular SCC.

Conclusion. The bolt failed by a combination of SCC and fatigue. The dual interaction of stress corrosion and mechanical fatigue is exemplified by the scanning electron photograph of the fracture surface (Fig. 56d), which shows characteristics of both cyclic fatigue and stress corrosion.

Recommendations. It was recommended that aerospace-quality fasteners meeting NAS 7104, NAS 7204, or NAS 7504 be used to replace the currently used fasteners.

Example 15: Failure of Tool Steel Pylon Attachment Stud.

The failed pylon attachment stud illustrated in Fig. 57(a) was reportedly found during a routine walk-around inspection. Half of the stud was found lying on the apron under the aircraft.

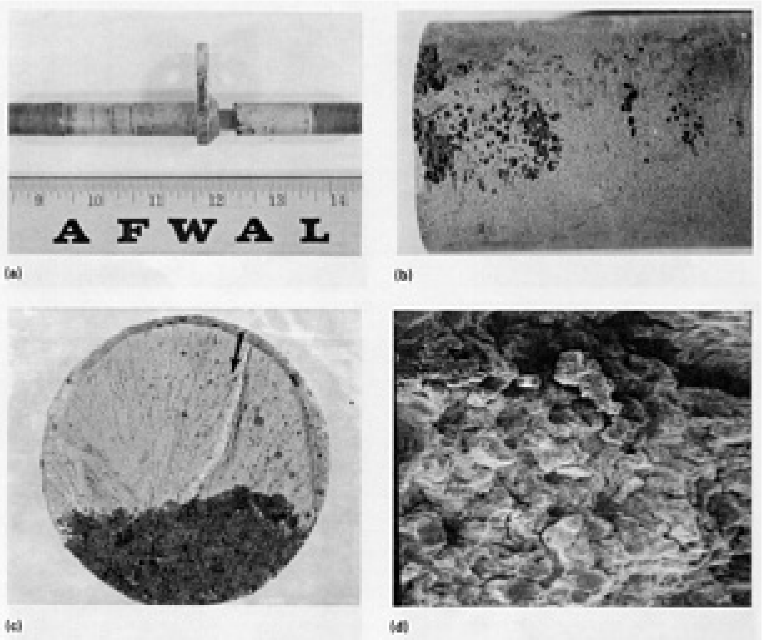

Fig. 57 H-11 tool steel pylon attachment stud (a) that failed by corrosion. (b) Gross pitting corrosion on the stud surface near the fracture site. Note the irregular, mottled appearance of the coating. (c) Fracture surface of the stud showing extent of corrosion within the stud (dark area). The arrow points to one major crack caused by stress corrosion. (d) SEM showing stress-corrosion damage on the fracture face. 315×

Investigation. The stud exhibited gross localized corrosion pitting at several different areas on its surface. Light general rust was also evident. Severe pitting near the fracture location is illustrated in Fig. 57(b). The extent of the corrosion damage into the stud is shown on the fracture surface (Fig. 57c). The relatively clean and recent area of the fracture face is not entirely overload failure mechanism, but contains evidence of intergranular SCC as well as ductile dimples. Figure 57(d) is a scanning electron micrograph showing intergranular SCC on the fracture face.

The bolt is specified to be H-11 tool steel heat treated to 46 to 49 HRC (ultimate tensile strength: 1517 to 1655 MPa, or 220 to 240 ksi). Hardness measurements of 47 HRC confirmed the heat treatment to be correct. The protective coating was found to be an inorganic water-base aluminide coating having a coating thickness of 7.5 to 13 μm (0.3 to 0.5 mil). It was noted that the coating was of a nonuniform mottled nature.

Conclusions. It was concluded that the failure of the pylon attachment stud was caused by general corrosion followed by SCC. The stud was not adequately protected against corrosion by the coating.

Recommendations. It was recommended that the coating be applied to a thickness of 38 to 75 μm (1.5 to 3 mils) to provide long-time corrosion resistance. The coating must be either burnished or cured at 540 °C (1000 °F) to provide cathodic protection to the steel. Other coatings, such as cadmium or aluminum, were also recommended if a thinner coating is needed.

Example 16: Corrosion of a Laser Mirror.

A failed laser mirror and another complete mirror of the same construction were submitted to the laboratory for analysis. The laser mirror consisted of three layers of material brazed together to form channels through which the cooling water flows. Portions of the top and middle layers from an area of the mirror that was visually determined to be the most damaged were included in the parts forwarded for analysis (Fig. 58a).

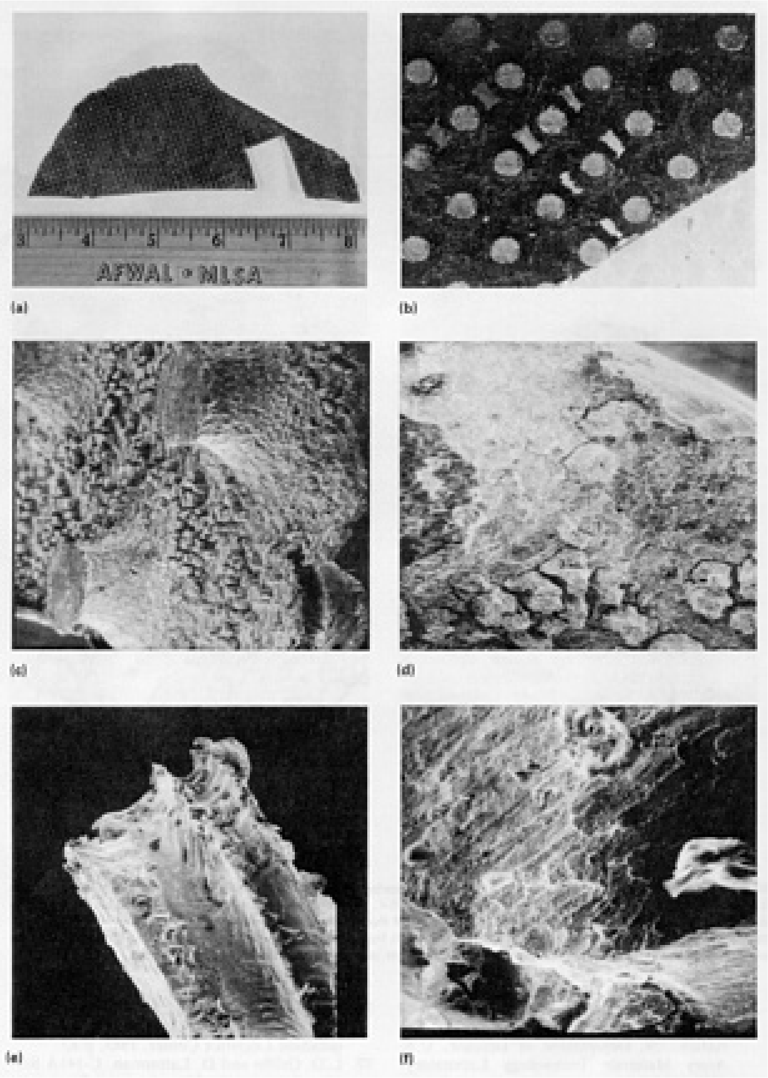

Fig. 58 Section of the most damaged area (a) of a failed laser mirror. (b) Section of area shown in (a) showing corrosion product and deterioration of the base metal. 5×. (c) Corrosion product and nodules in the cooling water channels. 30×. (d) SEM showing corrosion product and intergranular attack on the base metal. 40×. (e) Nodule on upper surface of middle layer of laser mirror showing failure in a ductile/tensile mode. (f) Nodule from lower surface of middle layer of the mirror showing failure due to compressive/shearing stresses

Investigation. Samples were analyzed with light optical and scanning electron microscopy. Portions of the mirror were sent out for analysis of the base material and visually identified corrosion products.

A portion of the middle layer from area A was noted to exhibit the highest corrosion attack, with many visible areas where the corrosion had completely perforated the base material (Fig. 58b). The corrosion product, which appeared under the SEM as distinct granular particles (Fig. 58c), was shown by chemical analysis to contain molybdenum and copper with a trace of gold. The base material was analyzed as molybdenum with negligible alloying additions.

The primary mode of corrosion attack on the base material appeared to be intergranular (Fig. 58d), although uniform corrosion was also evident as a general thinning of the material cross section. The corrosion product was shown to adhere loosely to the base material, and it was found that a gentle wash with acetone could dislodge the particles. This finding gave rise to another possible source for material degradation--that of erosion-corrosion, which may in part attribute to the worn, rounded appearance of the modules under the SEM (Fig. 58c).

Scanning electron microscopy examination of the portion of the sample with nodules on both sides (middle layer) showed that the nodules on one side failed in a ductile/tensile mode (Fig. 58e), while those on the opposite side appeared to have failed in a compressive/shearing mode (Fig. 58f). These findings are consistent with the concept of micro-bowing

expected to be present in this type of failure, that is, the water pressure forcing apart the two surfaces in the upper layer (tensile) while imparting compressive stresses to the layers below.

Portions of the mirror analyzed were seen to have areas in which the brazing alloy was corroded but the base material was relatively unaffected. This finding suggested the possibility of a galvanic couple between the brazing alloy and the base metal.

The sample mirror was radiographed and ultrasonically inspected. The radiograph did not show any areas of corrosion, with the ultrasonic c-scan able to image the rectangular pattern of pin-type spacers.

Conclusions. It was concluded that the corrosion attack noted sufficiently weakened the base material and the brazed joints, allowing catastrophic failure of the mirror due to the pressure of the cooling water.

Recommendations. It was recommended that the mirrors be cleaned of all corrosion products present as a result of past service conditions. The mirrors should be proof tested to determine if the residual structural integrity is sufficient for future operational requirements. It was recommended that the water system consisting of deionized water and formaldehyde be replaced with water having a low oxygen content and a cathodic inhibitor (oxygen scavenger).

Example 17: Failure of a Helicopter Rotor.

Several rotor blade components were received for laboratory analysis. These included the horizontal hinge pin and the associated nut the locking washer (Fig. 27a, b, and c in the section "Corrosion of Airframes" in this article).

Investigation. Visual examination of the submitted parts revealed that the hinge pin, fabricated from 4340 steel, was broken and that the fracture face showed a flat beach mark pattern indicative of a preexisting crack (Fig. 27d and e). Also noteworthy on the hinge pin was a ding or dent in the threaded area that occurred on only one side (Fig. 27f).

Optical examination of the hinge pin showed that the beach mark or preexisting crack had progressed to approximately one-fourth the total cylinder cross-sectional area. Further examination of the area at the fracture initiation site revealed corrosion pits and secondary cracking on the outer circumference of the pin adjacent to the primary fracture face. The cracks ran parallel to the primary fracture and propagated from small pits (Fig. 27g).

Close scrutiny of the threaded area of the pin revealed an embedded thread that did not appear to come from the pin (Fig. 27h). A chemical analysis was conducted on the embedded thread and on an associated attachment to determine the origin of the thread. This analysis showed that the thread and nut were 4140 steel.

Scanning electron fractographic examination of the fracture initiation site strongly suggested that the fracture progressed by fatigue. Hardness measurements taken on the pin produced a value of 41 HRC, which was within the 39 to 43 HRC drawing requirements.

Conclusions. It was concluded that the failure of the horizontal hinge pin initiated at areas of localized corrosion pits. The pits in turn initiated fatigue cracks, resulting in a failure mode of corrosion fatigue. The embedded thread was the same material as the associated nut and probably came from the attachment nut.

Recommendations. It was recommended that all of the horizontal hinge pins be inspected to determine the current existence of cracks, corrosion pits, and general corrosion. Those pins that are determined to be satisfactory for further use should be stripped of cadmium, shot peened, and coated with cadmium to a minimum thickness of 0.0127 mm (0.0005 in.).

Example 18: Corrosion Failure of Wing Flap Hinge Bearings.

Three wing flap hinge bearings were received by the laboratory for analysis (Fig. 59a). The bearings were fabricated from chromium-plated type 440C martensitic stainless steel.

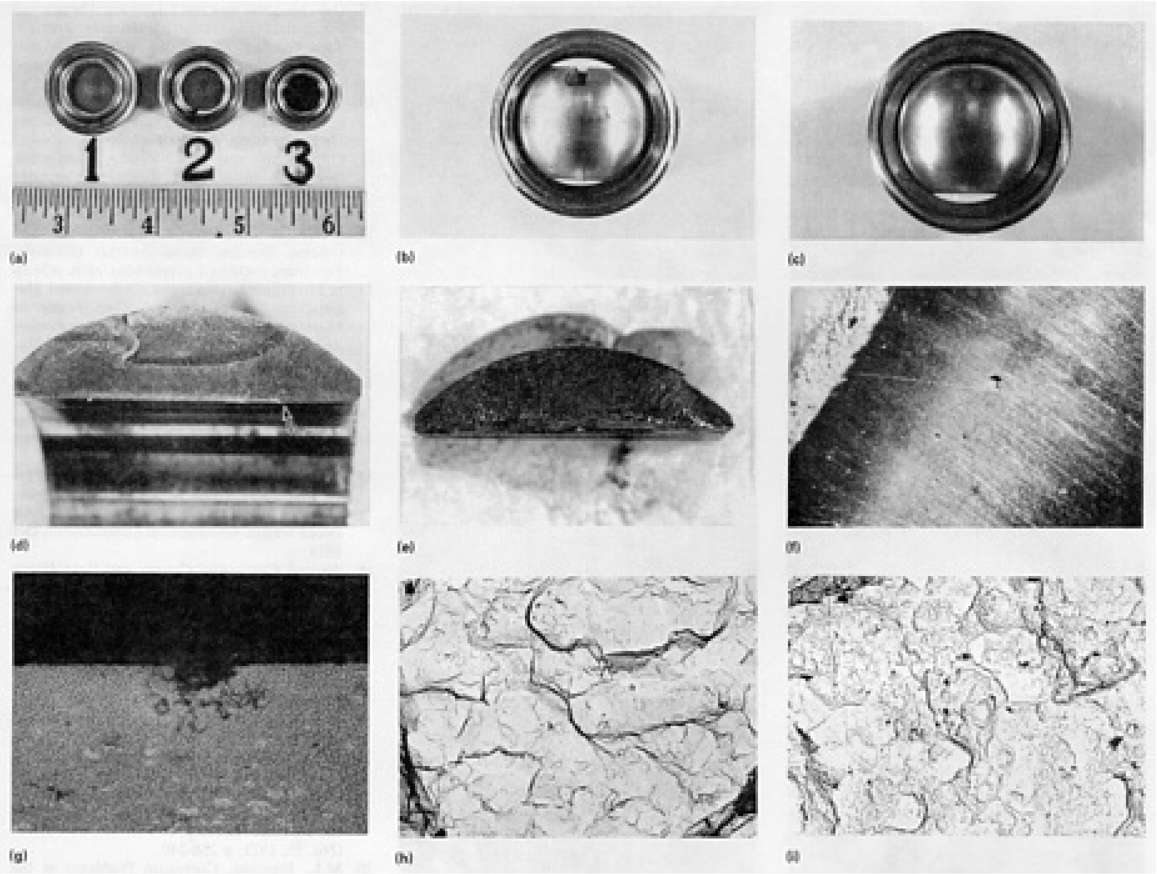

Fig. 59 Cracked type 440C stainless steel (a) aircraft wing flap hinge bearings. (b) Crack configuration of bearing 1 from (a). (c) Crack configuration of bearing 2 from (a). (d) Fracture surface of second crack in bearing 1. Arrow shows the probable fracture origin. 2.5×. (e) Fracture surface of bearing 2. The crack front was abraded, so the area of origin would not be clearly defined. 2.5×. (f) Corrosion pits on the inside surface of one of the bearings. All three bearings submitted had this type of damage. 10×. (g) Cross section of corrosion pit on one of the bearings; note the intergranular attack. 265×. (h) SEM fractograph of bearing 1 showing intergranular mechanism of fracture. 2690×. (i) SEM fractograph of bearing 2 showing intergranular fracture mechanism. Corrosion products are evident on the intergranular facets. 2690×

Investigation. Visual analysis of the hardware showed that two of the three bearings were cracked. One of these two bearings, designated bearing 1 in Fig. 59(a), contained two separate cracks. One of these cracks took the path shown in Fig. 59(b), while the second crack progressed straight across the bearing cross section. Bearing 2 in Fig. 59(a) exhibited the crack path seen in Fig. 59(c). Further visual examination of the bearing crack fractures showed that the cracks were flat and slightly fibrous (Fig. 59d and e). The fracture face of bearing 2 differed slightly from the two fractures seen on bearing 1 in that there was a chip missing on the outer edge of the bearing.

Optical examination of the bearings revealed numerous corrosion pits on the inner diameter of the failed bearings and on bearing 3, which had not failed (Fig. 59f). Metallographic examination showed that the pitting progressed in an intergranular corrosive pattern (Fig. 59g). The microstructure was acceptable for type 440C martensitic stainless steel. Electron optical examination of the fractures by transmission electron microscopy produced fractographs that depicted an intergranular failure mechanism (Fig. 59h and i). Chemical analyses and hardness measurements of bearings 1 and 2 showed the material to be within compositional requirements for type 440C stainless steel and heat treated to 54 to 55 HRC.

Conclusion. The intergranular fracture pattern seen in the electron fractographs, coupled with the corrosion pits observed on the inner diameter of the bearings, strongly suggested that the failure initiated by pitting and progressed by SCC or hydrogen embrittlement from the plating operation.

Recommendations. It was recommended that the extent of the flap hinge bearing cracking problem be determined by using nondestructive inspection because it is possible to crack hardened type 440C during the chromium plating process. An inspection for pitting on the bearing inner diameter was also recommended. It was suggested that electroless nickel be used as a coating for the entire bearing. Electroless nickel, when heated to 345 °C (650 °F) for 1 h after plating, has wear resistance equivalent to that of chromium. A review of the chromium plating and baking sequence was also recommended to ensure that a source of hydrogen is not introduced during the plating operation.

Corrosion in the Aerospace Industry

Introduction

CORROSION CONTROL is an essential part of the design of aerospace hardware, because a corrosion failure could result in the loss of a satellite, a booster, or the space shuttle orbiter. Of the three, satellites experience the most benign environments; they are usually handled in clean rooms with controlled humidity from the time they are built until they are launched. In low earth orbit, the corrosion effects of oxygen and moisture no longer exist, although some surface erosion from atomic oxygen can destroy optical (thermal control) surfaces. At the other extreme, a booster, such as the solid rocket motor case of the space shuttle system, becomes immersed in seawater after launch and must be pulled from the ocean and thoroughly cleaned to avoid salt-water corrosion. A solid rocket case is expected to be reused up to 19 additional times.

The space shuttle orbiter was originally designed to be maintenance free for 10 years. From a corrosion standpoint, this is a rather severe requirement for the highly corrosive Cape Canaveral environment. Because of unexpected delays in launching schedules, there is a high probability that shuttle orbiters will see service in excess of 20 years. Corrosion and structural inspection plans have recently been initiated to ensure the safety of the airframe as well as the systems, which are subjected to highly corrosive fluids. In these systems, corrosion failure from perforation could result in explosions or fire, or corrosion deposits in valves could cause malfunctions, possibly resulting in the loss of the spacecraft. Therefore, control of corrosion is considered to be vital for the safety and success of aerospace hardware.

Applicable specifications imposed by the National Aeronautics and Space Administration (NASA) on subcontractors to control or restrict material selection and to control corrosion are:

- SE-R-0006: NASA-JSC Requirements for Materials and Processes
- MSFC-SPEC-250(1): Protective Finishes for Space Vehicle Structures and Associated Flight Equipment, General Specification for
- MSFC-SPEC-522A: Design Criteria for Controlling Stress Corrosion Cracking
- NHB-8060.1: Flammability, Odor, and Offgassing Requirements and Test Procedures for Materials in Environments That Support Combustion
- JSC-30233: General Specification--Space Station Requirements for Materials and Processes

The following sections will detail the steps taken by engineering, design, and material and process groups to avoid spacecraft corrosion. Case histories of failures and their solutions will also be reviewed.

Corrosion of Manned Spacecraft

L.J. Korb, Rockwell International, Space Transportation & Systems Division

The prevention or control of the corrosion of manned spacecraft presents a wide variety of challenges to the corrosion engineer for at least four reasons. First, a manned spacecraft, such as the space shuttle orbiter, has structures and systems

operating at temperatures ranging from -253 °C (-423 °F) for liquid hydrogen tanks for approximately 1455 °C (2650 °F) for critical metallic pressure ports of the nose cap. Several hundred different alloys are required, including the light metals, such as beryllium, magnesium, aluminum, and titanium; steels, such as low-alloy, tool, corrosion resistant, precipitation hardenable, and maraging; nickel and nickel-base alloys, including pure nickel, Monel alloys, Inconel alloys, and other nickel- and cobalt-base superalloys; the refractory metals, principally niobium and molybdenum; the copper-base alloys, including pure coppers, beryllium coppers, bronzes, and brasses; the precious metals; and a variety of plating alloys. Quite often, intimate knowledge of the corrosion behavior of these alloys in the intended environment is simply lacking.

Second, because weight is so critical for manned spacecraft, the alloys were often chosen for their inherent high strength-to-density ratios rather than for their corrosion resistance. Early studies indicated that the savings per pound of weight in the orbiter vehicle structure of systems amounted to well over $30,000 during the mission life. Therefore, emphasis was directed toward corrosion control coatings for airframe structures rather than the selection of corrosion-resistant alloys. In fluid systems, however, material compatibility played an important role.

Third, the various parts of a spacecraft are subject to a wide variety of environments in addition to the temperature regimes discussed above. The seacoast exposure at Cape Kennedy, for example, is very severe because of the heat, high humidity, salt air, and the daily condensation of dew onto the structures. Fluid systems, on the other hand, are exposed to very aggressive chemicals: hot gaseous oxygen, nitrogen tetroxide, high-pressure hydrogen, hydrazine, and ammonia.

Finally, corrosion protection often must be subordinated to other critical functions, such as the spacecraft electrical grounding requirements. Often, where a corrosion engineer may wish to isolate a galvanic couple electrically by using an insulator, the requirements for grounding to ensure lightning protection and control of electromagnetic interference must overrule. Corrosion-protective measures must then be taken for the area of the grounded connection.

Early manned spacecraft, such as the mercury, Gemini, Apollo, and Sky Lab programs, were each designed for a single launch. The Mercury, Gemini, and Apollo capsules parachuted into the ocean and could not be refurbished economically. The Skylab, having no reentry capability, broke up and burned at the end of its useful life. The major emphasis in corrosion protection for these vehicles was to ensure freedom from general corrosion and stress corrosion for the 3 to 5 years preceding launch. In the case of the Apollo, and in-depth age life and corrosion reevaluation was made to ensure a 10-year operational life from its manufacture to its use on Skylab missions.

The space shuttle orbiter was originally designed to avoid corrosion for a 10-year life, and it was anticipated that it would fulfill its 100-mission launch capability during this period. Because of unforeseen launch problems, some orbiters have experienced less than 10 missions while approaching their 10-year design life. Reevaluations will be made to extend this life to 20 years and to maintain the corrosion protection systems as necessary. Because of its multiple-launch capability and its long design life, the space shuttle orbiter is unquestionably the most challenging of the manned spacecraft from a corrosion control standpoint. Its corrosion protection and the problems experienced will be discussed in detail. However, because other manned space vehicles have experienced some unusual corrosion problems, many of which involved unknown incompatibilities at that time, this article will also cover representative case histories of corrosion of several manned spacecraft.

Operational Mission of the Space Shuttle Orbiter

The space shuttle system is designed to provide an economical system for transporting personnel and supplies into low earth orbit. The system (Fig. 1) consists of four major elements: the solid rocket boosters, the space shuttle main engines, the external tank, and the space shuttle orbiter. Elements other than the orbiter itself are discussed in the section "Corrosion of Space Boosters and Space Satellites" in this article. The system is capable of launching up to 29,500 kg (65,000 lb) of payload into orbit and returning up to 14,500 kg (32,000 lb) of payload from orbit (Ref 1).

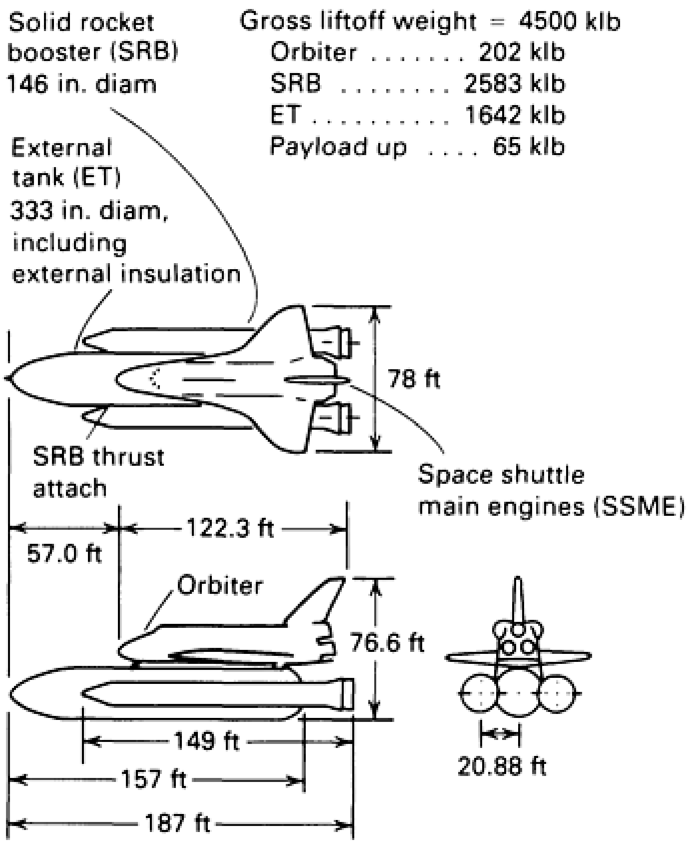

Fig. 1 Space shuttle system. The orbiter weight includes the 165-klb orbiter (including engines) plus 37-klb crew, consumables, and propellants. The external tank diameter includes external insulation. klb = 1000 lb

Nearly 89% of the thrust for launch is provided by the solid rocket boosters. The remaining 11% is delivered by the main engines, which burn hydrogen with oxygen supplied by the external tank. The orbiter, launched vertically in a piggyback position on the external tank, houses the astronauts, the main engines, and the payloads.

The orbiter must function as both a spacecraft and an aircraft. During entry from orbit, it must be protected from temperatures exceeding 1260 °C (2300 °F) on its lower fuselage and in excess of 1455 °C (2650 °F) along the leading edges and nose cap. At an altitude of approximately 46 km (150,000 ft), the orbiter will slow to about eight times the speed of sound and will pass through its maximum heating. At 15 km (50,000 ft), the orbiter will be maneuvered aerodynamically to land as a glider. A typical mission profile is shown in Fig. 2.

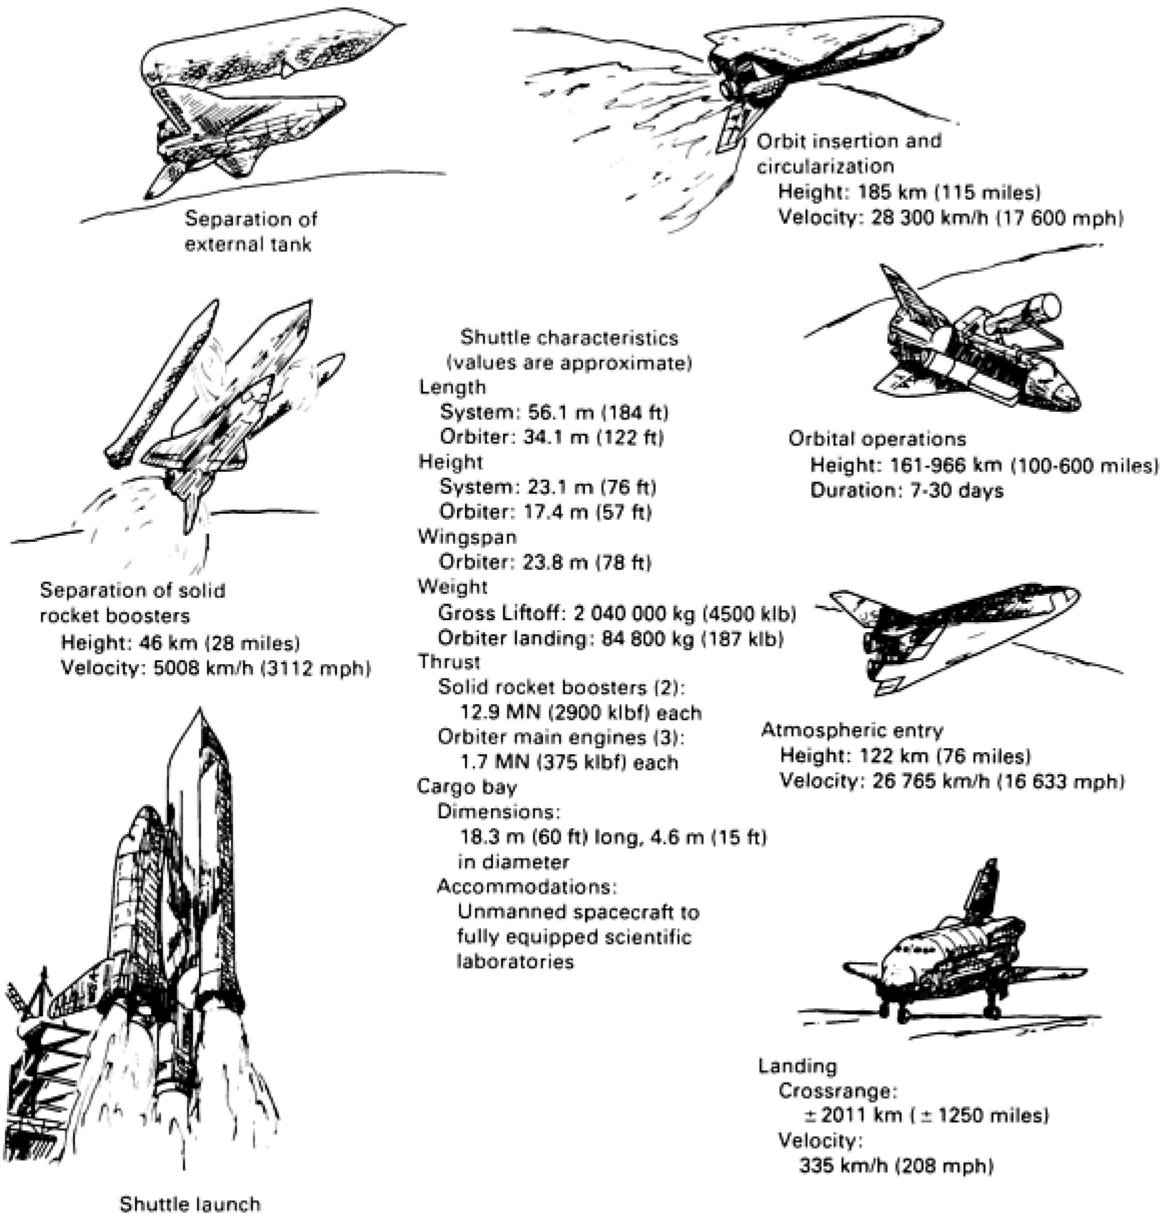

Fig. 2 Profile of shuttle mission. Each shuttle orbiter can fly a minimum of 100 missions and carry as much as 29,500 kg (65,000 lb) of cargo and up to seven crew members into orbit. It can return 14,500 kg (32,000 lb) of cargo to earth. klb = 1000 lb; klbf = 1000 lbf

The requirement to achieve a minimum-weight orbiter (68,000 kg, or 150,000 lb, dry weight) has necessitated use of the most efficient structural materials and processes. The requirement for 100-mission reuse has extended advancements in thermal protection materials well beyond the state-of-the-art existing at the inception of the design.

Corrosion Control Program: Space Shuttle Orbiter

The key to a successful corrosion control program for the space shuttle orbiter was to develop sound technical and management programs. Although the major structural parts of the orbiter, such as the wings, tail, fuselage, and cabin, were manufactured by only a few companies, it was estimated that more than 20,000 suppliers were responsible for providing systems and parts for the vehicle. It was necessary to review and control all orbiter parts to provide the high levels of reliability required.

The material and process management program consisted of the following key elements:

- A material and process group in engineering
- A drawing review system requiring sign-off by a materials engineer
- A tracking system for all materials
- An orbiter materials and process control specification
- A corrosion-control and finishes specification
- A stress-corrosion control plan

Each material application was reviewed by a qualified material and process engineer who had sign-off authority on drawing, engineering orders, and material rework dispositions. A material tracking system was set up at the inception of the program to prevent 12 material-related hazards from occurring on the orbiter. These include controls for atmospheric corrosion and stress corrosion, fluid and propellent incompatibilities, age life, flammability, toxicity, offgassing, and condensation of volatile condensible matters. Materials and finishes were identified, evaluated, and, when accepted, entered into a computer. Material identification even included those materials used in minute quantities, such as the ink used to stamp part numbers or the nearly invisible cetyl alcohol lubricants on fasteners. A master directory (index) of the behavior of each material in the 12 hazardous categories was maintained and used as a reference.

In each hazardous category, a series of encoded, acceptable engineering approaches for each "buyoff" was listed to assist the engineer. For example, a part may be made from a material having a stress-corrosion threshold of 50% of its tensile yield strength, yet be acceptable because:

- It is adequately coated
- It experiences no significant tensile stresses in the critical stress-corrosion direction (including residual and installation stresses)
- It is in a benign environment, such as the cabin

In a few cases, the complexity of the part, such as a motor, precluded a separate evaluation of each material, and the entire configuration was qualification tested in its intended-use environment to avoid these hazards.

A Material and Process Control Specification (MC999-0096) was placed on all major subcontractors. A similar specification controlled parts that were designed and manufactured in-house. These specifications included controls for fluid systems compatibility, stress corrosion, atmospheric corrosion, and galvanic corrosion. The controls imposed are summarized below.

Control of Fluid Systems Compatibility. A fluid systems compatibility analysis is required that covers all fluids and materials used in the system, such as testing, processing, inspection, and operation, along with known or expected trace contaminants. Fluid system compatibility refers to interaction problems involved with materials and the liquid or gaseous subsystems. The problems experienced generally fall into the following categories:

- *Autoignition:* Spontaneous ignition of the material or the fluid
- *Impact ignition:* Ignition brought about by shock or impact within the fluid
- *Catalytic reaction:* Reactions such as the catalytic decomposition of the fluid
- *Material degradation:* This includes such phenomena as chemical attack, corrosion, galvanic corrosion, stress corrosion, hydrogen embrittlement, and crack growth acceleration with metals and includes embrittlement, abnormal swelling, leaching of plasticizers, ultraviolet degradation, and so on, with nonmetallic materials
- *Fluid degradation:* Reactions in which the physical or chemical characteristics of the fluid are altered
- *Potential ignition:* Ignition due to proximity to electrical ignition sources

Materials selection was required to minimize the compatibility problems with the fluid systems. Material-fluid combinations that result in autoignition, impact ignition, or another catastrophic mode of failure were not permitted.

The use of electrical and electronic components exposed to nondielectric fluid systems was avoided. Buyer approval was required prior to using electronic components in hazardous fluid systems.

Metallic materials listed in Appendix I of MC999-0096 are rated for compatibility with gaseous oxygen (GOX), liquid oxygen (LOX), nitrogen tetroxide (N_2O_4), hydrazine (N_2H_4), monomethyl hydrazine (MMH), and low-pressure ($\leq$3.1 MPa, or 450 psi) and high-pressure (>3.1 MPa, or 450 psi) hydrogen. Nonmetallic materials listed in Appendix II of MC999-0096 are rated for compatibility with low- and high-pressure GOX, LOX, N_2O_4, N_2H_4, MMH, liquid hydrogen, and hydraulic fluid.

Materials that are compatible and noncompatible with titanium are listed in MF0004-018.

Lubricants for static service with special fluids (application to elastomers, metals, and threads) are:

Fluid	Lubricant
Ammonia	Krytox 240 AC; Braycoat 3L-38RP; Braycoat 815Z oil
Deionized water	Krytox 240 AC; Braycoat 3L-38RP; Braycoat 815Z oil
Freon 21	DC F-6-1101
FC 40	DC F-6-1101

Lubricants for dynamic service with special fluids must be resolved on an individual basis. Use of the above lists did not absolve the seller of full responsibility for verifying compatibility under the particular design conditions used by his fluid system.

Control of Stress Corrosion. The subcontractor was required to prepare a stress-corrosion plan utilizing MSFC Specification 522A as a guideline for controlling stress corrosion and to take the actions necessary to prevent such failures. Wherever possible, the supplier was required to select materials that are either not susceptible to stress corrosion or have a high resistance to stress corrosion in the anticipated life cycle environment. Where susceptible materials were used, the supplier was required, at the minimum, to take the following actions to reduce stress-corrosion problems to the extent feasible:

- Select less susceptible alloys, tempers, or clad products
- Reduce sustained stress levels on the part below stress-corrosion threshold levels, especially in the more susceptible short-transverse grain direction
- Protect the part from the detrimental environment by hermetically sealing or coating the part or by inhibiting the environment (closed system)
- Avoid or reduce residual stresses in parts or assemblies by stress relieving, by avoiding interference fits, or by shimming assemblies
- Avoid galvanic couples, which may tend to accelerate stress corrosion
- Provide for regular inspection of parts to determine surface flaws and cracking during the life cycle of the part
- Improve the surface quality by reducing surface roughness and/or increasing surface compressive stresses
- Avoid the use of titanium in contact with silver, silver-plated material, or silver-plated fasteners, such as silver-plated A-286 nuts

Control of Galvanic Corrosion. Dissimilar metals were not to be used in intimate contact unless they were suitably protected against galvanic corrosion. Because of the seriousness of galvanic corrosion, every effort was made to avoid the use of dissimilar metals, to exclude moisture or other electrolytes from the system, and to protect metal surfaces in the contact area. Metals were considered compatible if they were in the same grouping as specified in MSFC-SPEC-250, Class II, or if the difference in solution potential was 0.25 V or less.

Control of Atmospheric Corrosion. All parts, assemblies, and equipment, including spares, were finished to provide protection from corrosion in accordance with the requirements of MSFC-SPEC-250, Class II, as a minimum. All organic finishes and anodized aluminum that contact titanium were limited to surfaces not normally exposed to propellants. A finish specification delineating the finishes used on each specific material in any particular application and corrosion control procedure was prepared by the orbiter contractor. The finish specification and related procedures from the subcontractor were required to provide for in-process corrosion control. Specific requirements were also given for:

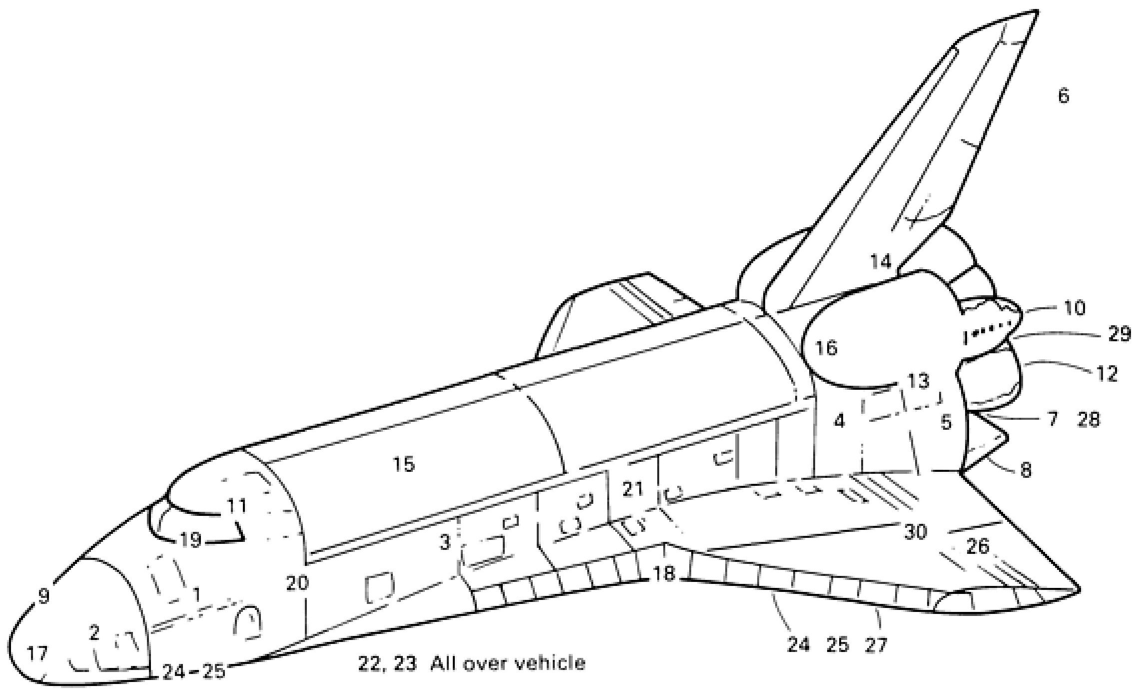
- Surface preparation for adhesive bonding
- Finish systems for interior and exterior surfaces (including those surfaces to which the thermal protection system was to be bonded)
- Fastener installations
- Joints and faying surface sealing
- Protection for parts to be shipped for vehicle final assembly

Designing to Control Corrosion of the Space Shuttle Orbiter

From a corrosion control standpoint, it is convenient to separate the space shuttle orbiter into four categories; primary structure, fluid systems, mechanical systems, and avionics systems. Each of these areas has its own unique problems.

Primary Structure

Weight and cost both dictated that the primary structure of the orbiter be made from aluminum. The majority of this structure was made from heat-treated alloys of the 2000 and 7000 series (Fig. 3). However, some 5000- and 6000-series alloys were also used.



1 Cabin: aluminum alloy 2219
2 Forward fuselage: aluminum alloy 2024
3 Mid fuselage: aluminum alloys 2124, 7075
4 Aft fuselage: aluminum alloy 2124
5 Aft heatshield: aluminum alloy 2124
6 Tail: aluminum alloys 2124 and 2024
7 Engine mounted heat shield: Inconel alloy 625 sandwich
8 Body flap: aluminum alloy 2024
9 ACS engine nozzles: niobium alloy C103
10 OMS engine nozzles: niobium alloy FS-85
11 Window frames: S-65 Beryllium
12 Thrust structure: Ti-6Al-4V (diffusion bonded), Ti-6Al-4V and boron epoxy
13 APU: René 41 turbine, Hastelloy alloy B, Hastelloy alloy X, René 95
14 Tail conical seal: Inconel alloy 718 sandwich
15 Cargo bay doors: Graphite/epoxy
16 OMS pod structure: Graphite/epoxy
17 Nose cone: RCC
18 Wing leading edges: RCC
19 Windows: Quartz (outer), aluminosilicate (inner)
20 Pressure vessels: Kevlar-Ti-8Al-4V, Kevlar-Inconel alloy 718, Ti-6Al-4V, aluminum alloy 2219
21 Mid fuselage support tubes: Boron-aluminum, diffusion bonded Ti-6Al-4V
22 Plumbing systems: Type 304 and 21-6-9 stainless steels, Ti-3Al-2.5V, Inconel alloy 718
23 High-strength fasteners: A-286, MP35N, Inconel alloy 718
24 Landing gear: 300M steel, aluminum alloy 7075
25 Brakes: Beryllium, carbon-carbon
26 Flipper doors/rub panels: Ti-6Al-4V, Inconel alloy 625
27 ET door: Beryllium S-65
28 High-temperature fasteners: Udimet 500
29 Main engine nozzle: Inconel alloy 718, A-286 tubes
30 Elevon cove seal: Niobium alloy C103

Fig. 3 Typical materials of construction for the space shuttle orbiter

Aluminum Airframe. Prior to alloy selection, two surveys were conducted. The first was to identify steps to be taken to avoid stress-corrosion problems with aluminum alloys, and the second to identify a corrosion protection system that could survive the unique spacecraft environment.

The stress-corrosion survey, conducted in the early 1970s, indicated that virtually all stress-corrosion failures in service occurred in the 2000-series alloys in the T3, T4, and T6*XX* tempers and in the 7000-series alloys in the T6*XX* tempers and perpendicular to the short-transverse direction. Only alloys 2024, 2124, and 2219 have high SCC resistance in the T6*XX*

tempers. In forgings, stress corrosion occurred in end grain runout along the forging parting lines. In extrusions and plate, failures occurred where parts were severely formed, where interference fits had occurred, or where assembly stresses were high. Theoretically, stress corrosion will not occur until all three of the essential elements are present: a susceptible microstructure, a corrosive environment, and surface tensile stresses. If any one of these was eliminated, stress corrosion should not occur. The approach used on the orbiter, however, was to eliminate or minimize all three of these conditions to the maximum practical extent.

First, only aluminum alloys were permitted with a minimum 170-MPa (25-ksi) stress-corrosion threshold (according to the supplier's standard test methods: 30 days in salt spray) in all directions. This eliminated the T3, T4, and T6*XX* tempers of nearly all the 2000- and 7000-series alloys, whose stress-corrosion thresholds could be as low as 48 MPa (7 ksi) or less in the short-transverse direction. The preferred microstructure of the -T73 and -T76 tempers was chosen for 7000-series alloys, and although some weight penalty was incurred, program reliability was well served. Because most of the aluminum structure is designed for compressive loading (buckling, crippling) or shear, a very small weight penalty actually resulted. For the 2000-series alloys, the T8*XX* tempers were used predominantly; however, in a few cases, the T6 or T62 tempers were used for alloys 2124 and 2219.

Second, every effort was made to reduce residual stress levels. Mill products were ordered in stress-relieved tempers (for example, T651 or T851) wherever possible to reduce machining distortion and susceptibility to stress corrosion. Interference fits were limited to stress levels below 67% of the stress-corrosion thresholds. Tables were prepared to allow the materials and process engineer to ascertain stress levels resulting from interference fit pins and bushings into various size lugs. Residual stresses in assembly were minimized by shimming. Forming by bending, which put the short-transverse direction into tension, was not permitted.

Finally, the corrosion-protective paint system (described below) was applied to all aluminum parts. As of 1986, no incidents of aluminum stress-corrosion failures have been reported on the orbiter since its inception in 1972.

The second survey conducted in the early 1970s involved the selection of a paint system that would meet the unique requirements of the shuttle. The system had to provide protection to aluminum from corrosion for a minimum of 10 years of seacoast exposure, without touchup, because it must also serve as the base to which the thermal protection system (TPS) tiles of the shuttle are bonded. Unlike commercial aircraft, the external surfaces could not be washed, repainted, or protected from water intrusion and crevice corrosion by using water-displacing chemicals.

The paint system had to endure temperatures of 175 °C (350 °F) during entry and landing because heat from reentry soaked back into the structure. It had to be capable of surviving space vacuum and low temperatures (-155 °C, or -250 °F) without degradation. Minimum offgassing was desirable to avoid giving off toxic fumes inside the cabin (crew hazard) or the condensation of volatile material on windows or optical (thermal) control surfaces. The need for exceptional corrosion resistance was further mandated by the floating bilge; that is, the orbiter is stacked and launched in a vertical attitude, operates in zero gravity, and reenters and lands horizontally. It was not possible to ensure that all water drains out of the structure in all attitudes.

The paint system chosen was a chromate-inhibited epoxy polyamine primer. This system was tough, abrasion resistant, and durable. Surfaces to be painted were either anodized according to MIL-A-8625 type II, Class 1, or chemically filmed according to MIL-C-5541, class 1A. Each coat of paint was 0.015 to 0.023 mm (0.6 to 0.9 mil) thick. A single coat of the chromated epoxy polyamine primer demonstrated 1500 h of salt spray protection without corrosion, even in areas scratched through to bare aluminum.

The surface to which the external TPS was bonded had a single coat of the chromated epoxy polyamine paint. It achieved additional corrosion protection from a room-temperature vulcanized (RTV) adhesive layer 0.13 to 0.23 mm (5 to 9 mils) thick used to bond the tiles. In the cargo bay area, the single coat of epoxy polyamine primer was overcoated with one coat of polyurethane (MIL-C-83286 or MIL-C-81773) to achieve the required optical properties--absorptivity (α), emissivity (ϵ), and the proper α/ϵ ratio for heat control. The interior of the cabin required the use of nonglare coatings and selected colors. Again, a single undercoat of the chromated epoxy polyamine primer was coated with polyurethane. In this case, the polyurethane not only provided a durable color but also acted as a barrier to unacceptable offgassing products of the primer.

Parts were painted as details, drilled and assembled, and then repainted upon assembly to coat the fasteners. Although it was desirable from a corrosion standpoint to install all rivets wet, practical manufacturing considerations did not permit it.

Automatic riveting machines, which were used to install nearly 90,000 rivets in the wing, could not use wet rivet installations.

The weight reduction demands of the program resulted in the elimination of the use of two coats of paint on interior surfaces. More than 500 kg (1100 lb) of paint were used to cover 8175 m^2 (88,000 ft^2) of surface. By substituting an anodize coating for one coat of primer, significant weight savings were realized. Consequently, the finish system for *Discovery* and *Atlantis* followed the general scheme:

Area	Coating
Exterior TPS surface	Anodize + 1 coat chromated epoxy polyamine primer + 1 coat RTV adhesive
Exterior non-TPS surfaces	Anodize + 1 coat chromated epoxy polyamine primer
Interior surface	Anodize + either 1 coat chromated epoxy polyamine primer or 1 coat polyurethane
Crew compartment	Chemical film or anodize + 1 coat chromated epoxy polyamine primer + 1 coat polyurethane or anodize only

The forward fuselage was fabricated as a sheet metal skin-stringer design in aluminum alloy 2024-T6. Suspended inside the forward fuselage was an all-welded aluminum pressurized cabin made from aluminum alloy 2219 using the T6 and T8 tempers. It was approximately conical in shape, about 5 m (17 ft) long and tapering from 5 to 2.4 m (17 to 8 ft) in diameter at its forward end. The mild and aft fuselage structures were machined from aluminum alloy 2124-T851 plate. Major frames were of aluminum alloy 7075 in the T76 or T73 tempers.

Aluminum honeycomb sandwich was extensively used in the wings and body flap area. Corrosion protection systems must prevent corrosion of the thin (0.025 to 0.075 mm, or 1 to 3 mil) honeycomb core (usually aluminum alloy 5056-H39) and delamination of the skins. Face sheet skins could not be alclad, because corrosion would proceed in the plane of the sheet, resulting in delamination of the bond line. To prevent corrosion, all aluminum cores were protected with conversion coatings and were nonperforated; the face sheets used corrosion-resistant adhesive primers, and the sandwich assemblies were sealed at the edges to prevent water entry.

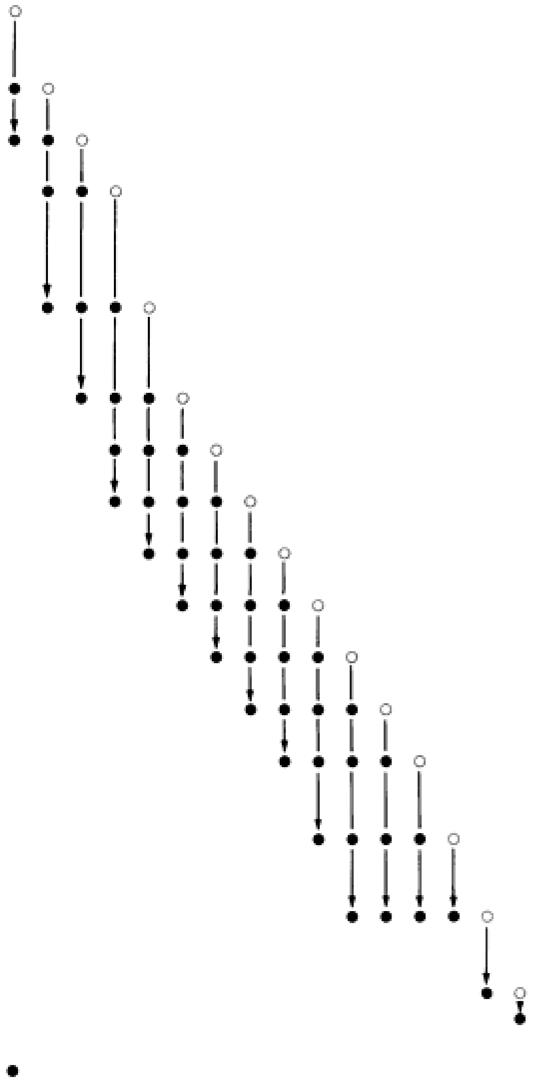
Structural Joints and Fasteners. The corrosion engineers favored the assembly of structural joints with RTV faying surface sealants; however, the electrical bonding requirements or grounding of each panel eliminated this approach. Electrical bonding requires a maximum dc resistance of 2.5 mΩ across joints requiring lightning protection or radio frequency grounding for electrical or electronic equipment. For a typical faying surface joints, local removal of the paint or anodize on the detail (down to bare metal) is required in the area of the fastener. Bare aluminum surfaces are subsequently coated with a chemical film (MIL-C-5541, class 1A). The joint is then bolted with stainless steel fasteners using stainless steel washers under the bolthead and nut to protect aluminum surfaces during application of torque. Fasteners are installed with the shank portion wetted with chromated epoxy polyamine primer. Joints are subsequently touched up with a chemical film and a coat of chromated epoxy polyamine primer around the washers. Faying surfaces are sealed with a continuous fillet of RTV 577, which is a white, thixotropic silicone rubber material.

There are approximately 30 different kinds of electrical grounding joints available to suite various designs on the orbiter; the grounding techniques used include jumpers, spot welds, staples, metallized tape, and the method described above. Even an adhesively bonded edge member or a T-section bonded to a honeycomb face sheet must be provided with a ground to the face sheet itself.

Dissimilar-metal joints are permitted on the orbiter without additional galvanic protection if they fall within the range shown in Table 1. Table 1 should be used only a guideline, and such factors as cathode-to-anode area ratios, corrosive environments, and other detrimental factors must be evaluated.

Table 1 Metals and alloys compatible in dissimilar-metal couples

Group number	Metallurgical category	emf, V	Anodic index(a), V	Compatible couples(b)
1	Gold, solid and plated; gold-platinum alloys; wrought platinum	+0.15	0	
2	Rhodium plated on silver-plated copper	+0.05	0.10	
3	Silver, solid or plated; high-silver alloys	0	0.15	
4	Nickel, solid or plated; monel metal, high-nickel-copper alloys	−0.15	0.30	
5	Copper, solid or plated; low brasses or bronzes; silver solder; German silvery high copper-nickel alloys; nickel-chromium alloys; austenitic corrosion-resistant steels	−0.20	0.35	
6	Commercial yellow brasses and bronzes	−0.25	0.40	
7	High brasses and bronzes; naval brass; Muntz metal	−0.30	0.45	
8	18% Cr type corrosion-resistant steels	−0.35	0.50	
9	Chromium plated; tin plated; 12% Cr type corrosion-resistant steels	−0.45	0.60	
10	Tin-plate; terneplate; tin-lead solder	−0.50	0.65	
11	Lead, solid or plated; high-lead alloys	−0.55	0.70	
12	Aluminum, wrought alloys of the 2000 series	−0.60	0.75	
13	Iron, wrought, gray or malleable; plain carbon and low-alloy steels; armco iron	−0.70	0.85	
14	Aluminum, wrought alloys other than 2000 series aluminum, cast alloys of the silicon type	−0.75	0.90	
15	Aluminum, cast alloys other than silicon type; cadmium, plated and chromated	−0.80	0.95	
16	Hot-dip-zinc plate; galvanized steel	−1.05	1.20	
17	Zinc, wrought; zinc-base die-casting alloys; zinc plated	−1.10	1.25	
18	Magnesium and magnesium-base alloys, cast or wrought	−1.60	1.75	



(a) Anodic index is the absolute value of the potential difference between the most noble (cathodic) metals listed and the metal or alloy in question. For example, the emf of gold (group 1) is +0.15 V, and the emf of wrought 2000-series aluminum alloys (group 12) is −0.60 V. Thus, the anodic index of wrought 2000-series aluminum alloys is 0.75 V. (b) "Compatible" means the potential difference of the metals in question, which are connected by lines, is not more than 0.25 V. An open circle indicates the most cathodic members of a series; a closed circle indicates an anodic member. Arrows indicate the anodic direction.

The fasteners chosen for the spacecraft are all basically corrosion resistant, but care must be taken with dissimilar-metal combinations. Bolts are typically made of alloys A-286 (965 to 1380 MPa, or 140 to 200 ksi), Inconel alloy 718 (1240 MPa, or 180 ksi), and MP35N (1655 MPa, or 240 ksi). For applications up to 870 °C (1600 °F), Udimet 500 is used (1035 MPa, or 150 ksi). Of these materials, only A-286 has shown any corrosion in service. Thecorrosion is only superficial and of on real concern. It is removed only for cosmetic reasons. None of these alloys is susceptible to hydrogen embrittlement in orbiter vehicle service.

Nuts are made from A-286 and Inconel alloy 718 and are lubricated with a thin (0.005 to 0.01 mm, or 0.2 to 0.4 mil) silver plate. Bolts and nuts are always installed with washers. The aluminum, therefore, never contacts the silver plate. Because the hole, as previously mentioned, is coated with wet chromated epoxy polyamine primer, no moisture can penetrate between the stainless or nickel shank and the aluminum hole. Stainless steel washers are separated from the aluminum surface with a dry coat of primer (where electrical grounding is not required) or a chemical film coating plus a

touchup of the primmer around the washer (where electrical grounding is required). No problems with galvanic corrosion are experienced in these installations.

Inserts, made from A-286, are silver plated and must also be installed into aluminum wetted on their exterior with the chromated epoxy polyamine primer. Where nuts are used in contact with titanium, only molybdenum disulfide-type dry film lubricants are used. Experience has shown that silver in contact with titanium at approximately 265 °C (500 °F) or above can bring about stress-corrosion cracking (SCC) of titanium (Ref 2, 3, 4). Titanium contact with silver is also prohibited by MIL-S-5002.

Titanium pin and collar fasteners are used for shear applications. To save weight, the orbiter uses aluminum alloy 2024 collars rather than A-286. Again, the holes are wet coated with the chromated epoxy polyamine primer by applying primer to the fastener shank away from the threads. Both ends of the fastener are subsequently touched up with the primer. Where such fasteners are used on the graphite cargo bay doors, it is necessary to use RTV rubber as a corrosion barrier, thus completely encapsulating the aluminum collar to prevent corrosion.

Rivets used on the spacecraft are made from aluminum alloy 2219-T62. These rivets provide good shear strength while avoiding the need to "ice box" rivets after solution treating, as is required with aluminum alloy 2024 rivets. Further, aluminum alloy 2024 rivets would undergo aging at entry temperatures of the orbiter (175 °C, or 350 °F), resulting in an increased susceptibility to corrosion as grain-boundary precipitation initiated. Aluminum alloy 2219-T81 rivets, although also commercially available, lack sufficient ductility to prevent cracking of driven heads. (The widely used aerospace aluminum alloy 7050-T73 rivets were unavailable when the shuttle orbiter was being built.)

Other Structural Alloys. No corrosion protection (except for passivation treatments after fabrication) is considered necessary for stainless steels. Stainless steels, particularly the precipitation-hardenable grades, will often display light surface corrosion products after extensive exposure. A light abrasion will remove the corrosion. No effort is made to passivate stainless parts as installed, because chemical spillage is considered more detrimental to the structure than any enhanced corrosion protection gained from passivation.

Nickel alloys such as Inconel alloy 718 and Inconel alloy 625 are used for elevated-temperature service with no corrosion protection. Inconel alloy 718 brazed honeycomb panels are used for the conical seals on the vertical stabilizer and for outboard elevon rub panels and flipper door panels. Inconel alloy 625, made as a resistance-welded sandwich, is used to temperatures of 870 °C (1600 °F). The surface of the sandwich is coated with a wear-resistant high-emittance chromium oxide coating.

Titanium also requires no further corrosion protection. Titanium, principally as Ti-6Al-4V, is widely used as forging, bar, and plate products throughout the spacecraft. Many other high-strength titanium alloys are also used. The major structural members of the aft thrust structure are made of Ti-6Al-4V. These transmit the thrust of the liquid rocket engines to the orbiter structure. Titanium honeycomb sandwiches, made by the liquid interface diffusion (LID) bonding process, are used as inboard elevon and flipper door panels. Although the honeycomb has a perforated core, no corrosion is experienced.

Because of prior experience in which processing and testing solutions had resulted in SCC of titanium alloys, a control specification, MF0004-018, has been imposed. This specification defines a list of fluids that are suitable for titanium and the specific conditions under which their contact is appropriate.

Beryllium alloy S-65 (99% Be min) is used structurally for the external tank door and for windshield retainers. Beams providing structural support in the windshield area use either S-65 or CIP HIP-1 (Ref 5), which is also nonstructurally for the navigational base and the star tracker boom, as well as for heat sinks. Beryllium must be protected in service. The beryllium is anodized according to a Rockwell internal specification and is painted with one coat of chromated epoxy polyamine paint or chemically filmed in a manner similar to that used for aluminum (MIL-C-5541). Two coats of the chromated epoxy polyamine paint are then applied. The anodized coating (0.05 mm, or 0.2 mil, minimum) reveals no corrosion when tested in 168 h of salt spray according to ASTM B 117.

Steels must be protected in service from the seacoast environment. Steels are often painted with chromated epoxy polyamine paint or plated with nickel or chromium, depending on the service. Cadmium plating is not used except under rare circumstances, because it can easily sublime in space and redeposit on cooler adjacent surfaces. To avoid problems with SCC and hydrogen embrittlement, steel alloys are restricted to 1380 MPa (200 ksi) or less in tensile applications, and precipitation-hardenable steels are restricted to the H1000 or higher-temperature tempers. Steels with tensile strengths as

high as 2070 MPa (300 ksi) can be used for applications that involve bearing, compressive, or shear loads; such applications include ball or roller bearings,valve seats, and springs. A more complete description of the corrosion protection of steel alloy parts that are in moving contact with each other can be found in the discussion "Mechanical Systems" in this article.

Niobium is used for low-stress applications in the orbiter airframe structure. Tubes and nozzle parts fabricated from niobium alloy C-103 (Nb-10Hf-1Ti-0.5Zr) are used in the reinforced carbon-carbon nose cap for the shuttle entry air data system (SEADS) program involving measurements of aerodynamics pressures. These parts have a VH109 silicide coating to prevent high-temperature oxidation. The coating was chosen because of its performance at the design temperatures (1455 °C, or 2650 °F) (see the discussion "Case Histories" in this section). Niobium alloy C-103 parts are used as closeout members in elevon seals to shield the hot plasma from the interior structure and mechanisms. These parts are coated with an R512E silicide coating. They were designed for service at maximum temperatures of 1370 °C (2500 °F). Silicide coating systems are ceramic in nature and may be chipped by impact on edges or surfaces. Tests were conducted to verify that parts with coating damage down to bare metal could still function for a limited number of flights (see the discussion "Case Histories" in this section).

Composite materials are widely used on the orbiter and present no corrosion problems except for graphite epoxy structures. Although graphite is compatible with titanium, corrosion-resistant steels (A-286 and 300-series stainless steels), nickel, and cobalt-base alloys, the galvanic potential between graphite and aluminum or graphite and steel requires special design considerations. Suitable galvanic isolation is accomplished by using a layer of titanium foil, Tedlar, Kapton, or type 120 glass fabric with suitable resin plus two coats of chromate epoxy polyamine primer. All edges of the joints between the graphite and the aluminum or steel are sealed with RTV silicone to preclude moisture intrusion.

More than 300 boron/aluminum composite tubes with diffusion-bonded Ti-6Al-4V clevises are used on the orbiter, principally in the mid fuselage to stabilize frames or as pressure vessel supports. The aluminum portion is painted with chromated epoxy polyamine primer. These present no special corrosion design problems. Also, there are no corrosion problems with boron epoxy-bonded reinforcements on titanium thrust structure tubes in the aft thrust structure.

Fluid Systems

The space shuttle orbiter fluid systems must provide for the storage, transfer, and regulation of 17 different fluids, as shown in Table 2. The fluid systems can be grouped into major functional areas:

- Environmental control and life support system (ECLSS)
- Electrical power system (EPS)
- Reaction control system (RCS)
- Orbital maneuvering system (OMS)
- Main propulsion system (MPS)
- Auxiliary power units (APU)
- Hydraulic system (HYD)

Table 2 Fluids used on the space shuttle orbiter

See also Fig. 4.

Index number	Fluid/gas	Location	System	Quantity	Explosive limit	Threshold limit value, ppm	Remarks
1	Ammonia (NH_3)	Aft fuselage	ECLSS	44.27 kg (97.6 lb)	16%	25	Two tanks
2	Breathing oxygen (GOX)	Mid fuselage	ECLSS	32.21 kg (71 lb)	NA[(a)]	[(b)]	One tank
3	Freon-21	Mid and aft fuselage	ECLSS	272.16 kg (600 lb)	NA	1000	System
4	Freon-1301	Crew compartment	ECLSS (fire extinguisher)	5.17 kg (11.4 lb)	NA	1000	Three tanks

5	Fluorinert, FC-40	Mid fuselage	EPS	17.5 kg (39 lb)	NA	. . .	Fuel cell coolant loops
6	Helium	Forward RCS module	Forward RCS	3.81 kg (8.4 lb)	NA	(c)	Two tanks
		OMS/RCS modules	OMS	44 kg (97 lb)	NA	(c)	Two tanks
		Aft fuselage	MPS	529.52 L (18.6 ft^3)	NA	(c)	Four tanks
		Mid fuselage	MPS	1843.4 L (65.1 ft^3)	NA	(c)	Six tanks
		Aft fuselage	Aft RCS	7.62 kg (16.8 lb)	NA	(c)	Four tanks
7	Hydrazine (N_2H_4)	Aft fuselage	APU	131.99 kg (291 lb)	4.7%	1	Three tanks
8	Hydraulic fluid	Forward, mid, and aft fuselage	HYD	344 L (90.9 gal)	204 °C (400 °F)	(d)	Three systems
		Landing gear struts	LDG	13.6 kg (30 lb)	110 °C (230 °F)	(d)	Nose and main gear
9	Liquid hydrogen (LH_2)	Aft fuselage	MPS	142.43 kg (314 lb)	4%	(c)	Feedlines and main engine
		Mid fuselage	EPS	83.47 kg (186 lb)	4%	(c)	Two tanks
10	Liquid oxygen (LOX)	Aft fuselage	MPS	2219 kg (4892 lb)	NA	(b)	Feedlines and main engine
		Mid fuselage	EPS, LSS	708.5 kg (2162 lb)	NA	(b)	Two tanks
11	Lubricating oil	Aft fuselage	APU	8.16 kg (18 lb)	245 °C (475 °F)	(d)	Three systems
12	Monomethyl hydrazine (MMH)	Forward RCS module	Forward RCS	480.75 L (127 gal)	3.0%	0.2	One tank
		Aft RCS modules	Aft RCS	961.5 L (254 gal)	3.0%	0.2	Two tanks
		OMS modules	OMS	4845.31 L (1280 gal)	3.0%	0.2	Two tanks
13	Nitrogen	Mid fuselage	ECLSS	103.42 kg (228 lb)	NA	(c)	Four tanks
14	Nitrogen tetroxide (N_2O_4)	Forward RCS module	Forward RCS	465.6 L (123 gal)	NA	5	One tank
		Aft RCS module	Aft RCS	935 L (247 gal)	NA	5	Two tanks
		OMS	OMS	4845.31 L (1280 gal)	NA	5	Two tanks
15	Water (deionized)	Crew module	ECLSS	29.5 kg (65 lb)	NA	None	Two cooling loops
		Aft fuselage	ECLSS	194.14 kg (428 lb)	NA	None	Three tanks
16	Water (potable)	Lower crew module	LSS	289.4 kg (638 lb)	NA	None	Four tanks
17	Water (waste)	Lower crew module	LSS	72.7 kg (159.5 lb)	NA	None	One tank

(a) NA, not applicable.

(b) No threshold limit value; upper limit is 6 h at 1 atm of pressure, lower limit is 19%.

(c) Simple asphyxiant, no threshold limit value.

(d) No threshold limit value; inhalation of vapors not encountered in normal use.

The locations of the pressure vessels used to contain these fluids are shown in Fig. 4. Design information covering these pressure vessels is given in Table 3.

Table 3 Major shuttle orbiter pressure vessels

Fluid/gas	System	Alloy	Number per vehicle	Size, diameter or length × diameter		Factor of safety	Operating pressure		Proof pressure		Burst pressure	
				mm	in.		MPa	psi	MPa	psi	MPa	psi
Ammonia (NH_3)	ECLSS	Ti-6Al-4V	2	437	17.2	4.0	2.2	320	4.3	625	8.9	1290
Breathing oxygen	ECLSS	Kevlar/Inconel alloy 718	1	660	26	1.5	22.8	3300	29.2	4240	34.1	4950

Note: The pressure vessels listed in Table 3 may differ slightly from Table 2, because Table 3 includes major accumulators, pressure vessels integral to a particular hardware system, and extra pressure vessels needed for some missions.

(a) Annealed.

(b) Solution treated and aged.

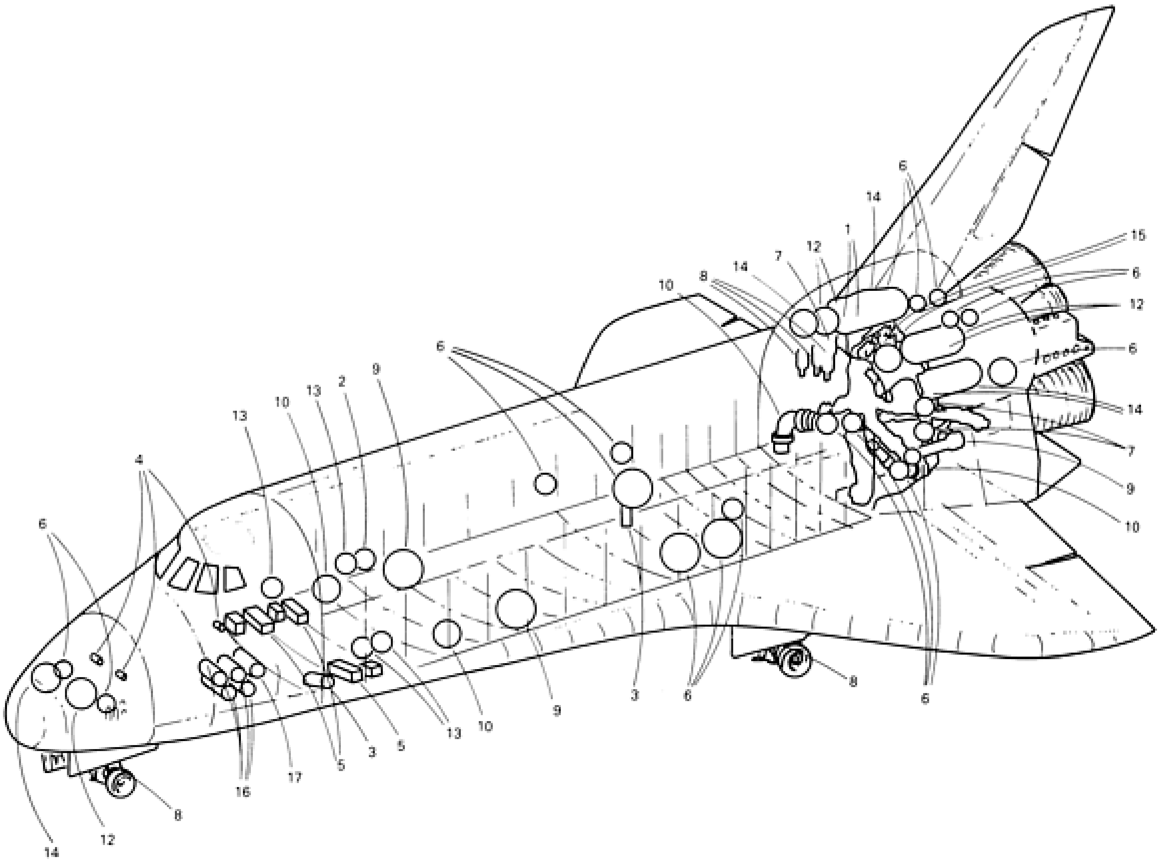

Fig. 4 Locations of liquids and gases in the space shuttle orbiter. Numbers correspond to the fluid index numbers used in Table 2.

Plumbing Lines. The philosophy followed in corrosion control for fluid systems and pressure vessels was to select materials that were compatible with the fluids without protective coatings and to control the fluid chemistry, not only as purchased but also during vehicle loading and operations. Stainless steel lines are used for all systems except hydraulic fluids and hot gaseous oxygen. Hydraulic fluids are contained in Ti-3Al-2.5V lines. Inconel alloy 718 is used for hot gaseous oxygen lines.

Because many of the fluids are hazardous (toxic, explosive), metallurgical joints were used in all permanent connections of stainless and Inconel alloy lines. Type 304L stainless steel was used for service with helium, hydrazine, liquid hydrogen, liquid oxygen, monomethyl hydrazine, nitrogen, and nitrogen tetroxide. Type 304L was selected to avoid potential sensitization. Most of the permanent joints were automatically welded by orbiting arc equipment, using an external sleeve of the same alloy to supply reinforcement to the weld bead, as shown in Fig. 5(a). The bead geometry on the inside of the tube is smooth and free from crevices that may initiate chemical attack. The stainless steel tubing, in many cases, is in the one-eight hard condition, and the sleeve also provides added strength to compensate for the localized annealing at the welds and heat-affected zone (HAZ); this results in the full efficiency of the one-eighth hard material.

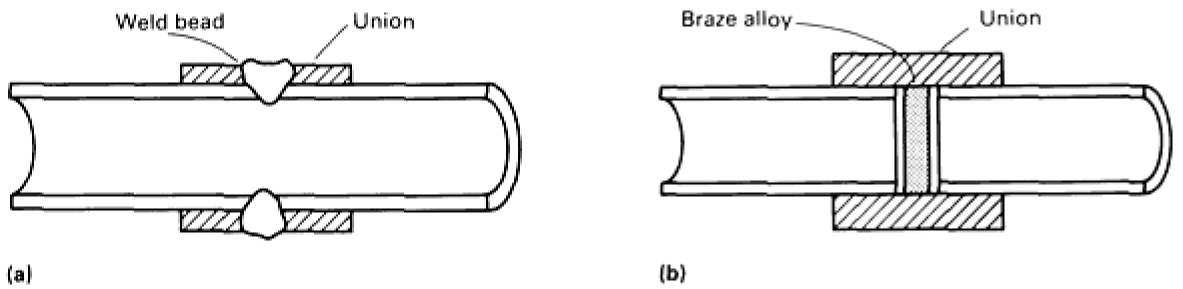

Fig. 5 Stainless steel and Inconel alloy fluid system permanent joints. (a) Automatic weld, inert gas, tungsten arc. (b) Braze joint

Alloy 21-6-9 stainless steel was used in lines carrying ammonia, breathing oxygen, freons, oxygen, hot gaseous hydrogen (280 °C, or 540 °F), nitrogen, and waters. The stainless steel was usually brazed with gold alloy Nicoro 80 (81.5 Au-16.5Cu-2Ni) in a configuration shown in Fig. 5(b). This configuration also eliminates an internal crevice in the lines, because the brazing alloy flows along the capillary between the tube and sleeve, seals it, and forms a fillet along the periphery of the sleeve. There were two concerns with this braze combination. First, would the braze alloy create a galvanic-corrosion problem? Testing of the electrode potentials and exposures with actual fluids showed no galvanic effect that could be detected. Second, would the copper in the braze alloy cause liquid-metal embrittlement? The literature indicated the 21-6-9 alloy to be particularly susceptible to copper embrittlement. Joints were made and sectioned to reveal the microstructure of the brazed joint.

Intrusion of the brazing alloy into grain boundaries did occur, but never exceeded 0.05 mm (2 mils) even after four induction brazing cycles. The intrusion did not affect the static or fatigue strength of the joint; in fact, it appeared to give a superior attachment to the substrate.

In many cases, stainless steel lines must connect pressure vessels made from titanium alloys such as Ti-6Al-4V. Typically, a bimetallic joint is used in which a steel tube is joined to a titanium tube or fitting, which is then welded to the pressure vessel. The steel-to-titanium tube joints are made by coextrusion or, in the case of the APU water tank, by swaging. Aluminum-stainless steel joints are required for attachment of plumbing to the aluminum alloy 2219-T6 tank. These joints are made friction welding. No galvanic-corrosion problems have been experienced with the fluids involved.

For hot gaseous oxygen lines operating to 31 MPa (4500 psi) and 300 °C (570 °F), it was more efficient to use Inconel alloy 718 to obtain the required strength at temperature. Inconel joints were welded in the same manner as the type 304L stainless steel joints described above. The Inconel alloy joints also had a type 304L stainless steel sleeve, which provided sufficient reinforcement to ensure that nearly the full heat-treat properties of the Inconel alloy 718 tubing were realized (ultimate tensile strength: 1240 MPa, or 180 ksi; tensile yield strength: 1035 MPa, or 150 ksi). Initial attempts were made to braze this alloy, but because of its tenacious high-temperature oxide film, repeat braze-debraze cycles (even over nickel-plated ends) could not be achieved.

The environmental control and life support system was designed to provide:

- Atmospheric control to the pressurized crew cabin (oxygen, nitrogen, carbon dioxide, water vapor, odor)
- Pressure control to the crew cabin
- Thermal control to the crew cabin and avionics boxes
- Potable water and waste management control

The temperature of the crew cabin is maintained between 16 and 32 °C (61 and 90 °F). Oxygen partial pressure is maintained at 22,000 N/m^2 (3.2 psi), and nitrogen is added to achieve pressures of 70,500 N/m^2 (10.2 psi) for space operations and 101,000 N/m^2 (14.7 psi) for launching conditions. Relative humidity is controlled to prevent condensation of moisture. Therefore, the cabin atmosphere is a benign environment from a corrosion standpoint.

Aluminum cold plates are used to remove heat from the electronic boxes in the mid and aft fuselages. The cold plates are fluxless brazed with aluminum alloy 6951 face sheets and aluminum alloy 6061 cores. Freon 21 (dichloromonofluoromethane) is the coolant. Stainless steel cold plates are used in the crew cabin to carry heat from avionics boxes within the cabin. These coldplates are brazed from AISI type 304L sheet using Amdry 930 (Ni-22.5Mn-5Cu-7Si). Deionized water is used in the stainless steel cold plates. A water loop transfers the excess heat from the cabin and cabin avionics equipment to the freon cooling loop by way of the cabin heat exchanger. The freon cooling loop delivers this heat, together with the heat from the fuel cells, payloads, and mid and aft avionics equipment, to a large aluminum radiator (111 m^2, or 1195 ft^2) where the heat is radiated into space. When the cargo bay doors are closed during ascent of immediately before reentry, an active thermal rejection system, the flash evaporator, is employed. Heat is rejected by the boiling of water in this system.

Stainless steel was chosen for water lines because of the prior difficulties encountered on the Apollo program with aluminum lines and cold plates. Despite the use of inhibitors such as triethanolaminephosphate (TEAP) and sodium mercaptobenzothiozole (NABT) on Apollo aluminum systems, serious corrosion problems were encountered. Solutions had to be continuously circulated to avoid solution concentration gradients leading to localized corrosion (pitting) of the aluminum lines. Pits as deep as 0.7 mm (28 mils) were found in aluminum lines after limited service.

To preclude problems with corrosion in water systems on the space shuttle orbiter, it was decided that stainless steel would be used for all water (cooling and potable) lines. Each material in the water path was identified, evaluated and accepted or changed, and tested in a control loop at NASA (Houston) for up to 2 years of service. Orbiter water chemistry was controlled to limit oxygen content to 0.5 ppm (to avoid localized oxygen concentration cells), conductivity was limited to $3.3 \times 10^{-6}\ \Omega^{-1} \cdot cm^{-1}$, and the pH was controlled within the 6.0 to 8.0 range. After more than 5 years of service, no corrosion problems have been experienced with stainless steel.

Waste water is handled by 21-6-9 stainless steel lines and is stored in aluminum alloy 6061-T6 tanks. Waste water tends to be extremely corrosive to aluminum. However, coatings such as Tufram, a tetrafluoroethylene-impregnated anodize, have been used effectively to protect aluminum tanks from urine.

The ammonia (NH_3 boiler provides for heat rejection at altitudes below approximately 30.5 km (100,000 ft); at these altitudes, the cargo bay doors are closed, and the boiling of the flash evaporator can no longer provide sufficient cooling to the freon. The ammonia boiler is a shell and tube heat exchanger with a single pass on the ammonia side and two passes for each Freon-21 coolant loop. The ammonia flows through the bank of 77 small-diameter stainless steel tubes, and the Freon-21 flows over the exterior of the tubes. Because these tubes have such thin walls (0.2 mm, or 8 mils), perforation by corrosion is a major concern. Corrosion has been experienced as isolated areas of intergranular attack due to misprocessing of type 304L stainless steel tubing. Very small amounts of carbon residue left on a thin-wall tube such as this will result in sensitization during its brazing cycle. A change has recently been made to a stabilized grade (type 347 stainless steel) to avoid these problems.

Ammonia is stored on a titanium Ti-6A1-4V pressure vessel. No corrosion problems have been experienced in this application. Nitrogen is stored at 22.8 MPa (3300 psi) in Ti-6A1-4V pressure vessels that are filament overwrapped with Kevlar 49 aramid. It presents no corrosion problems.

Gaseous breathing oxygen is stored in a pressure vessel made from Inconel alloy 718 that is also overwrapped with Kevlar 49 aramid filament. It also operates at 22.8 MPa (3300 psi). Extreme care must be taken when designing either liquid or gaseous oxygen systems because of the dangers of ignition with metals and organic materials (Ref 6). Titanium and magnesium are not used in oxygen systems for this reason and are considered to be highly reactive under impact. Materials that are considered satisfactory for use must pass an impact test consisting of 20 consecutive impacts at an energy level of 98 J (72 ft·lb) when tested in the Army Ballistic Missile Agency (ABMA) Impact Tester according to NHB 8060.1, Test 13. Further, when gaseous oxygen pressures exceed 6.9 MPa (1000 psi), materials must also pass dynamic qualification (pneumatic impact) according to NHB 8060.1, Test 14.

Although extreme care is taken in material selection for oxygen systems, this is not enough to ensure an ignition-free system (see the discussion "Case Histories" in this section). Because an oxygen ignition is a catastrophic event that results in an explosion and significant molten metal, it is not always possible to reconstruct the precise cause of a failure. Metallic materials that pass the above tests can still ignite if design or manufacturing operations result in:

- Energetic particle impact, caused by particles accelerated to sonic velocities
- Contamination

- Pneumatic shock from rapid valve opening across large pressure differences
- Fretting or galling, generating particles and localized high temperatures
- Frictional heating, such as by flowing past a feather edge
- Gaseous heating, such as by adiabatic compression and Helmholz resonance (resonance in blind columns) (Ref 7, 8)

Of the various engineering metals tested, Inconel alloy 718 and Monel alloy 400 offer superior resistance to ignition problems and are preferred in valves in which dynamic problems can occur. When properly designed and manufactured, stainless steel has been successfully used in oxygen and LOX valves. Aluminum, stainless steel, and Inconel have been employed without incident in numerous oxygen pressure vessels.

The electrical power system uses fuel cells to generate electricity by combining gaseous hydrogen and oxygen. The electrolyte in the fuel cell--potassium hydroxide--is contained between gold-plated magnesium electrodes. For corrosion protection, the magnesium substrate is plated with zinc, copper, and nickel beneath the gold.

The hydrogen and oxygen are stored as supercritical gases in double-wall pressure vessels. The hydrogen is contained in an aluminum alloy 2219-T6 inner shell that has been electron beam welded; the oxygen is stored in an inner pressure vessel of electron beam welded Inconel alloy 718. Both tanks are suspended within pressure-tight external shells made of aluminum alloy 2219-T6. A series of 12 S-glass/epoxy straps suspend the inner tank from the forged girth ring of the outer shell. The annulus between the vessels contains multilayered reflective insulation. A pressure level 1×10^{-5} torr is maintained by a vacuum ion pump. Aluminum alloy 2219-T6 is very susceptible to intergranular pitting corrosion, and care must be taken during fabrication to prevent dirt particles and/or moisture from coming in contact with it (see the discussion "Case Histories" in this section).

The reaction control system uses rocket engines burning monomethyl hydrazine (MMH) with N_2O_4 to achieve the desired attitude control of the orbiter while in orbit. The 38 reaction control engines are each capable of providing 3870 N (870 lbf) of thrust. Six vernier RCS engines allow fine tuning of the orbiter attitude. They develop 111 N (25 lbf) of thrust each.

Both N_2O_4 and MMH are stored in pressure vessels made of Ti-6A-4V. Several precautions must be taken in the case of N_2O_4. First, ingestion of moisture will result in the formation of nitric acid, which can be corrosive to some elements of the system.

Second, N_2O_4 spills can be dangerous because of toxicity and can be destructive to spacecraft hardware. Nitrogen tetroxide will readily corrode nickel, strip off protective paints, and dissolve nylon. In addition, because it is an aggressive oxidizer, N_2O_4 can react violently and ignite organic materials.

Third, N_2O_4 will cause SCC of titanium in the absence of a trace of nitric oxide (NO) (Ref 9, 10, 11, 12) (see the discussion "Case Histories" in this section). Current specifications call for 1.5 to 3% NO; but repeated loading causes volatile loss of NO, and storage may cause stratification. Although only a trace of NO (perhaps as little as 0.2%) will prevent SCC, care must be taken to ensure at least 0.6% NO to be safe.

Fourth, impact ignition of titanium can occur in N_2O_4. Tests have shown that threaded fasteners can suffer localized melting and that even an impact of inert material, such as glass or sand, on the titanium surface can result in localized melting in N_2O_4. Unlike the oxygen reaction, the reaction is quickly quenched and occurs as low as the 54- to 68-J (40 to 50-ft-lb) level on the ABMA Impact Tester. Therefore, only aluminum fasteners threaded into titanium N_2O_4 tanks are permitted on the space shuttle orbiter, this ensures that designs are free of contamination and potential impacts.

Finally, one of the major problems with N_2O_4 is not the problem of spacecraft corrosion but the deposition of corrosion products (picked up during storage) into valves, preventing valve closure and restricting flow. Nitrogen tetroxide dissolves small amounts of iron (a few parts per million) from storage tanks. The solubility of the iron is a function of temperature, water content, and NO content. Proper conditioning of N_2O_4 prior to loading will precipitate out complex iron nitrate compounds; this will prevent problems caused by corrosion product deposition (see the discussion "Case Histories" in this section).

Monomethyl hydrazine itself can cause problems. Although it is not as unstable or reactive as neat (pure) hydrazine, which will be covered in detail in the discussion "Auxiliary Power Unit" in this section, it must be handled in essentially the same way as pure hydrazine.

Rocket chambers used in the reaction control system are made from niobium alloy C-103. These are coated with an R512A silicide coating that prevents oxidation in high-temperature service (up to 1315 °C, or 2400 °F). No oxidation problems with reaction control engine chambers have been experienced in service. The primary chambers are film cooled with hydrazine. Burnthrough has occurred in laboratory testing under off-limit conditions (engine instability); however, current design modifications prevent further structural damage to the spacecraft by using automatic sensing devices that shut off fuel and oxidizer valves if penetration of chamber walls occurs.

The vernier engines have also shown localized burnthrough during extensive laboratory testing when hot oxidizer impinges on the silicide coating. This condition is aggravated by the thousands of thermal cycles (thermal fatigue) required by this engine, the inability of the coating to accommodate minor machining offsets or discrepancies without fracture, the lack of a fuel-cooling film along the inside of this chamber design, and a doublet-type injector that limits the mixing of the fuel and oxidizer (see the discussion "Case Histories" in this section).

Helium pressure vessels (28 MPa, or 4000 psi) made of annealed Ti-6Al-4V liners overwrapped with Kevlar 49 aramid filament provide the pressure necessary to feed the propellants. Some corrosion problems have been encountered in helium systems. The orbiter has experienced problems with hydrazine vapors migrating into the fine orifices of helium valves. Reactions with surface contaminants have resulted in plugging of orifices due to complex hydrazine deposits (see the discussion "Case Histories" in this section). Helium systems must always be designed to be compatible with the fuels and oxidizers with which they are used, because back migration (diffusion) of these substances will occur.

The orbital maneuvering system provides the propulsion to insert the shuttle orbiter into earth orbit, to change orbit, to rendezvous, and to deorbit. As with the reaction control system, it also uses the storable propellants N_2O_4 and MMH, as well as a helium pressurant system. The two OMS engines are capable of providing 267,000 N (6000 lbf) of thrust. The propellant tanks have the capacity to provide a change in velocity of 300 m/s (1000 ft/s) when carrying a full payload of 29,500 kg (65,000 lb).

The nozzles are made of niobium alloy FS-85 coated with an R512E silicide coating that is used for the RCS rocker chambers. These nozzles are used for service to 1350 °C (2480 °F) (Ref 13). Injectors are made from diffusion-bonded 300-series stainless steel platelets. Platelets have injector hole patterns etched in them by a photographic etching process.

The pressure vessels for the fuel and oxidizers, operating at 2.2 MPa (315 psi), are made from annealed Ti-6Al-4V. The helium pressure vessels (33 MPa, or 4800 psi) are made from annealed Ti-6Al-4V overwrapped with Kevlar 49 aramid filament.

The fuel and oxidizer present the same types of problems as those experienced in the RCS, except for the nozzle extensions. High-temperature oxidation of the nozzle extensions has occurred in areas where mechanical deformation (buckling) caused cracking and spalling of the silicide coating and where thermocouple attach brackets were broken off in service (see the discussion "Case Histories" in this section).

The main propulsion system provides the vacuum-jacketed lines for carrying liquid hydrogen and liquid oxygen from the external tank to the shuttle main engines. These lines are also used to carry high-pressure high-temperature gaseous oxygen and hydrogen back to the external tank as a pressurant to expel the liquid hydrogen and liquid oxygen.

The compatibility problems with gaseous oxygen have been covered in the discussion "Environmental Control and Life Support System" in this section. With gaseous hydrogen, the compatibility issue concerns the embrittlement of metals by hydrogen under certain specific conditions. The extent of embrittlement is a function of hydrogen pressure, strain level, and, probably, time of exposure. the embrittlement is thought to occur from rupture of the protective oxide film of the metal, followed by some mechanism by which atomic (nascent) hydrogen enters the metal. In mild cases, this embrittlement takes the form of a reduction in notched strength in hydrogen compared with specimens exposed to helium or air. In more severe cases, the ductility or tensile strength of the alloy changes significantly.

In the case of titanium, embrittling hydrides are formed; within a few minutes, these hydrides can result in the destruction of the entire cross section of a part (see the discussion "Case Histories" in this section). For this reason, exposure of titanium to hydrogen is totally avoided.

With other metals, it is important to verify compatibility at the maximum service pressures. Most metals do not show significant property changes below 3.45 MPa (500 psi). At hydrogen pressures of 13.8 MPa (2000 psi), materials such as Inconel alloy 718 show measurable loss of ductility, and at 69 MPa (10,000 psi), even austenitic stainless steel is affected.

No accepted criterion exists for the use of metals in gaseous hydrogen. At the Rockwell Space Transportation System Division, for example, an alloy is used in gaseous hydrogen if its sharp notched ($K_t \sim 17$) to unnotched strength ratio at maximum design pressure does not fall below 1.0 and if a factor of safety of four is maintained in the system. At the Rockwell Rocketdyne division, materials are strain limited, and materials susceptible to high-pressure gaseous hydrogen are copper plated (0.1 to 0.25 mm, or 4 to 10 mils) to ensure that no adverse reactions occur. Welds in nickel alloys are overlayed on the root side by two layers of Inconel alloy 903.

Leakage of hydrogen is a major concern in design because hydrogen can form an explosive mixture with air at concentrations between 4 and 96% hydrogen. The aft areas of the orbiter are extensively purged with helium before launch to avoid this problem if a leak occurs.

The vacuum-jacketed lines carrying LOX and LH_2 are of two size--305 mm (12 in.) and 430 mm (17 in.) in diameter--and are made of welded Inconel alloy 718. Inconel alloy 718 is ideal for this service because it is compatible with both liquid and gaseous hydrogen (at these pressures) and maintains high ductility below -253 °C (-423 °F). The vacuum-jacketed lines must accommodate expansion and contraction and are designed to do so by articulation and angulation at joints. Bellows of Inconel alloy 718 accommodate angulation while containing the cryogens. The articulation is provided by gimbal rings and internally supported ball-strut tie-rod assemblies. The hardened balls, ranging in size from 32 to 57 mm ($1\frac{1}{4}$ to $2\frac{1}{4}$ in.) in diameter, are made of a tungsten carbide (Stoody 2) alloy.

Inconel alloy 718 (see the discussion "Plumbing Lines" in this section) is used for the high-pressure high-temperature oxygen lines (31 MPa, or 4500 psi, at 280 °C, or 540 °F) that deliver pressurant to the external tank. Helium pressure vessels are made from annealed Ti-6Al-4V and annealed Ti-6Al-4V overwrapped with Kevlar 49 filament.

The auxiliary power unit provides hydraulic pressure for the actuation of a number of flight control systems, including the rudder, speed brake, body flap, elevons, landing gear, and brakes. Power is obtained by vaporizing and decomposing neat (pure) hydrazine in a catalyst bed and passing it through a two-stage turbine, which in turn drives a hydraulic pump. Each of the three APUs develops 100 kW (135 hp), and the pump delivers 18 MPa (3000 psi) to the hydraulic system.

The compatibility of hydrazine with materials in a system must consider several points. First, hydrazine can be unstable and will decompose into N_2, H_2, and NH_3, causing a rapid pressure rise and, if not properly vented, an explosion. Neat (pure) hydrazine tends to be more reactive (unstable) than monomethyl hydrazine. Decomposition is catalyzed by metal surfaces and/or contaminants left on surfaces, even after cleaning. The data base in aerospace is large and highly inaccurate regarding metal-hydrazine compatibility for several reasons:

- Many of the early investigators rated compatibility as satisfactory based on appearance of the metal specimen exposed, not the fluid reaction
- No uniform cleaning method or decomposition criteria existed when data were generated
- No uniform controls were used in testing

The current approach at the Space Transportation and System Division is to use materials that have a history of satisfactory hydrazine service at the temperatures expected. Where a new material is used, pressures rise tests of the new material versus time are made, along with controls of compatible materials cleaned in the same manner. Literature data, because of their unreliability, are not used except to indicate which materials should be tested.

Second, a metal should also be checked with hydrazine to determine its autoignition temperature (AIT). This is done to ensure the AIT is safely below operating temperature. No standards are available for autoignition testing. Frequently, the fluid is allowed to drip onto a heated plate of the test metal, and the temperature of the test metal is slowly raised until ignition occurs.

Third, hydrazine, with even short exposure to air (a few seconds), will react with CO_2 to form carbazic acid--a very viscous, sticky compound which can clog lines, orifices, or valves. It can also aggressively attack certain metals, such as cobalt and nickel. Hydrazine systems must always be kept under an inert gaseous blanket whenever opened.

Fourth, hydrazine (and carbazic acid) will dissolve or selectively leach certain metals. This may later result in malfunction of a valve by the flow-decay phenomenon, in which hydrazine salts of these metals end up precipitating at valve seat areas (see the discussion "Case Histories" in this section).

Fifth, every effort must be taken to avoid hydrazine spills, because hydrazine is very toxic (Table 2) and highly flammable in air if spread out over a large area (large surface-to-volume ratio). Ignition has occurred when hydrazine was spilled or orbiter thermal protection system tiles made from sintered pure SiO_2 filaments.

The metals used in the APU in contact with hydrazine include 300-series stainless steels, precipitation-hardening steels, tungsten carbide (for valve seats), and Hastelloy alloy B. After the hydrazine has been decomposed by the catalyst bed, its major compatibility problem is with the formation of nitrides by the hot ammonia gas formed. The catalyst bed exceeds 925 °C (1700 °F), and the turbine operates at 595 °C (1100 °F). Alloys are chosen both for high-temperature properties and resistance to nitriding. The turbine wheel and blades are made from René 41. The wheel has a circumferential Inconel alloy 625 shroud welded with Hastelloy alloy W wire to the blade tips. The injector section and catalyst bed housing are from Hastelloy alloy B.

The hydraulic system uses predominately type 300 series stainless steel valves and components attached to Ti-3Al-2.5V lines. The titanium lines were chosen because they saved approximately 270 kg (600 lb) over stainless steel Permanent joints are externally "swaged" with Permaswage fittings that also incorporate RTV 630 rubber seal rings as a backup to the metal-to-metal seal. In the presence of hydraulic oil, the rubber expands, ensuring a tight joint capable of sealing hydraulic oil. Hydraulic oil per MIL-H-83282A is used throughout the spacecraft except in the landing gear struts, where oil per MIL-H-5606C is used. Control of the chlorine content of hydraulic oil is the most important approach to ensuring corrosion-free systems. (Chlorine concentrations above 100 ppm can cause corrosion problems.) No major corrosion problems have been experienced in the shuttle orbiter hydraulic systems.

Mechanical Systems

Mechanical systems include primarily mechanical devices, pyrotechnical devices, and landing gear systems. These systems mainly employ high-strength steels. Inconel alloys, and some aluminum alloys.

Mechanical Devices. Steels, because of their high strengths and hardnesses, are often preferred for mechanical devices. Higher loading can be directed into a smaller space volume than with aluminum or titanium, which are less dense. Typical applications involve 4130 and 4340 low-alloy steels for mechanical devices and 4340 or alloy steel carburized grades for gears. Low-alloy steel parts must be protected from corrosion. Depending on the design and service, the following types of systems are used:

- Paints, such as chromated epoxy polyamines
- Phosphate coating (DOD-P-16232) with oils
- Cadmium-titanium or cadmium plating plus an overcoating
- Electroless nickel
- Chromium , electroplated
- Black oxide
- Nickel/tin, electroplated
- Electroless nickel plus electroplated chromium
- Vapor-deposited aluminum

In addition, lubrication coatings such as Braycoat grease (space compatible), molybdenum disulfide in an organic matrix, or Vitrolube NPI-1220 (a high-temperature vitreous-base lubricant) are used. Where sufficient corrosion resistance cannot be achieved with steels, corrosion-resistant alloys are used, such as Inconel alloy 718, titanium Ti-6Al-4V or Ti-6Al-2Sn-4Zn-6Mo, and precipitation-hardenable steels (such as 17-4PH, 15-5PH, AM350, AM355, and Custom 455).

For bearings, type 440C stainless steel and 52100 bearing steel area used, protected with Braycoat grease. High-strength springs are made of type 301 stainless steel in the condition B spring temper, Elgiloy, and 17-7PH in the CH900 condition. High-strength Belleville washers, using 6150 low-alloy steel, exhibit the best resistance to hydrogen embrittlement if they are coated with vapor-deposited aluminum (see the discussion "Case Histories" in this section). Some use is also made of maraging steels and 9Ni-4Co-0.3C steel for such applications as hydraulic cylinders.

Pyrotechnic devices are used to separate the external tank from the orbiter, to release umbilicals, and to open emergency escape hatches or panels. Pyrotechnic devices operate in a number of different ways. In some designs, the explosive device is within the bolt or nut, forcing its separation. Other designs may cut a panel with a linear-shaped charge or blow a panel joint apart far enough to break bolts at a prenotched section. Explosively actuated guillotines have been used on the Apollo to cut cables or shrouds and have been used in some shuttle applications. Pyrotechnic devices have been used to deploy parachutes or to release landing gear. On the shuttle orbiter, most pyrotechnic devices are made of Inconel alloy 718. This includes the frangible nuts attaching the external tank to the orbiter in the aft section, the explosive bolts that mate the external tank with the orbiter in the forward section, and the crew escape and emergency egress hatches.

Guillotine blades have been made of Inconel alloy 718, A-286, and corrosion-protected tool steels. No corrosion problems have occurred in these areas.

The orbiter landing gear system is a conventional aircraft tricycle configuration with steerable nose gear and the main left and right landing gear. The major parts of the system include the shock strut assembly, wheels and tires, axles, brakes and antiskid controls, and nose wheel steering and damping controls. Initiation of the system hydraulically releases uplock hooks that permit the landing gear to free fall into the extended position. Springs and hydraulic actuators assist in the free fall. Pyrotechnic actuators may also unlock the uplock hooks if the hydraulic system malfunctions. When fully extended, the gear is locked by spring-loaded bungees.

Minimum weight was a prime consideration in the design of the landing gear. This resulted in the need to use high-strength materials, highly efficient braking materials, and minimum thicknesses for tires and wheels. Tires were designed for 2 landings, brakes for 5 landings, and wheels for 100 missions, although increased loading has reduced wheel life somewhat. The steel used for parts carrying high loads was primarily 300M at a 1895-MPa (275-ksi) strength level. The use of high-strength steels in this manner represented a deviation from limitations placed by the Material and Process Group on steel strength levels throughout the spacecraft (see the discussion "Primary Structure" in this section). At this high strength level, steel is notch and impact sensitive, has limited toughness, is prone to stress-corrosion problems, and is highly susceptible to hydrogen embrittlement. Its selection, however, was based on a history of satisfactory use in landing gear applications for both civilian and military aircraft over a 20-year period. Nevertheless, serious embrittlement problems were encountered during development and in early orbiter service.

The 300M steel was corrosion protected on functional surfaces by either cadmium alone or by chromium plating. Nonfunctional surfaces were coated with a cadmium-titanium plating plus a chromated epoxy polyamine paint primer and a polyurethane topcoat. Normally, cadmium plating would be avoided because of its tendency for sublimation and redeposition in the space environment, but the environment of the landing gear in the orbiter wheel wells precluded space exposure and sublimation problems. No corrosion problems have been identified with the 300M finish system in service; however, several misprocessing problems with chromium plating and plating of the cadmium-titanium finish have resulted in hydrogen embrittlement failures (see the discussion "Case Histories" in this section). The cadmium-titanium plating is considered to be a low-embrittlement plating process and is currently covered by MIL-STD-1500.

The current brake designs use thermal grade beryllium heat sink disks (both rotors and stators) with reinforced carbon-carbon linings. They are chemically filmed in a manner similar to that described for aluminum in MIL-C-5541 and are unprotected on their mating (working) surfaces. Temperatures during braking can be very high locally because of uneven pressure distributions and have occasionally resulted in beryllium carbide formation (>1095 °C, or 2000 °F) during high-energy stops in early brake designs. Carbide formation results in embrittlement, cracking, and potential failure of the braking system. Unfailed parts showing this condition are scrapped. Galvanic corrosion between the carbon and beryllium would appear to be a concern, but such a problem has never occurred. Newer brake designs will use structural carbon-carbon to replace the beryllium; this will result in longer life (lower lifetime costs) and higher energy absorption capability, but higher axle and wheel temperatures are expected.

Axles were made of 300M steel. The nose landing gear axle was later changed to Inconel alloy 718 for improved fatigue life. The cadmium-titanium coating on the 300M main landing gear axles will not exceed 230 °C (450 °F) during normal operation and is safe from liquid cadmium embrittlement. In a rare, high energy level emergency stop, this temperature

could be exceeded, resulting in a potential for cadmium embrittlement. This would occur as heat from the brakes soaks back into the axle well after the vehicle has stopped. Under these conditions, the axle would be replaced.

Wheels are currently made of die-forged halves of aluminum alloy 7049-T73 that are bolted together with high-strength MP35N fasteners. The main wheels are chemically filmed according to MIL-C-5541, followed by a chromated epoxy polyamine primer (MIL-P-23377) and a topcoat of polyurethane according to MIL-C-83286 for corrosion protection. The nose wheel substitutes anodizing for the chemical film treatment; otherwise, it is identical. No corrosion problems have been experienced.

Aluminum alloy 7075-T73 is used for hydraulic actuators. Exterior surfaces are protected by chromate conversion coating plus chromated epoxy polyamine primer and polyurethane topcoat. Interior surfaces are immersed in hydraulic fluid and are not coated. No corrosion problems have occurred with the aluminum acuators.

Avionics

All orbiter avionics systems are located within the spacecraft structure or pressurized cabin; therefore, from a corrosion standpoint, they experience a controlled and relatively benign atmosphere that is free of rain and salt spray. Electronic equipment located within the orbiter cabin or cargo bay areas, because of the controlled humidity, cannot experience condensation of moisture, but equipment within the aft equipment bays can experience potential condensation. Based on the types of equipment, corrosion protection can be further examined in three areas:

- Black boxes
- Electronic circuits
- Electrical connectors

Black boxes are typically made of the relatively corrosion-resistant 6000-series aluminum alloys, either welded or dip brazed and resin sealed. The boxes are painted or anodized according to MIL-A-8625 on the exterior. They are chemically filmed according to MIL-C-5541 on the interior and on areas that contact coldplates to ensure maximum heat transfer and electrical grounding. The paint system is not fixed; it may be the chromated epoxy polyamine primer used for the spacecraft or a system chosen by the manufacturer; however, it must meet the requirements for exposure to humidity and salt spray of Federal Test Method Standard 141, Methods 6201 and 6061, respectively. Some boxes are sealed with a gasket; others are environmentally sealed and filled with an inert gas. Air-cooled black boxes located in the crew cabin are unsealed.

All electrically active surfaces of electrical and electronic circuits, including solder joints, printed circuits, and wire terminations, are conformally coated. The coatings used include Dow Corning 3140 and 3145, Columbia Technology Hysol and Furane Plastics polyurethanes, and General Electric RTV 560 and RTV 566. Printed circuit conformal coating thicknesses range from 50 to 250 μm (2 to 10 mils). Coatings on other surfaces range from 100 to 375 μm (4 to 15 mils).

Electrical connector metallic parts are made of various aluminum alloys of 300-series stainless steels. All aluminum parts are nickel plated. Plating thickness is not always specified, but conectors must pass salt spray corrosion tests per MIL-STD-202, method 101, test condition B.

Connector pin and socket contacts are electrolytically gold plated over a copper and nickel strike. A gold plate thickness of 1.25 μm (50 μin.) is considered to be borderline between porous and nonporous plating. All orbiter connector contacts include a minimum gold plating thickness of 2.5 μm (100 μin.). When mated, the connectors are environmentally sealed by peripheral gaskets.

No major problems have occurred with corrosion of avionics devices. Nitrogen tetroxide spills in the OMS pod areas and forward RCS areas have required in-depth evaluation of the suitability of connectors and pin contacts; however, no abnormal functions were noted even though connector bodies turned green.

Case Histories

Despite extensive efforts to anticipate and avoid corrosion problems with manned spacecraft, such problems will inevitably occur. Corrosion problems, as a group, have clearly become the most critical and costly problems with metals used on space vehicles. Because many corrosion problems can result in unexpected or catastrophic failures, especially those of SCC, hydrogen embrittlement, and metal ignition (in oxidizers), their impact is usually severe. Extensive efforts must be made to identify the precise cause of failrue and to provide suitable inspections and rework for existing hardware; the lives of the astronauts cannot be jeopardized nor can the risk be taken of severe damage to a $2 billion orbiter. As a consequence, some corrosion problems have resulted in rather expensive launch delays, and the inevitable questions are asked: "Why did this occur? Why was this not foreseen?"

There are no simple answers. Field experience is unparalled in revealing differences in behavior from laboratory test results or the deficiencies in the hardware designs. The reasons for corrosion problems discussed in this section can be broadly categorized as follows:

- Lack of adequate protection of parts during the manufacturing cycle
- Failure to remove processing chemicals or fluids completely
- Failure to provide an adequate hydrogen embrittlement relief
- Use of improper or contaminated fluids during manufacturing or testing
- Failure to control fluid chemistry within a spacecraft fluid system
- Inadequate corrosion protection
- Unknown reactions or unforeseen problems

In this section, a variety of different corrosion problems that have occurred will be presented. These embrace many metal systems, such as aluminum, stainless steel, low-alloy and precipitation-hardenable steels, nickel, titanium, and niobium, as well as several different types of corrosion attack. The descriptions that follow will identify the specific causes of the corrosion, its characteristics, and how it was corrected.

Pitting Attack

Pitting attack of metals is caused by local breakdown in a protective oxide film due to local surface inclusions or defects, local changes in microstructure (such as by precipitates that strengthen the metal), or local corrosion cells brought about by deposition of more cathodic materials on a surface. When a pit occurs, the bottom of the pit is anodic and often continues to grow until perforation occurs.

Pitting attack of the 2000- and 7000-series aluminum alloys often occurs during the manufacturing cycle if parts are not properly protected with oil or chemical film (MIL-C-5541). Many parts are transported to machining sources, chemical milling plants, and heat-treating companies for processing, often in open-top trucks in California. Occasionally, parts are not unloaded over the weekend and are left exposed to the elements. In other cases, parts may be stored outside, perhaps protected by plastic or a tarp, or even stored inside next to doors; these methods of storage alloy condensation to form on the parts. No outdoor storage is satisfactory. Dust that collects on the parts absorbs moisture from the air, resulting in significant pitting--in some cases within 24 h. Moisture condensation under plastic in contact with the part results in severe attack.

Aluminum Spacecraft Structural Parts. Typical pitting attack (Fig. 6) occurred on an aluminum alloy 2014-T6 tests part during the Apollo program. The maximum depth of attack was 0.1 mm (4 mils), about the same as the diameter. The pitting is intergranular. If the quench rated is sufficiently rapid during the heat treating of aluminum, no intergranular corrosion occurs within a pit (see the article "Heat Treating of Aluminum Alloys" in *Heat Treating,* Volume 4 of *ASM Handbook*). Because pits such as that shown in Fig. 6 are only slightly larger in diameter than a human hair, they may be missed unless close surface examination of aluminum is made at a magnification of 5 to 10×. This has made it difficult to convince in-house manufacturing personnel or subcontractors of the seriousness of protecting surfaces, and it is only when a gross area of pitting becomes obvious that arguments cease. Another Rockwell facility in Tulsa insisted that the pitting problem was characteristics of the California environment and even ran 6-month exposure tests of unprotected aluminum to prove it. Results are shown in Fig. 7. The coupon shown in Fig. 7(a) was heat-treated aluminum alloy 2024 exposed in the metal-processing area, and the one shown in Fig. 7(b) was heat-treated aluminum alloy 2014 exposed in the manufacturing area.

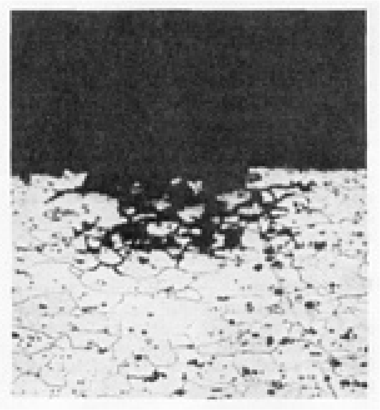

Fig. 6 Pitting corrosion of an aluminum alloy 2014-T6 sheet. Pitting occured during the manufacturing cycle. Note the intergranular nature of the pit. 150×.

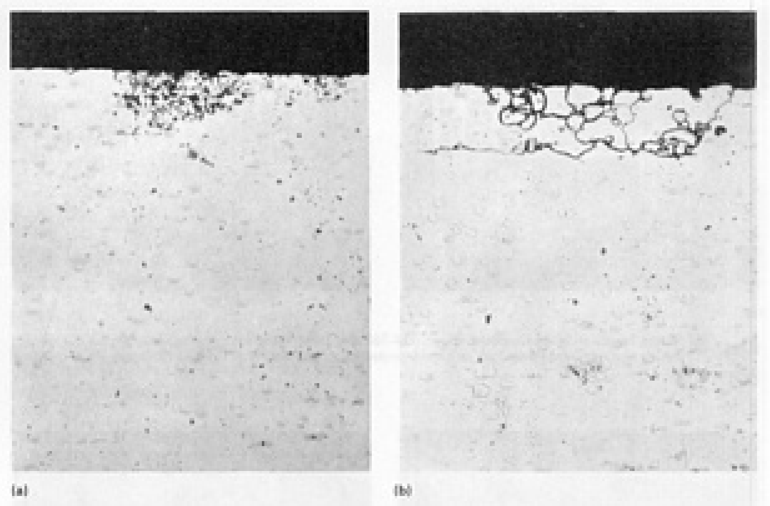

Fig. 7 Heat-treated aluminum pitted from 6 months of in-plant exposure. (a) Aluminum alloy 2024 exposed in the metal-processing area. (b) Aluminum alloy 2014 exposed in the manufacturing area. Note the intergranular nature of the pits. Both 285×

Typical pitting on improperly protected spacecraft parts is shown in Fig. 8. The pits shown are typical of those found in a 7075-T6 radial shear beam of the Apollo Service Module after a fatigue test failure. Although the fatigue test represented an overtest of the structure, pitting and extensive end-grain attack from the chemical milling process contributed to the failure. Figure 9 shows typical pitting corrosion of an aluminum alloy 2024-T62 fitting resulting from inadequate protection during manufacturing.

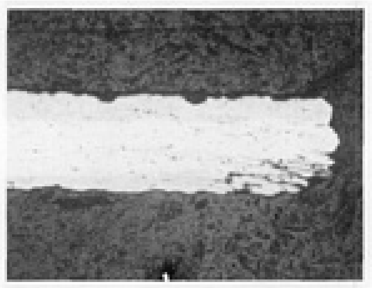

Fig. 8 Pitting corrosion of an aluminum alloy 7075-T6 aluminum radial shear beam from the Apollo program. The beam is machined and chemically milled from a 64-mm (2.5-in.) think plate to a final nominal thickness of 0.45 mm (0.018 in.). Pitting occurred from improper protection either during manufacturing or in service. 30×

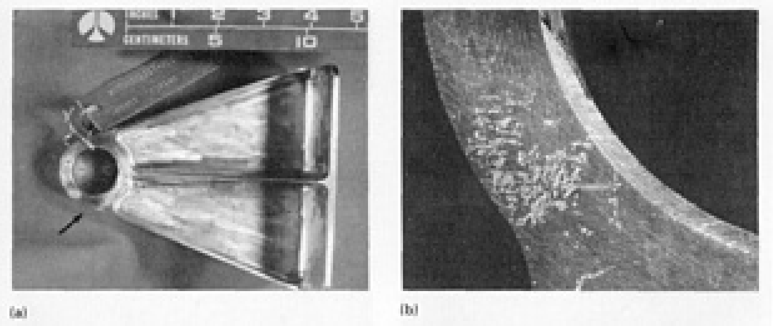

Fig. 9 Pitting corrosion of an aluminum alloy 2024-T62 structural fitting used on the space shuttle orbiter. (a) Fitting that was pitted from lack of interim protection after machining. 0.25×. (b) Enlargement of pitted surface. ~4×

Pitting of structures may lead to premature fatigue failure in critically loaded or cycled parts; however, in many cases, it is not critical. Pitting of honeycomb sandwich face sheets may undermine the integrity of the sandwich by moisture ingestion. Pitting of gear teeth or springs often leads to failure in mechanical systems. Pitting in fluid-containing hardware (pressure vessels, tubes) may lead to perforation and leakage. By the time pitting is discovered on structural parts, the part may have already cost $25,000 because of extensive machining, or it may be part of a welded assembly worth over $1 million dollars; therefore, every effort is made to save the part.

Pitting corrosion is aluminum must be deactivated, or pits will continue to grow as the aluminum oxide that is formed continues to absorb moisture from the air. Pits can be deactivated in place by using a proprietary deoxidizer, followed by a deionized water rinse, wipe, and pH test of the pits. Local masking is used. Pits are then brush chemically filmed according to MIL-C-5541 and painted. Where stress analysis permits, pits can be sanded flush or removed with a dental drill or hole drill. In some cases, bonded doublers are added to restore strength.

Filiform Corrosion

Filiform corrosion is a special form of corrosion that occurs underneath a protective film. It is a moving oxygen concentration cell. Corrosion takes the form of threadlike or filamentary trails and proceeds along the metal surface rather than penetrating through the thickness. Significant filiform corrosion can occur in a matter of hours or days. It develops in the presence of relative humidities as low as 60%. A key condition for the development of filiform corrosion is that the film is semipermeable, permitting oxygen as well as humidity to pass through it. Filiform corrosion, therefore, is essentially a form of crevice corrosion in which one member forming the crevice (the protective film) is semipermeable.

In filiform corrosion, an anodic head, typically 0.08 to 0.13 mm (3 to 5 mils) wide, advances and dissolves the metal in its path. The pH of the head is highly acidic (often as low as 1), and the tail or trail increases in pH, often exceeding a pH of

8. As the anodic head advances, the cathodic region behind it fills with corrosion products. Filiform corrosion can be recognized by the following characteristics:

- Relatively shallow corrosion of the metal surface
- Meandering, filamentary pathways
- Occurrence below a paint or other protective film

To prevent filiform corrosion, coatings with lower permeability to water and oxygen are required. The following is an example of failure of a pressure vessel by filiform corrosion.

Liquid Hydrogen Pressure Vessel. During modification of the *Columbia* vehicle, an aluminum alloy 2219-T6 liquid hydrogen tank used for supplying hydrogen to the fuel cells was removed from the vehicle and stored inside the plant for a 3-month period; the tank was inadvertently exposed to the atmosphere. When this was discovered a moisture test was conducted of the air inside the vessel. It indicated higher than acceptable levels. The exterior of the pressure vessel was covered by a vacuum jacket (see the discussion "Electrical Power System" in this section) and protected from corrosion. Boroscopic examination of the interior of the tank revealed a corroded zone completely encircling the vessel on both sides of the electron beam girth weld. The zone was approximately 4.7 mm ($\frac{3}{16}$ in.) wide and centered 9.5 mm ($\frac{3}{8}$ in.) from the edge of the girth weld (Fig. 10).

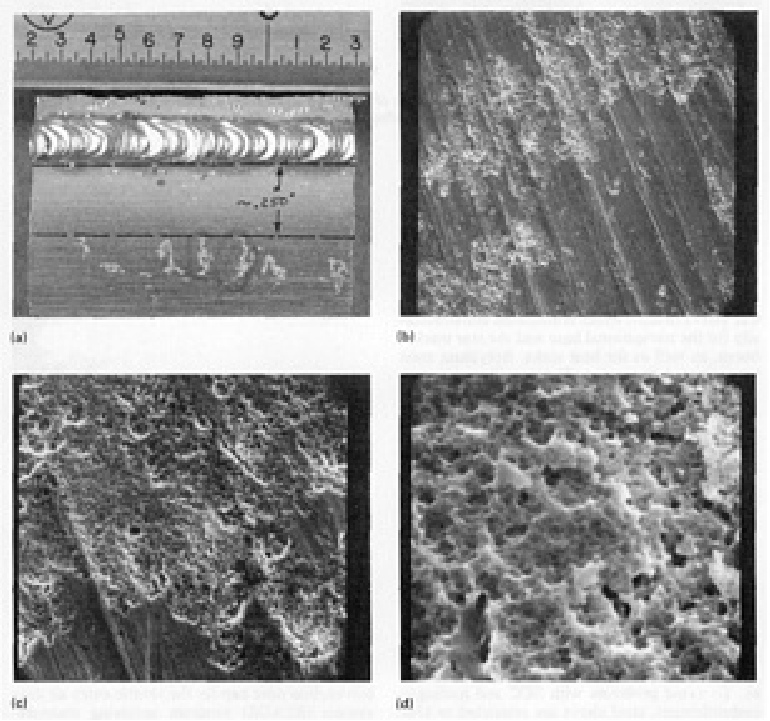

Fig. 10 Filiform corrosion in an aluminum alloy 2219-T6 hydrogen tank used on the space shuttle orbiter. Attack was due to atmospheric humidity. Small spherical beads in (a) are splatter from electron beam welding. (a) Root side of weld showing filiform corrosion beyond the HAZ. (b) to (d) Enlargements of the corrosion attack at 60×, 235×, and 1180×, respectively

It was not possible to verify the depth of the attack or to deactivate the corrosion in place. Therefore, it was necessary to remove the tank from service and examine it metallographically. Although the attack turned out to be superficial, the fatigue life of the vessel could not have been evaluated nondestructively.

At the time of examination, it was believed that the corrosion zones on both sides of the welds were brought about by a preferential anodic phase in the weld HAZs or a preferential anodic zone caused by differences in permeability and thickness of the protective oxide coating. If moisture had condensed in the tank, corrosion would have taken place at the

tank bottom. Because the corrosion path encircled the weld, it was suspected that corrosion occurred in the water vapor phase.

Surprisingly, metallographic examination revealed that the corroded areas were entirely free of corrosion products (Fig. 10). This indicated that the corrosion had occurred at an earlier stage of manufacture and was passivated and removed by chemical cleaning. Although searches of manufacturing records could not verify it, the most probable cause of corrosion was believed to be filiform corrosion occurring under a tape used to attach a protective paper or film over the surfaces prepared for welding. No other explanation adequately accounted for the lack of corrosion products, the shallowness of attack (0.1 mm, or 0.4 mil), and the filamentary network observed.

Galvanic Corrosion

Galvanic corrosion results from or is accelerated by dissimilar-metal contact. The more electronegative metal becomes the anode and is corroded. The more electropositive metal becomes the cathode and is not attacked. The severity of galvanic corrosion depends on the flow of current; therefore, corrosion rates tend to be accelerated when larger differences in potential exist between the two metals. Corrosion damage to the anode becomes more severe as the cathode-to-anode ratio increases. Corrosion rates also increase as solution conductivities increase. To prevent galvanic corrosion, parts can be isolated from each other electrically, can be coated, or the anode can be cathodically protected by impressed current or other sacrificial, more anodic materials or coatings. If paint is used, the most effective member to coat is the cathode because the reduction in the cathode-to-anode ratio is extremely effective. If the anode alone were coated, corrosion would rapidly occur at coating defects accelerated by the very large cathode-to-anode area ratios.

When galvanic couples occur in spacecraft structures that exceed the requirements given in Table 1, the accepted design practice is to use two coats of paint as a moisture barrier and for electrical isolation. Designs should prevent entrapment of water and should provide for sealing of crevices. In fluid systems, detrimental galvanic couples are avoided. In the first 6 years of service of the space shuttle orbiter, four major galvanic problems arose: three with structural components and one in a fluid system.

Forward Wing Spar. Attached to the forward wing spar on the space shuttle orbiter are A-286 stainless steel fittings that support the reinforced carbon-carbon leading edges of the wing. Leading edge temperatures exceed 1260 °C (2300 °F), and the wing spar made from an adhesive-bonded aluminum sandwich structure must be insulated to keep its temperature below 175 °C (350 °F). The spar face sheets are made of aluminum alloy 2024-T81 and have been chemically milled down to 0.35 mm (0.014 in.) in some areas. The insulation blanket material is a Dynaflex (alumina silica chromia fibers) felt with a density of 130 to 390 kg/m^3 (8 to 24 lb/ft^3). It was packed in an embossed, resistance-welded Inconel alloy 601 foil that is 0.1 mm (0.004 in.) thick.

During inspection of the wing of the *Columbia* vehicle after one of its early flights, blisters were seen in the chromated epoxy polyamine paint used to protect the spar (Fig. 11). The blisters occurred mostly along the edge pattern of the Inconel blankets. Removal of the paint revealed highly localized pitting with depths ranging from 12 to 350 μm (0.5 to 14 mils), perforating the face sheets in the thinnest areas.

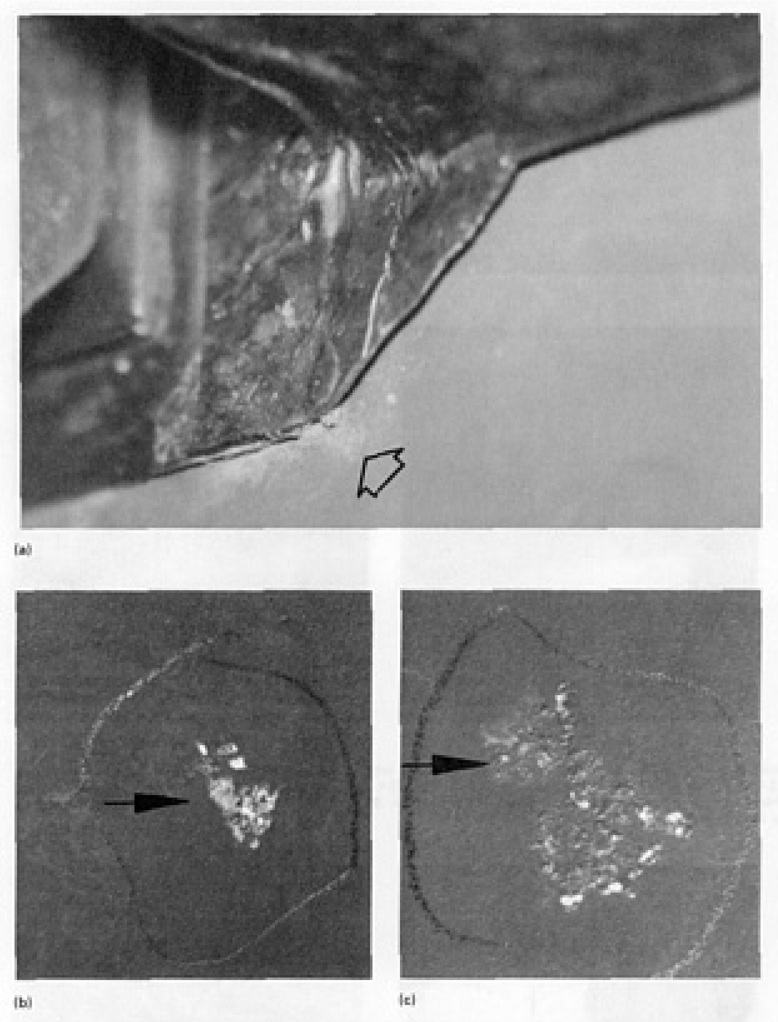

Fig. 11 Galvanic corrosion of aluminum alloy 2024-T8l sheet of orbiter front wing spar from the *Columbia* orbiter. (a) Corrosion appeared as aluminum oxide deposits (arrow) along the edge of an Inconel alloy 601 foil covered insulation blanket. (b) Open pits (arrow) in an area that was in contact with the foil insulation blanket. (c) Oxide buildup under paint in a similar contact area causes formation of "bubbles" (arrow)

The interface between the Inconel foil package and the wing spar permitted capillary moisture entrapment, especially while the orbiter was vertical on the launch pad. Although it was protected with two coats of the chromated epoxy polyamine paint, the galvanic current was able to perforate the paint. Because the foil blankets were unpainted, the cathode-to-anode ratio at paint flaws was extremely large.

Accelerated salt spray testing showed that the corrosion could appear within 300 h with two coats of paint, but aluminum was fully protected from the galvanic corrosion with a 75-μm (3-mil) coating of RTV 560 or three coats of paint. The pits on the orbiter were deactivated. Pit depths were measured. More than 700 local areas exceeded acceptable pit depth criteria and required the bonding of approximately 200 doublers to prevent fatigue or perforation into the honeycomb core. The spar was refinished with three coats of paint; the edges of the foil blankets were coated with 75 μm (3 mils) of RTV 560.

Elevons. Similar galvanic corrosion of aluminum alloy 2024-T81 occurred in the elevons under flipper doors and rub panels where Inconel alloy 601 foil insulation blankets rested against painted aluminum honeycomb face sheet. Corrosion was deactivated; however, in this case, a nylon-type surface insulation was used to replace the foil blankets, eliminating the galvanic couple.

Orbital Maneuvering System Pod Structure. Galvanic attack similar to that discussed above occurred in the OMS pod of the *Columbia*, where goldized Kapton multilayer reflective insulation was in contact with painted aluminum. In this case, a faulty environmental seal permitted water entry, but no provisions were available to drain the water. The pits

were sanded, ground out, or deactivated. The area was chemically filmed and painted with two coats of chromated epoxy polyamine paint and then recoated with 75 to 125 μm (3 to 5 mils) of RTV 560. Organic-coated aluminized Kapton insulation was also substituted for the goldized Kapton insulation.

Environmental Control and Life Support System Outlet Water Valve. After the sixth flight of the orbiter, a potable water valve was discovered to be leaking. The leak emanated form a zone of corroded material that traversed the length of the valve forging. Although the valve body was manufactured from a type 304L stainless steel forging, the material within the corroded zone was found to be low-carbon steel. It was learned that the carbon steel had been accidentally introduced in the ingot in the final stages of solidification. Subsequently, the ingot was rolled into bar and then forged. Because any of more than 50 other valves from that heat could have the same defect, a complete review of all parts was made. The defect could be detected easily by the copper sulfate test according to Method 102 of MIL-STD-753A. It was recommended that this test be performed followed by repassivation.

Figure 12(a) shows the tube section with a longitudinal streak through it (appears similar to a crayon mark). Figure 12(b) shows the corroded area that laked. Attack is seen completely through the tube wall in Fig. 12(c). The microstructure was then etched with 3% nital to bring out the carbon steel (Fig. 12d). Figures 12(e) and 12(f) show x-ray dot maps of nickel and chromium concentrations, respectively, through the inclusion shown in Fig. 12(d). Figures 12(b) to (d) show that the carbon steel is anodic to the stainless steel in water and that corrosion was accelerated by this galvanic couple. Although this problem could not have been anticipated, the supplier would have recognized the problem if he had passivated and inspected the stainless steel properly.

Intergranular Corrosion

Intergranular corrosion results where the microstructure of an alloy provides a preferred corrosion path along grain boundaries. Often, the material adjacent to the grain boundary is depleted of a particular element that precipitates out as an intermetallic compound at the grain boundary. In the case of aluminum alloys of the 2000 series, the precipitation of

$CuAl_2$ at grain boundaries occurs. The $CuAl_2$ is more noble than the adjacent aluminum, and intergranular corrosion of the adjacent aluminum takes place. Artificial aging of aluminum causes precipitates to occur throughout the grains as well as in the grain boundaries, thus minimizing localized corrosion. Stainless steels, when heated into or cooled through the 425- to 870-°C (800- to 1600-°F) range, will precipitate chromium carbides preferentially at grain boundaries, resulting in anodic paths adjacent to these grain boundaries. Lowering carbon levels to below 0.03% (to avoid a continuous carbide grain-boundary network) or adding niobium or titanium (to precipitate carbides) will permit the chromium in the grain boundaries to keep the steel from becoming sensitized.

Intergranular corrosion is insidious in that little actual corrosion is required before the structural integrity of a part or the perforation of a fluid container occurs. A knowledge of metallurgy is important in preventing intergranular corrosion attack because microstructure is sensitive to composition, temperatures, cooling rates, and surface contamination.

The ammonia boiler, as previously described, is a heat exchanger using Freon-21 and ammonia. The Freon-21 picks up heat from the orbiter electronic boxes, the crew cabin, and the payloads, and the heat is dissipated by boiling ammonia when the orbiter radiators cannot be deployed, such as during the final stages of reentry. Accidental contamination of these tube surfaces prior to brazing of the heat exchanger resulted in the sensitization of some of the thin-wall (0.2 mm, or 8 mil) type 304L stainless steel tubes. The sensitized tubes were attacked and perforated by the fluid (Fig. 13).

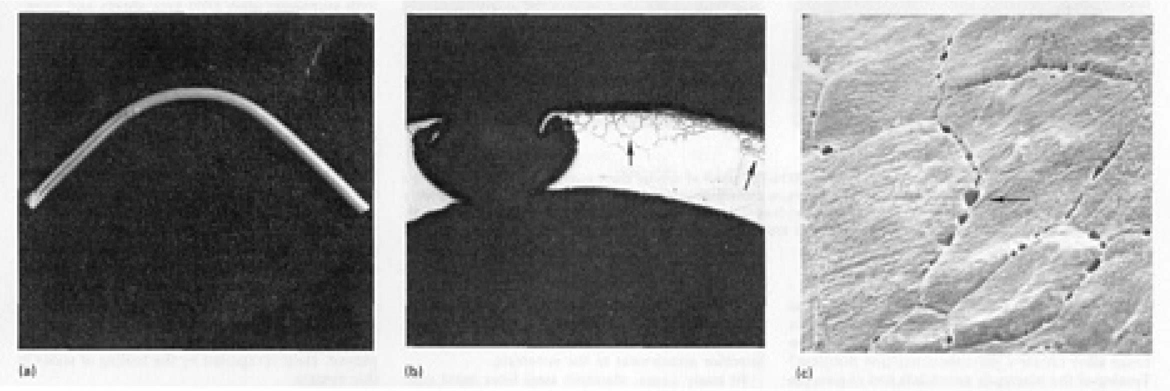

Fig. 13 Intergranular corrosion of a type 304L stainless steel tube in a shuttle orbiter ammonia boiler. (a) Test performed to show tube ductility. 1×. (b) Cross section through the thin-wall (0.2 mm, or 8 mils) tube revealing sensitization on outside diameter due to carbonaceous deposit formed during brazing. 75×. (c) Surface SEM showing grain-boundary carbides are being removed from outside diameter during corrosion. 980×

The corrective action was to change the tubing to type 347 stainless steel to prevent chromium carbide precipitation at grain boundaries if parts were accidentally contaminated prior to brazing. In addition, procedures to prevent contamination in the future were upgraded. Particular emphasis was placed on removal of carbonaceous, drawing compounds from tube surfaces before brazing.

Selective Leaching

Selective leaching (also called parting, dealloying, or demetallification) occurs when the corrosion process removes one or more elements from the alloy matrix. Specific categories of selective leaching often carry the name of the dissolved element in their title, such as dezincification, dealuminification, denickelification, or decobaltification. In the case of gray cast iron, selective leaching is called graphitic corrosion. The process can occur in single-phase alloys, for example, with brasses having high zinc content such as a 70Cu-30Zn alloy. It can also occur in multiphase alloys.

In the selective leaching process, typically one of two mechanisms occurs; alloy dissolution and replating of the cathodic element or selective dissolution of an anodic alloy constituent. In any case, the matrix that is left is spongy and porous and has very little strength or integrity. In some cases, a large, localized area of metal (a plug) is attacked.

Selective leaching can be prevented by proper alloy selection, that is, matching the alloy system to a particular environment. Changing ratios of alloying elements and adding inhibition elements are often satisfactory approaches. In

aerospace, selective leaching is a rare problem. Where it occurs, a proper alloy selection or changing the processing medium is the key to prevention.

Gas Generator Valve Module (GGVM) Valve Seats. The APU of the shuttle orbiter contains a GGVM that utilizes four tungsten carbide valve seats to regulate hydrazine flow to the catalyst bed. The 5-mm (0.2-in.) diam valve seats have sealing lands that are only 115 to 150 μm (0.0045 to 0.0060 in.) wide. The seats are manufactured from sintered KZ-96 tungsten carbide containing 5% Co as binder.

In mid-1985, valve leakage problems during acceptance testing were traced to a breakdown of the valve seat sealing lands. The problem became widespread, with a high rejection rate during acceptance testing procedures (ATP).

It was determined that revised cleaning procedures that had been implemented recently to correct a GGVM contamination problem early in the program were subjecting the seats to long periods of exposure to deionized water and ultrasonic cleaning. Tests proved that such exposure produced leaching of the cobalt binder from the sintered tungsten carbide alloy. Subsequent impacting of the valve seats by the poppets (during ATP) resulted in breakdown of the seats and the noted leakage failures (Fig. 14).

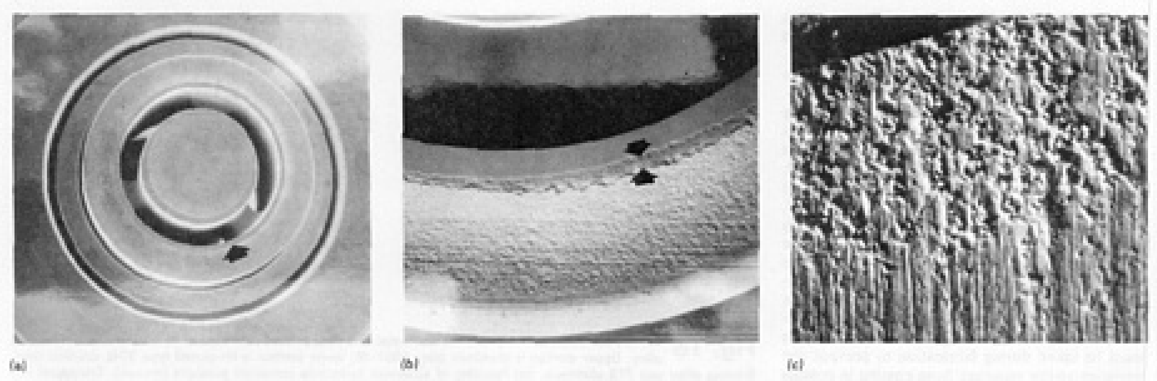

Fig. 14 Selective leaching of a tungsten carbide valve seat in a shuttle orbiter APU gas generator valve module. Leaching of the cobalt binder was caused by excessive exposure to water during ultrasonic cleaning and hot water rinsing. (a) Valve seat showing narrow sealing surface 0.1 to 0.15 mm (4.5 to 6 mils) wide. 8×. (b) Loss of sealing surface due to selective leaching and poppet impact. 45×. (c) SEM cross section showing depth of leaching. 1600×

As a by-product of the testing, it was found that a small amount of leaching of the cobalt also occurs from exposure to decomposition by-products of hydrazine, the system fluid. This leaching action is several orders of magnitude less than that from deionized water. Tests were underway in the time period from 1985 to 1986 to identify alternative tungsten carbide alloys that might be acceptable substitutes for KZ-96. Alloys under investigation included those with different binders and those with finer grain sizes. The corrective action taken during the manufacturing cycle was to substitute isopropyl alcohol for deionized water in all operations.

Crevice Corrosion

Crevice corrosion results from a concentration cell formed between the electrolyte within the crevice, which is oxygen starved, and the electrolyte outside the crevice, where oxygen is more plentiful. The material within the crevice acts as the anode, and the exterior material becomes the cathode. This is similar to pitting, in which the base of the pit becomes the anode. The author finds it convenient to view a crevice as a plane of corrosion, that is, a two-dimensional pit. The resistance of materials to crevice corrosion varies widely. Those metals whose protective oxides films result from oxygen adsorbed to the surfaces and are in dynamic equilibrium with the outside environment, such as stainless steels, appear to suffer most when shut off from oxygen by crevices.

In good corrosion design practice, crevices are avoided whenever possible. Crevices not only trap water or the chemical being processed but also become sumps for the other contaminants in the system, often resulting in major corrosion problems. Spacecraft structural faying surfaces, for example, either include a faying surface sealant or the edges are fillet

sealed (see the discussion "Structural Joints and Fasteners" in this section). Sometimes, however, a crevice cannot be avoided, as shown in the cases below. Therefore, additional care is required to avoid detrimental corrosion.

Anodized Aluminum Window Frames. The exterior window frames on the space shuttle orbiter are made of aluminum alloy 2124-T851 that has been anodized according to a Rockwell specification by using a sulfuric acid anodize, a black dye, and a sodium dichromate seal. The window frames are protected from heat during spacecraft entry by pure silica tiles. Two grooves within each window frame contain the fibrafax thermal seal (to prevent hot gas plasma flow) and the Viton pressure (environmental) seal. The side windows, when the orbiter is stacked for launch on the pad, provide for possible water entrapment in a small portion of the periphery of the windows. Rain can wash down window surfaces, picking up salt deposits from seacoast exposure. The aluminum window frame peak temperature is approximately 55 °C (130 °F).

After the eighth flight of the space shuttle orbiter, two side windows were removed from the *Challenger* vehicle for examination. The window surfaces had appeared to have a hazy opacity even after polishing. The opacity was due to microscopic erosion of unknown origin. Examination of the window frame showed several localized areas of corrosion through the anodized coating in and adjacent to the seal grooves. The areas away from the crevice were uncorroded (Fig. 15). The recommended corrective action for new window frames was to add a coat of chromated epoxy polyamine primer, followed by a coat of polyurethane over the black anodize.

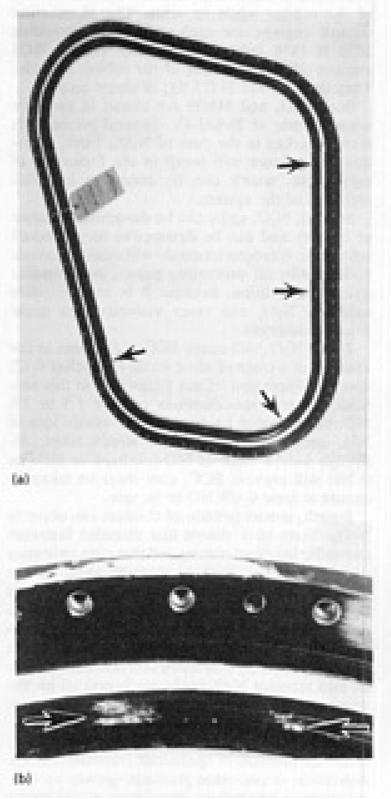

Fig. 15 Crevice corrosion of an anodized aluminum alloy 2024-T851 window frame from the space shuttle *Challenger.* Corrosion occurred along both thermal and environmental sealing grooves. (a) Window frame showing locations of corrosion (arrows). (b) Enlargement of (a) showing corrosion in Viton seal area (arrows). Rain water carrying dissolved salt deposits from the window was the corrosive medium.

Aluminum Brazed Joints. The nature of the brazing process is to provide a gap between faying surfaces that will act as a capillary for braze alloy flow. Selection of the braze processes used for the plumbing systems lines on the Apollo and the space shuttle orbiter depended on the braze alloy filling the capillary gap to ensure the inside of the tube would not have a crevice (see the discussion "Plumbing Lines" in this section). These stainless steel brazes were made under an inert gas shield, and no flux was required.

In brazing aluminum, however, it is necessary to use a flux to remove its tenacious oxide film and to ensure wetting of the faying surfaces. The brazing fluxes usually consist of mixtures of alkali and alkaline earth chlorides and fluorides, sometimes containing aluminum fluoride or cryolite ($3NaF \cdot AlF_3$). Braze fluxes will often become entrapped between the faying surfaces, and if the joint is completely sealed by a fillet, no problems arise. However, when incomplete fillets occur, the brazing fluxes, which are generally hygroscopic, will bleed out and cause corrosion.

Cleaning of the part and verifying that surfaces are free of fluorides and chlorides do not always solve the problem, because weeks later the part can be covered with flocculent aluminum hydroxide corrosion products. Brazing of aluminum is generally avoided on the shuttle orbiter wherever possible. Aluminum cold plates are made by fluxless brazing in inert gas under temperatures and pressure sufficient to ensure braze alloy flow. In electronic boxes in which braze designs have been used, the joints are vacuum impregnated with a resin seal to avoid bleedout of entrapped fluxes. This appears to be quite satisfactory.

On the Apollo program, aluminum-to-stainless steel tube brazes were used in discrete applications. The stainless tube was tin plated. Problems experienced with braze bleedout are shown in Fig. 16.

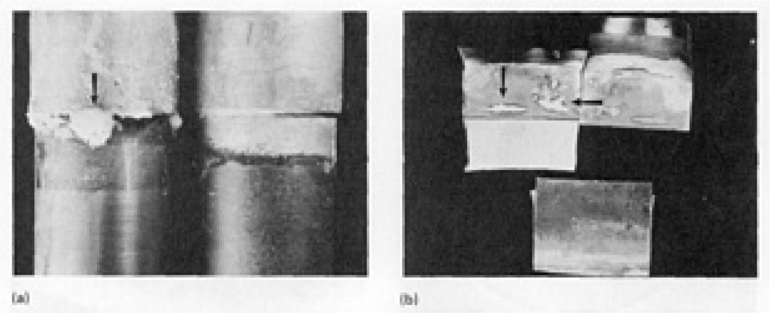

Fig. 16 Crevice corrosion of an Apollo aluminum-stainless steel brazed joint caused by bleedout of the brazing alloy. Upper portion is aluminum alloy 6061-T6, lower portion is tin-plated type 304L stainless steel. Brazing alloy was 718 aluminum. (a) Foaming of aluminum hydroxide corrosion products (arrows). Entrapped flux exposed to air caused corrosion. 1×. (b) Cross section through pockets of entrapped flux (arrows)

Fretting Corrosion

Fretting is the abrasive wear of two touching surfaces subject to cyclic relative motions of extremely small amplitude. Fretting corrosion is an increased degree of deterioration that occurs because of repeated corrosion or oxidation of the freshly abraded surface and the accumulation of abrasive corrosion products between these surfaces. Although fretting is often limited to small, localized patches of wear, it can eventually provide a path for leakage (for example, valve seats) or an initiation site for fatigue. Fretting corrosion can be controlled by lubrication of the faying surfaces, restricting the degree of movement, or by the selection of materials and combinations that are less susceptible to fretting (see Table 4 in the article "Corrosion in the Aircraft Industry" in this Volume).

Rudder Speed Brake Power Drive Unit Spacer. The mounting bolts of the rudder speed brake power drive unit of the space shuttle orbiter are made of A-286 stainless steel heat treated to 965 MPa (140 ksi). Bolts are either 15.9 or 22.2 mm ($\frac{5}{8}$ or $\frac{7}{8}$ in.) in diameter. The bolts are sleeved with a spacer that passes through a spherical bearing. The spacer is made of 17-4 PH steel (H1150M), and the bearing is Inconel alloy 718 heat treated to 1240 MPa (180 ksi). The surface finish on the spacer is 16 RHR (root height reading). When the power drive unit was removed from the *Enterprise* vehicle, fretting corrosion was discovered on the exterior of the spacer and the interior of the ball. The fretting corrosion of the 17-4PH was quite severe, as shown in Fig. 17. The corrective action consisted of changing the spacer to Inconel alloy 718 and applying a dry film (molybdenum disulfide) coating.

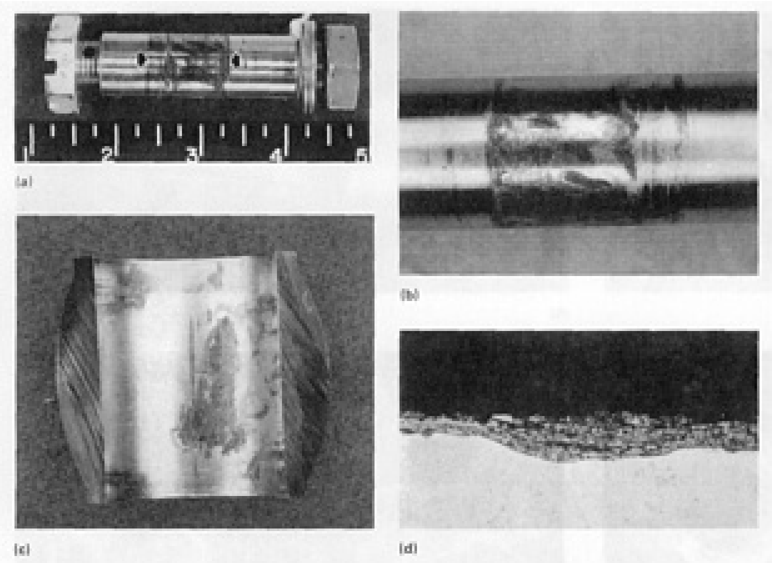

Fig. 17 Fretting corrosion of a steel spacer used to mount the rudder speed brake on the shuttle orbiter. The spacer is made of 17-4PH H1150M stainless steel. (a) Spacer on bolt shows contact area with an Inconel alloy 718 spherical bearing. Fretted area is between arrows. (b) Enlargement of fretting corrosion. 1×. (c) Mating Inconel alloy 718 bearing showing a similar pattern but only superficial marring of surface. 1.5×. (d) Cross section through fretting corrosion. 175×

Stress-Corrosion Cracking

Stress corrosion requires the simultaneous occurrence of three conditions: a susceptible material or microstructure, a corrosive environment, and surface tensile stresses. Control of stress corrosion is achieved by avoiding any one of these conditions (see the discussion "Control of Stress Corrosion" in this section). Each metal family has its own unique environments in which it displays susceptibility to stress corrosion.

Stress-corrosion cracking is one of the most insidious forms of corrosion because it often comes on without any warning and results in major, sometimes catastrophic, structural failures. In fluid systems, the presence or absence of a trace element can make the difference between no reaction and a major failure. Prior laboratory testing may have missed a potential problem that occurs in service, as illustrated in some of the failures below. It is mandatory that the cause of a stress-corrosion failure be demonstrated in the laboratory after a suspected stress corrodent has been identified and that testing be conducted as closely as possible to the chemical and metallurgical conditions experienced by the failed hardware.

The injector tube of the space shuttle orbiter auxiliary power unit carries liquid hydrazine to a catalyst bed, where it is heated and decomposes into nitrogen, hydrogen, and a trace of ammonia. The hot decomposed gases drive a turbine wheel to generate secondary power for spacecraft systems. Shortly after touchdown from the ninth launch of the orbiter, two of three APUs detonated (Ref 14). Extensive investigation determined that the cause of the detonations was the decomposition of hydrazine. While the orbiter was in orbit, hydrazine had leaked through cracks in the Hastelloy alloy B injector tube walls of two different APUs. In the space vacuum, evaporation withdrew heat from the leaking fluid, resulting in the formation of hydrazine snow balls. During reentry, the snow balls melted and ignited--somewhere below 12 km (40,000 ft) in altitude--and the heat resulted in decomposition and detonation of the hydrazine.

The fractures on each tube were intergranular, started on the inside diameter, occurred in almost identical locations, and extended 220 to 240° around the periphery (Fig. 18). The cracks were determined to be caused by stress corrosion, as evidenced from their appearance and by extensive testing that eliminated all other failure mechanisms.

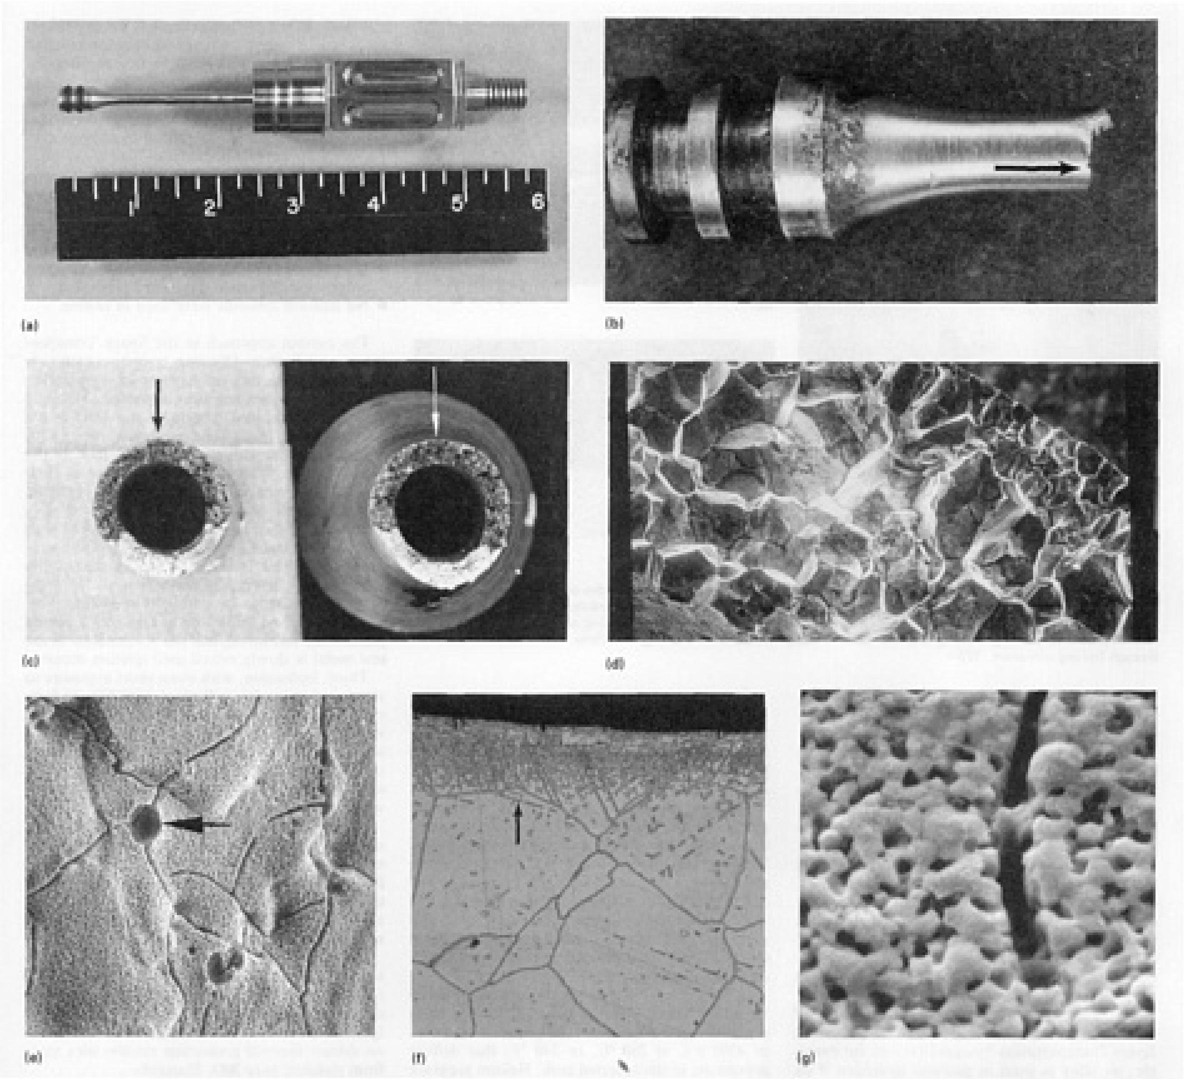

Fig. 18 Stress-corrosion cracking of a Hastelloy alloy B orbiter APU injector tube in a hydrazine environment. (a) Typical injector tube and catalyst bed. (b) Failed tube of APU #1. Arrow shows area of SCC. (c) Fracture faces of failed APU #2 injector. Dark areas (arrows) have been stress corroded. Bright areas were ductile fracture from tensile load used to separate parts. 6×. (d) Enlarged fracture face of (c) showing intergranular character. 940×. (e) Surface SEM of tube inside diameter showing etching of carbides in grain boundaries (arrow) and surface. 370×. (f) Sensitized surface layer on inside diameter due to carbide contamination (from electrical discharge machining process) entering braze cycle. 285×. (g) Enlargement of surface corrosion. 3450×

It was demonstrated by laboratory testing that ammonia or ammonium hydroxide was the only potential fluid that could cause stress corrosion of Hastelloy alloy B on the spacecraft. The ammonium vapors resulted from decomposition of hydrazine in the catalyst bed, probably as a result of hydrazine leaking into the injector tubes through the valve seat or from the equilibrium of the gas generator environment within the tube after shutdown. Moisture, resulting in the formation of ammonium hydroxide, was available from atmosphere migrating back into the exhaust duct. Misalignment and cocking of the injector tubes during installation resulted in high stresses in the failure area (up to yield stress). A sensitized microstructure of precipitated carbides along inside diameter grain boundaries provided a preferred path for stress corrosion to proceed. A carbide network found on the inside diameter of the injector tubes was the result of carbon deposited during the electrical discharge machining process to machine the injector tube bore. Subsequent injector tube brazing and cool-down cycles permitted grain-boundary diffusion and precipitation.

The solution was to eliminate the preload stresses on the injector tube by instrumenting the installation and to eliminate the sensitized carbide network by reaming the tube inside diameter. The braze cycle was raised to 1185 °C (2165 °F) to ensure uniform diffusion of any carbides, followed by rapid cooling to ensure that any carbides inherent to the basic alloy

(0.05 max) would not precipitate at grain boundaries. Later designs of injector tubes were also internally coated with a thin chromized layer.

The Reaction Control System injector of the Space Shuttle orbiter is made from uncoated niobium alloy C 103. This injector is bolted to a titanium mounting ring section. A niobium alloy C 103 chamber is then welded to the injector face. Cracking was observed in the sharp radius of the injector adjacent to the bolting ring. Examination of the fracture face showed that the attack was intergranular and had fine eruptions (popcorn balls) of niobium oxide on its surface.

A review of the manufacturing sequence isolated the problem to those steps performed between the bolting of the titanium flange section to the injector flange and the final operation in which the engine was baked at 315 °C (600 °F) for 20 h to remove resin from the insulation encasing the engine. The most probable cause of cracking was thought to be stress corrosion occurring from entrapment of an etchant (50% HNO_3-50% HF) used to remove traces of iron and copper from the niobium prior to welding of the chamber to the injector. Repeated laboratory attempts to duplicate failure were unsuccessful until a method was devised to entrap the etchant between two pieces of niobium while tensile stresses were applied during sustained heating in the 290- to 315-°C (550- to 600-°F) range. The failure was duplicated and attributed to hot fluoride salt SCC (Fig. 19) (Ref 15). Performing the acid etching and rinsing prior to bolting the injector assembly prevented future occurrences.

Reaction Control System Oxidizer Pressure Vessels. Nitrogen tetroxide, a storable hypergolic oxidizer, was used in the service propulsion system (SPS) and in the reaction control system on the Apollo program. The SPS provided the propulsion for orbit insertion, lunar flight, return from the moon, and deorbit for entry. The RCS provided for vehicle attitude control through roll, pitch, and yaw engines. Titanium alloy Ti-6Al-4V was chosen for pressure vessels in both systems as a result of laboratory tests on corrosion, stress corrosion, and impact ignition with N_2O_4.

Qualification testing of the SPS pressure vessel for 46 days of exposure under a membrane stress of 690 MPa (100 ksi) was completed without problems in mid-1964. In January 1965, an RCS pressure vessel of the same alloy, protected from N_2O_4 by a teflon positive expulsion bladder, cracked in six adjacent locations (Ref 9, 10, 11, 12). The cracks were parallel to each other and perpendicular to the maximum stress. The fracture surface had a red stain and was flat and brittle in appearance. Because no N_2O_4 was supposedly in contact with the vessel, it was believed that misprocessing may have

caused the fractures. Subsequent testing of ten pressure vessels without bladders in June of that year was conducted to ascertain if misprocessing could be bracketed to certain manufactured pressure vessel lots over a period of time. Within 34 h after testing, one of the pressure vessels blew up (Fig. 20) and within a few days most of the others had failed.

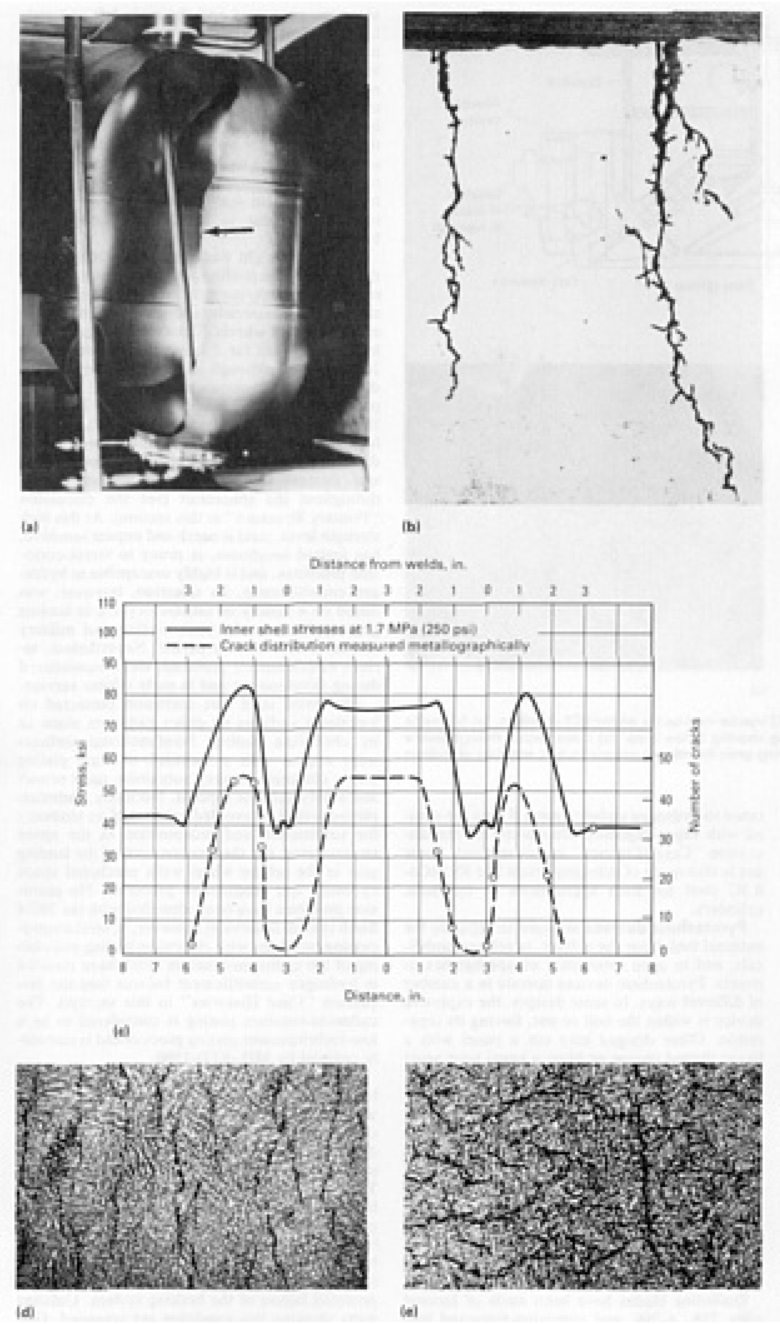

Fig. 20 Stress-corrosion failure of an Apollo Ti-6Al-4V RCS pressure vessel due to nitrogen tetroxide. (a) Failed vessel after exposure to pressurized N_2O_2 for 34 h. (b) Cross section through typical stress-corrosion cracks. 250×. (c) Correlation between the number of cracks per square inch and stress level. (d) Cracking in cylindrical section where hoop stress predominates. (3) Cracking in biaxial area where stresses are approximately equal. (d) and (e) Both 35×

The cause of the failure was immediately suspected to be stress corrosion, but the aggressive fluid that contacted these surfaces was not immediately determined. Cracks occurred very close together on the inside of the pressure vessel, and the number of cracks per unit area was proportional to the local stress. Pressure vessels of the same design, when tested with N_2O_4 by Rockwell on the West Coast, did not fail. The RCS tank contractor. Bell Aerosystems Company, was soon able to demonstrate coupon failures in N_2O_4, but Rockwell could not, although over 300 specimens were cleaned and tested under more than 40 variables, including various contaminants.

Chemical testing of the propellants used at Bell and Rockwell revealed no differences or out-of-specification conditions. Existing chemical techniques were not capable of accurately quantifying all species present in the N_2O_4, especially compounds of nitrogen; however, cooling of the propellants revealed a color difference in N_2O_4 between the supplies at Bell and Rockwell. The N_2O_4 at Rockwell, when cooled to -18 °C (0 °F), turned green because of the presence of nitric oxide (NO), but the N_2O_4 at Bell was yellow. The green color resulted from a mixture of N_2O_4 (yellow) and dissolved NO as N_2O_3 (blue). Rockwell supplies of N_2O_4 had been purchased earlier than those of Bell Aerospace.

Investigation revealed that a change in the military specification MIL-P-26539 had been made during this time period to improve the specific impulse of N_2O_4 by oxygenating the trace quantities of residual NO. This simple change had a devastating effect on its stress-corrosion behavior with titanium. Testing indicated as little as 0.2% NO was probably sufficient to inhibit the SCC of titanium. Specifications were changed thereafter to require a minimum NO content of 0.6%; present grades contain 1.5 to 3% NO. Addition of NO to existing supplies solved the problem.

Early in the investigation, it was believed that no stress corrosion could occur in solutions as nonconductive as N_2O_4 (specific conductivity at 25 °C or 80 °F, is $3.1 \times 10^{-13}\ \Omega^{-} \cdot \text{cm}^{-1}$). However, because of the low conductivity of N_2O_4, only closely spaced local cathodes and anodes could carry corrosion currents (Fig. 20). This resulted in a large number of cracks (up to 70 cracks/in.) rather than a single crack. This investigation also illustrated how past stress-corrosion test results or pressure vessel qualification can be voided by minor chemical changes in the corroding medium. This is further illustrated in the following discussion.

Service Propulsion System Fuel Tanks. The storable hypergolic fuel used for the service propulsion system on the Apollo Service Module was a blend of 50% hydrazine and 50% unsymmetrical dimethyl hydrazine. It was contained in two titanium Ti-6Al-4V pressure vessels approximately 1.2 m (4 ft) in diameter and 3 m (10 ft) long. Because hydrazine compounds are toxic and dangerous to handle, a "referee" fluid with similar density and flow characteristics was used in system checkout testing. Methanol was chosen as a safe fluid based on subcontracted studies conducted for the program. Methanol had been successfully used as a fluid in a tri-flush cleaning process for propellant systems at that point in time. Among the other advantages, it had a low explosive potential, was miscible with both fuel and water, and would leave surfaces residue free.

During an acceptance test of the Apollo Spacecraft 101 service module prior to delivery, an SPS fuel pressure vessel (SN054) containing methanol developed cracks adjacent to the welds (Fig. 21). The test was stopped. This acceptance test had been run 38 times on similar pressure vessels without problems. Failure analysis could not reveal the cause of the cracking. The fractures had branching cracks characteristic of stress corrosion yet fracture faces exhibited a somewhat featureless quasi-cleavage appearance without typical stress-corrosion features. The adjacent material was ductile and within chemistry.

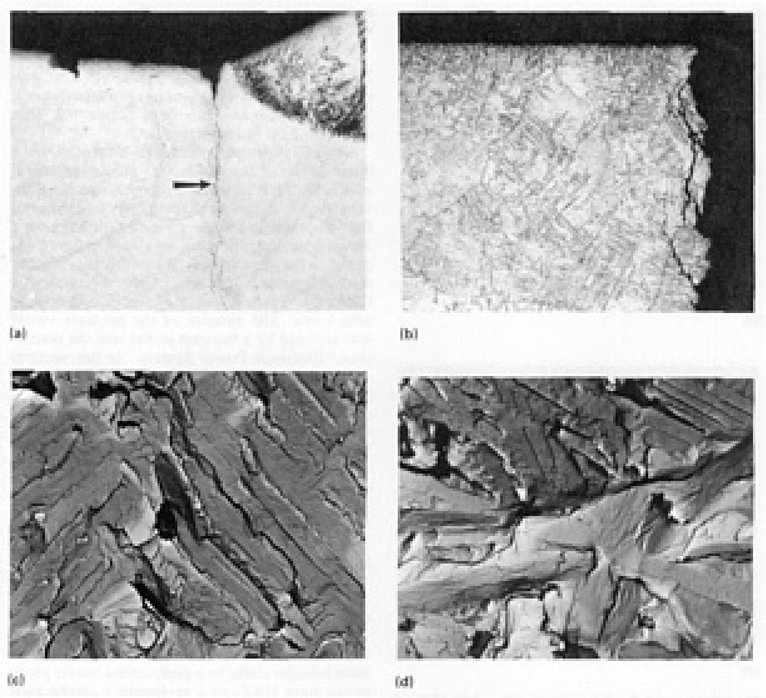

Fig. 21 Stress-corrosion cracking of a solution-treated and aged Ti-6Al-4V Apollo SPS fuel pressure vessel during a system checkout test. Fluid test medium was methanol. (a) Cross section adjacent to weld in cracked vessel. 65×. (b) Another crack near the same weld. 65×. (c) and (d) TEM fractographs of fracture surface showing no particular stress-corrosion features. Both 2500×

Misprocessing of pressure vessels during manufacturing was suspected, because the supplier had previously demonstrated that pickup of cleaning agents and contaminants on a Ti-6Al-4V pressure vessel prior to a heat-treat aging cycle would result in delayed stress-corrosion failure. These included such contaminants as finger prints, chlorinated kitchen cleansers, and liquid hand soap. A similar crack adjacent to the weld occurred on the first development pressure vessel for this program was thought to be caused by such contamination (Fig. 22).

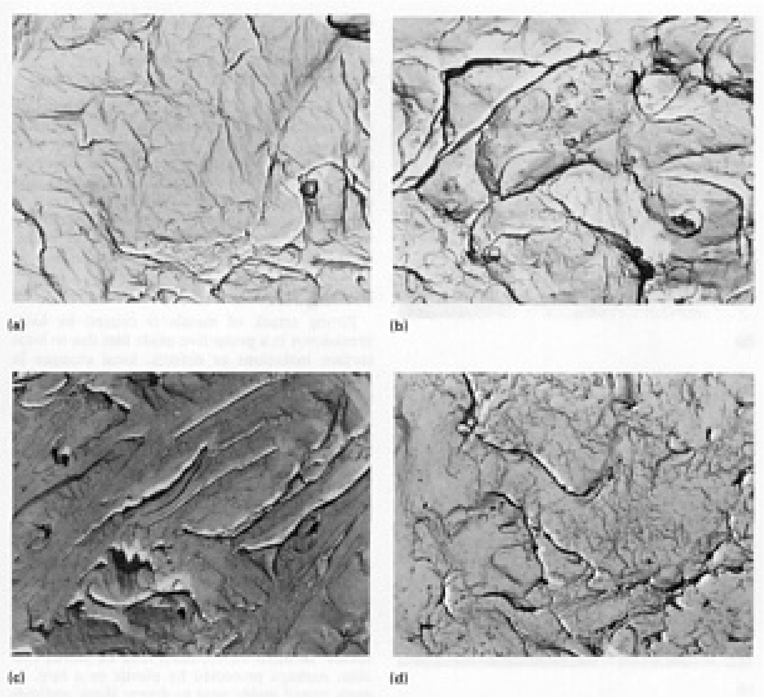

Fig. 22 Stress-corrosion failure in an Apollo Ti-6Al-4V pressure vessel development test. (a) and (b) TEMs of fracture face of stress-corrosion crack in the vessel in a 24-h distilled water exposure after contamination of titanium with soap prior to heat treatment (aging). Fine hairlike wrinkles are characteristic of stress corrosion. (c) and (d) Stress-corrosion failure of first Apollo SPS development pressure vessel of Ti-6Al-4V. Cause unknown

The Spacecraft 017 service module was then put into test. An additional test was initiated to ensure that no marginal SPS pressure vessels would pass through system checkout. This additional test consisted of 25 pressure cycles, followed by a 24-h pressure hold. After only a few hours into the hold cycle, the replaced SPS pressure vessel failed catastrophically (Fig. 23).

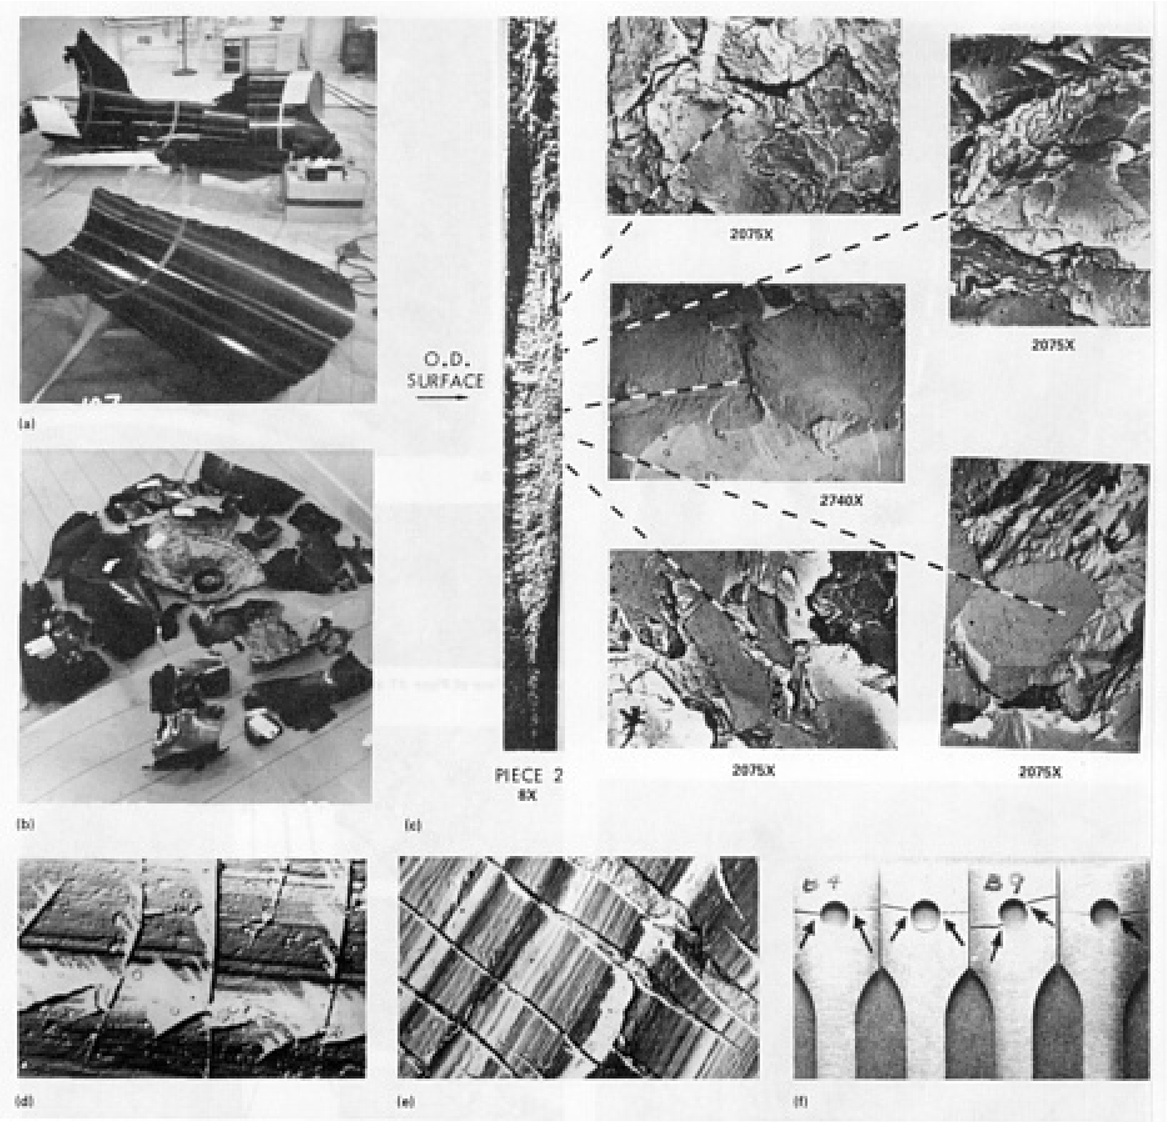

Fig. 23 Stress-corrosion failure of a solution-treated and aged Ti-6Al-4V Apollo SPS fuel pressure vessel during a sustained pressure test in methanol. (a) Explosive failure of the tank occurred, resulting in severe ripping of the cylinder section. (b) Dome section fragmented by explosion. (c) Fracture origin and TEM fractographs of fracture face showing quasi-cleavage failure. (d) Surface of outside diameter showing crazing of oxide film under load and machining lines. 2500×. (e) Similar view of inside diameter surface. 2500×. (f) Titanium notched stress-corrosion specimens cracked at pin-loading areas in methanol. Pins were austenitic stainless steel.

The investigation conducted after this failure disclosed that titanium will undergo SCC in methanol (Ref 9, 16, 17, 18, 19, 20). Attack is promoted by crazing of the protective oxide film. It was learned that minor changes in the testing procedures could inhibit or accelerate the reaction. For example, the addition of 1% H_2O inhibited the reaction completely. It could be restarted by a 5 ppm addition of chloride. Initial stress-corrosion testing in the laboratory was performed with available aluminum text fixtures, with 300-series stainless steel, and then with titanium. No failures occurred in aluminum fixtures (apparently it provided cathodic protection). Failures in stainless steel fixtures occurred at the specimen pin areas, not at the sharp notches used to initiate stress cracking. Failures occurred in only a few hours with stainless steel because it apparently accelerated the reaction by galvanic coupling. Specimens tested to the same stress levels in titanium fixtures often took several times as long to fail.

The obvious solution to the problem was to replace the methanol with a suitable alternate fluid. Isopropyl alcohol was chosen after considerable testing. This incident further resulted in the imposition of a control specification (MF0004-018) for all fluids that contact titanium for existing and future space designs.

This failure further illustrates the importance of trace chemicals in accelerating or inhibiting a failure. It also points out that test fixture materials can affect test results. Although it is preferable to use fixtures of the same alloy, it may not always be critical in the screening of possible stress-corroding fluids, because it is often desirable to accelerate stress-corrosion testing during the screening phase. This acceleration can be carried out by significantly increasing the stress (using a notch), by raising the temperature (usually), or by making the specimen the anode in a fluid. It is notable that failures involving stainless steel fixtures did not occur when 1% H_2O was added to methanol, nor did failures occur in isopropyl alcohol, benzene, Freon TF, Freon MF, and distilled water and MMH, even if HCl was added or bubbled through the solutions.

Tower Leg Frangible Nut. The launch escape tower was designed to pull the Apollo command module free of the Saturn V launch system in the event of an abort to ensure astronaut safety. Under normal launch conditions, the tower is jettisoned. It is separated from the command module by firing two pyrotechnic charges at opposite sides of each of the four attach nuts (frangible nuts). The detonation separates each of the frangible nuts into two pieces. The tower attachment to the command module lay inside the tower leg well. The frangible nut was made of 4340 steel heat treated to 1520 MPa (220 ksi). A few days before a scheduled launch, one of the nuts was reported to have fractured (Fig. 24).

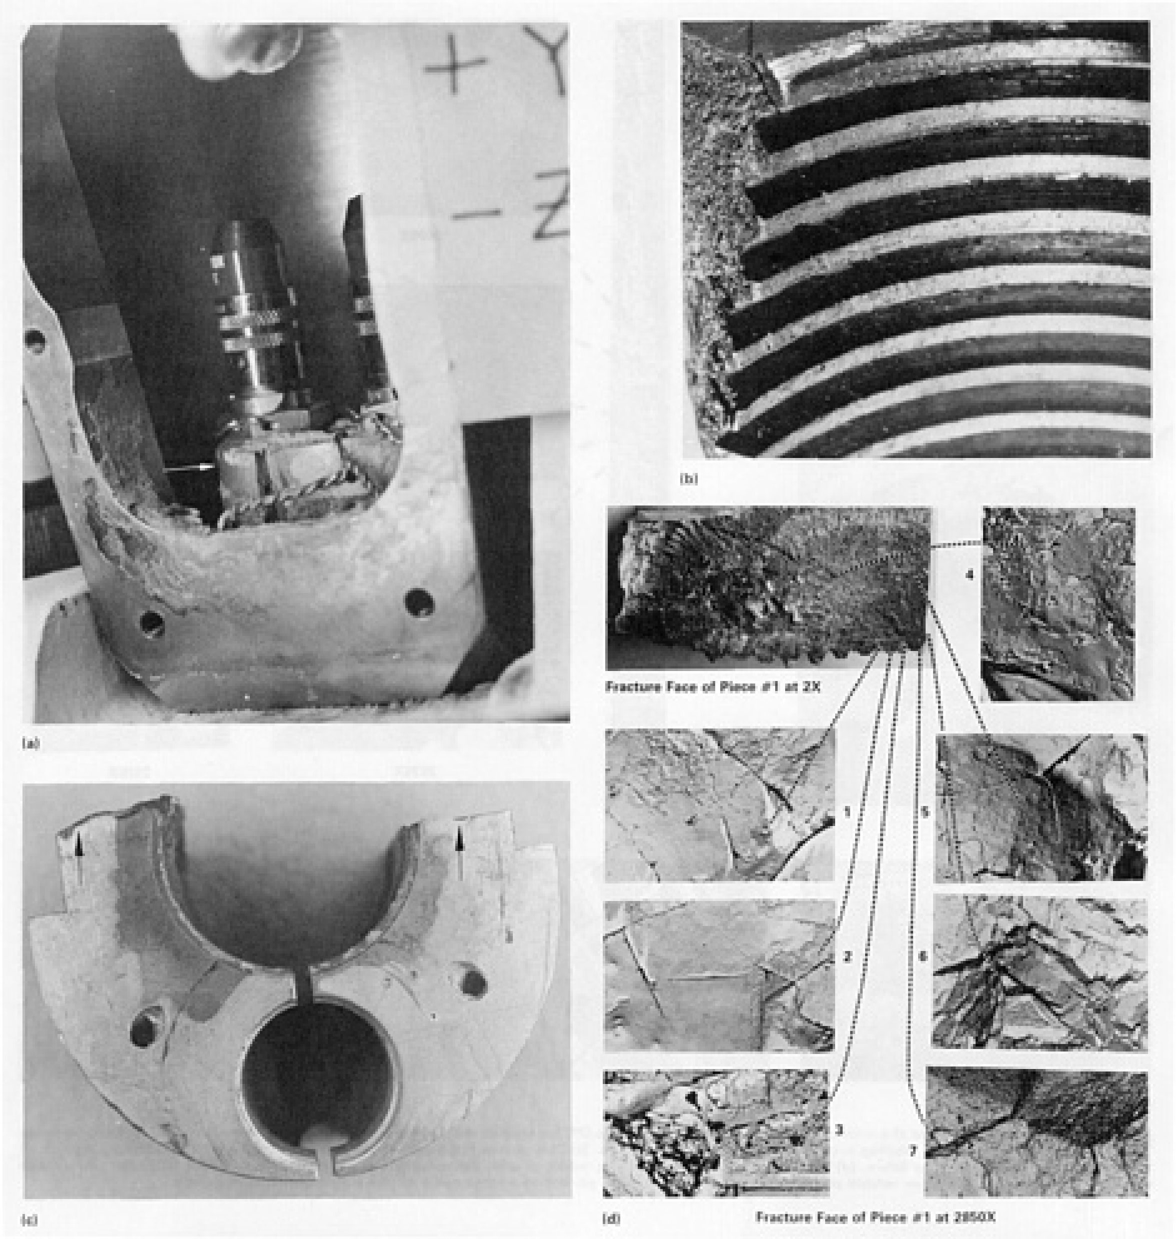

Fig. 24 Stress-corrosion failure of an Apollo launch escape tower leg frangible nut. The nut was made of 4340 low-alloy steel heat treated to 1520 MPa (220 ksi). The corroding medium was ammonium fluoborate leached from the ablative on the solid rocket engine nozzle extensions of launch escape tower. Note salt accumulation.

(a) Frangible nut (arrow) located within launch escape tower leg. (b) Fracture face of failed nut in (a) showing extensive rusting. (c) Top view of nut. The fracture face is at top. (d) TEM fractographs. Views 6 and 7 are origin area. Note intergranular attack and corrosion of grain faces.

The part and fracture face were rusted and encrusted with salt. The access door to the tower leg well had been left open in a rain storm. Laboratory efforts to duplicate the stress-corrosion failure in salt (NaCl) water were unsuccessful after 30 days of exposure. The encrusted salt on the fractured nut was analyzed during this testing period; it was ammonium fluoborate, not salt from the sea coast. Stress-corrosion testing in this solution produced an immediate failure. Subsequent investigation disclosed that the ammonium fluoborate was a salt added to the ablative material on the launch escape motor nozzle skirts. Apparently, this salt had been leached out during a storm and ran down the tower leg in through the open access door. Obviously, this is not a scenario that would have been anticipated during design. The corrective action was to ensure that the doors were sealed in the rain and that the ablative was painted.

Aluminum Structural Elements. In October 1967, a structural failure occurred on a Lunar Excursion Module (LM) test article (Ref 17). A crack occurred in a web splice plate made of aluminum alloy 7075-T651. Investigation revealed that shims had been omitted from the assembly and that high installation stresses resulted in a stress-corrosion failure in the atmospheric environment. The low stress-corrosion threshold of the alloy and temper (<55 MPa, or 8 ksi) was contributory. In December 1967, numerous aluminum alloy 7075-T6 tubes on the same test article were also found to be cracked. The ends of the tubes had been swaged down to mate with a tubular fitting. A tolerance buildup problem resulted in high sustained tensile stresses and the eventual SCC of 20 tubes. This prompted a thorough review of all Apollo and LM hardware to evaluate whether other parts had similar problems. More than 130 LM parts were found to have been cracked as a result of stress corrosion. The corrective action taken involved shimming, relieving fabrication stresses, shot peening, and the application of protective coatings.

Fluid Fittings. Separable mechanical fittings of the B-nut type used in aerospace hardware as AN, MS, and MC fittings in the 1950s and 1960s were often very troublesome in terms of leakage and SCC. Because of the toxicity and the potentially explosive nature of aerospace fuels and oxidizers, it was decided early in the Apollo program to use a bending beam type conical seal as the standard separable fitting (Fig. 25a).

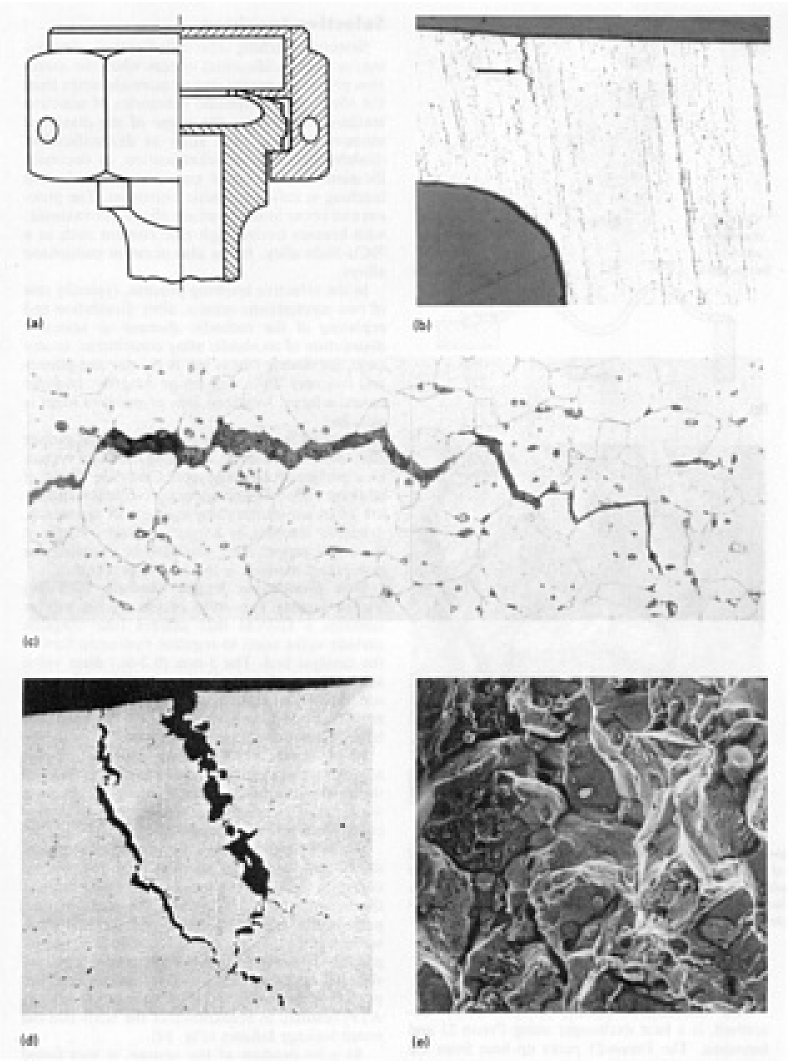

Fig. 25 Stress-corrosion cracking of 17-7PH (TH1060) fluid fittings on the Apollo and shuttle programs. (a) Illustration of assembled bending beam type fluid fitting showing the exterior (left) and cross section (right). (b) Cross section of stress-corrosion crack in location of maximum bending stress. Etchant: Kroll's reagent. 60×. (c) to (e) Stress-corrosion cracking in same alloy, temper, and design occurring 15 years later on shuttle orbiter. (c) Close-up showing intergranular cracking. 320×. (d) Similar location to cross section in (b) showing stress-corrosion crack. 105×. (e) SEM of fracture surface showing intergranular facets. 700×

This seal, which was made of precipitation-hardenable stainless steel, had both the conical face and the mating surface polished to an 8 RHR finish. As the seal was tightened, the face was spring loaded against its mating part, acting in some respects as a Belleville spring. Fittings were made from either 17-4PH or 17-7PH alloys. Rockwell used 17-4PH fittings and experienced no problems. An Apollo RCS engine subcontractor, however, reported circumferential cracking of the face seal in 1965 after 10 months of service in N_2O_4. The failure analyses conducted at Rockwell erroneously reported that the failure was due to overstressing, perhaps aggravated by cycling of the fretted areas on the face. Interestingly, however, the failure was intergranular in nature and had the characteristics of stress-corrosion branching networks (Fig. 25c to e). The subcontractor switched to 17-4PH fittings.

Fifteen years later, this time in the space shuttle orbiter program, the subcontractor for the gas generator valve module of the auxiliary power unit reported cracking of the same fitting design made from 17-7PH stainless steel. This fitting also failed in a circumferential manner, and cracking was intergranular in nature. Calculations indicated that high tensile stresses (1240 MPa, or 180 ksi) were applied to the face when the nut was tightened well above the 515-MPa (75-ksi) stress-corrosion threshold for this alloy as supplied in the TH1060 condition. In this case, chlorides from a machining (cutting) lubricant were accidentally introduced to the inside diameter of this assembly. The chlorides brought about SCC. Replacement of these fittings with 17-4PH steel (H1075) was made in 1980.

Potable Water Pressure Transducer. A 17-7PH stainless steel diaphragm of a potable water pressure transducer (Fig. 26) failed during the eighth flight of the space shuttle orbiter, causing the transducer to malfunction. The pressure transducer had completed three prior flights without failure and experienced only a nominal pressure and temperature of 215 to 240 kPa and 25 °C (31 to 35 psi and 75 °F). The 17-7PH steel was in the TH1050 condition. The failure occurred near an electron beam weld and was intergranular; therefore, sensitization was suspected. Hardness was 34 HRC rather than the 38 to 44 HRC expected. A review of the specification and heat-treat records of the supplier indicated that the part was processed properly.

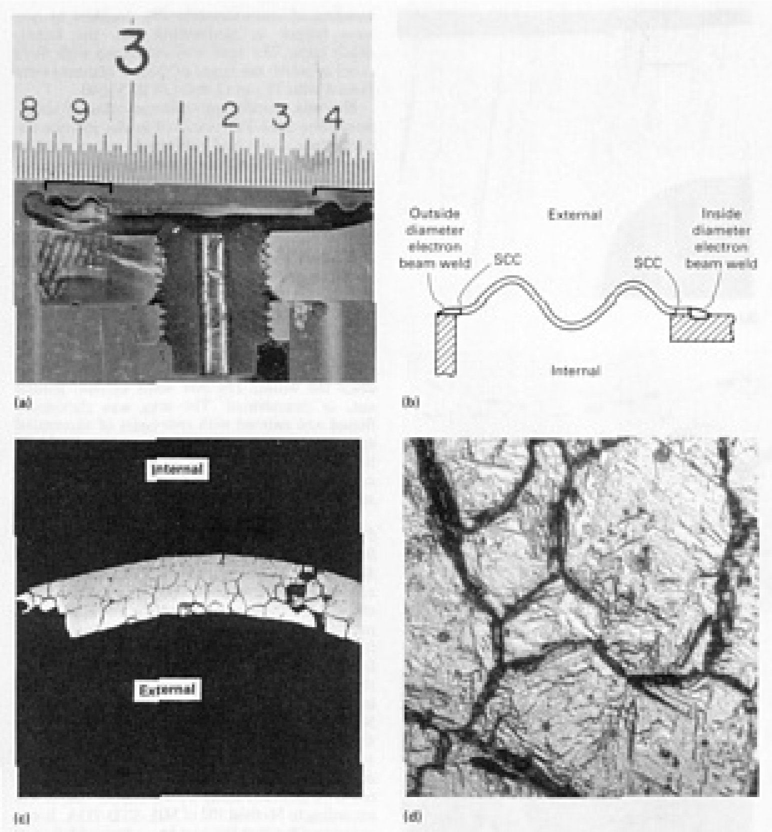

Fig. 26 Stress-corrosion cracking of the 17-7PH stainless steel diaphragm of a potable water transducer used on the shuttle orbiter. (a) Cross section of transducer and corrugated diaphragm. (b) Sketch of diaphragm showing electron beam welds and crack at points of highest bending. (c) Intergranular corrosion at the failure location. The part was sensitized along its entire length. 130×. (d) Cross section showing martensitic grain boundaries with grain-boundary carbides surrounding austenitic grains. 140×

Metallography revealed carbide precipitation in grain boundaries, with primary austenite in the grains and a martensitic network in the grain boundaries (Fig. 26d). Because the alloy is a martensitic alloy, this microstructure was highly irregular. Contamination could explain grain-boundary carbides but could not explain why grains failed to transform. A leading raw material supplier of 17-7PH was contacted and verified that this alloy, if improperly balanced in chemistry (even though within specification limits), may exhibit this unusual behavior.

Although the entire diaphragm was sensitized and had anodic (martensitic) grain boundaries, failure occurred as a circumferential crack in the area of highest bending stress, a stress calculated to be approximately 690 MPa (100 ksi), which is well above the stress-corrosion threshold of the alloy. The failure was therefore judged to be SCC.

Ferry Lock Pin. During ferry flight of the space shuttle orbiter back to Cape Kennedy, the thrust vector control servoactuator system is locked into place with shear pins. Originally, 17-4PH stainless steel (AMS 5643) was used. Later, the design was changed to 300M steel, which was heat treated to 1895 MPa (275 ksi) minimum ultimate tensile strength and 1585 MPa (230 ksi) minimum tensile yield strength. The part is internally threaded for about one-third of its length and silver plated in accordance with AMS 2412 after a nickel and copper strike. The total plating thickness does not exceed 10 μm (0.4 mil), and the part is baked for hydrogen embrittlement relief for 23 h at 190 °C (375 °F).

The pin failed during torquing prior to ferrying the shuttle orbiter back to the Cape after the fourth shuttle flight (Fig. 27). Examination by scanning electron microscopy (SEM) (Fig. 27d) revealed that the final failure was ductile. A visible rusted area on the bolt showed intergranular attack, and the metallographic cross section showed a branching crack network (Fig. 27c). Failure appeared to start on the interior threaded area where maximum tensile stress occurred. The SCC was probably accelerated by the silver plating through galvanic action. The inability to plate a threaded hole uniformly to this depth probably contributed to the corrosion problem. Even though this part was not associated with the launch vehicle configuration, this failure points out how other interfacing parts could result in expensive failures if careful engineering, manufacturing, and quality control steps are not taken.

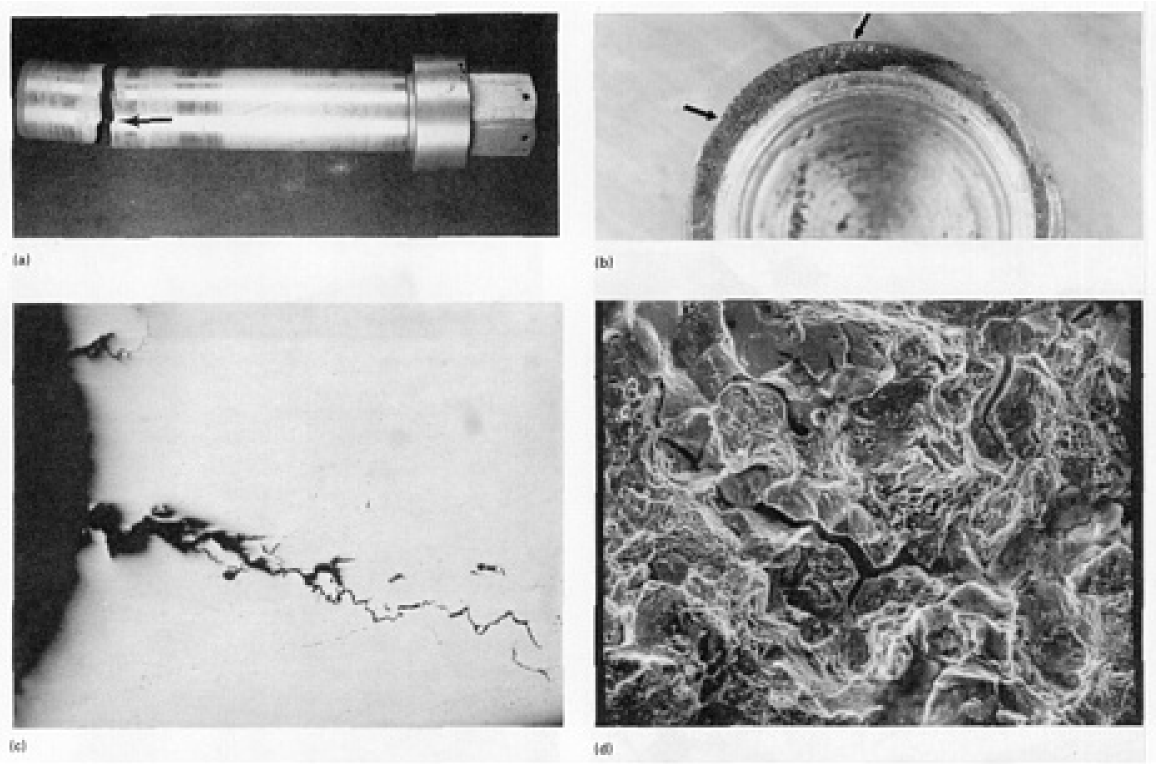

Fig. 27 Stress-corrosion failure of a 300M steel shear pin used for a shuttle ferry flight. The 300M alloy is heat treated to 1895 MPa (275 ksi). (a) Shear pin showing failure at the runout area of internal threads. (b) Fracture face showing zone where SCC occurred (between arrows). Hydrogen Embrittlement

The term hydrogen embrittlement, as used in this discussion, refers to the pickup of hydrogen by metals that results in either the immediate loss of ductility or the delayed failure by subcritical crack growth under sustained stresses. Hydrogen may enter the metal from ionic species in processing solutions, from the gaseous phase at moderate or high pressure or temperature where the protective oxide is broken or permeable, or from the corrosion process itself, where the metal acts as the cathode.

To prevent hydrogen embrittlement on manned spacecraft, several steps are taken. For example, titanium is no longer used in hydrogen systems (Ref 21) (see the following discussion). Steel parts are restricted in strength to below 1380 MPa (200 ksi) for tensile-loading applications. Steel parts with tensile strengths greater than 965 MPa (140 ksi), which are processed in potentially embrittling fluids, must receive in-process baking as well as a final 23-h bake at 190 °C (375 °F). Certain highly embrittling platings are avoided. Finally, by designing to avoid fluid entrapment where possible and by proper coating selection, parts can be protected from the corrosion process. Nevertheless, hydrogen embrittlement never seems to be eliminated totally, because hydrogen always seems to find new ways to manifest itself.

Some of the examples below point out that hydrogen failures often occur where preexisting defects are present. The hydrogen assists subcritical crack growth until the crack becomes unstable. It is believed many of these failures would not

have occurred in either the absence of the defect or the absence of hydrogen. Testing a failed part to determine the existing hydrogen content is almost always useless because the destructive hydrogen has long since left the failed part.

Liquid Hydrogen Pressure Vessel. The supercritical cryogenic hydrogen pressure vessels used in the Apollo service module were made from Ti-5Al-2.5Sn ELI. The ELI grade was chosen to ensure adequate ductility to -253 °C (-423 °F). The pressure vessel was designed for 1.7-MPa (245-psi) service and was of a dewar design described in the discussion "Electrical Power System" in this section. As a part of the development testing of the cryogenic system, the hydrogen tank and lines were being flow tested at fuel cell purge rates; that is, the hydrogen was heated and allowed to pass through the welded titanium plumbing joints to an exhaust. During this period, which was approximately 1 h long, the titanium alloy tubes failed, literally flaking and crumbling (Fig. 28). The walls were almost completely consumed (Ref 22).

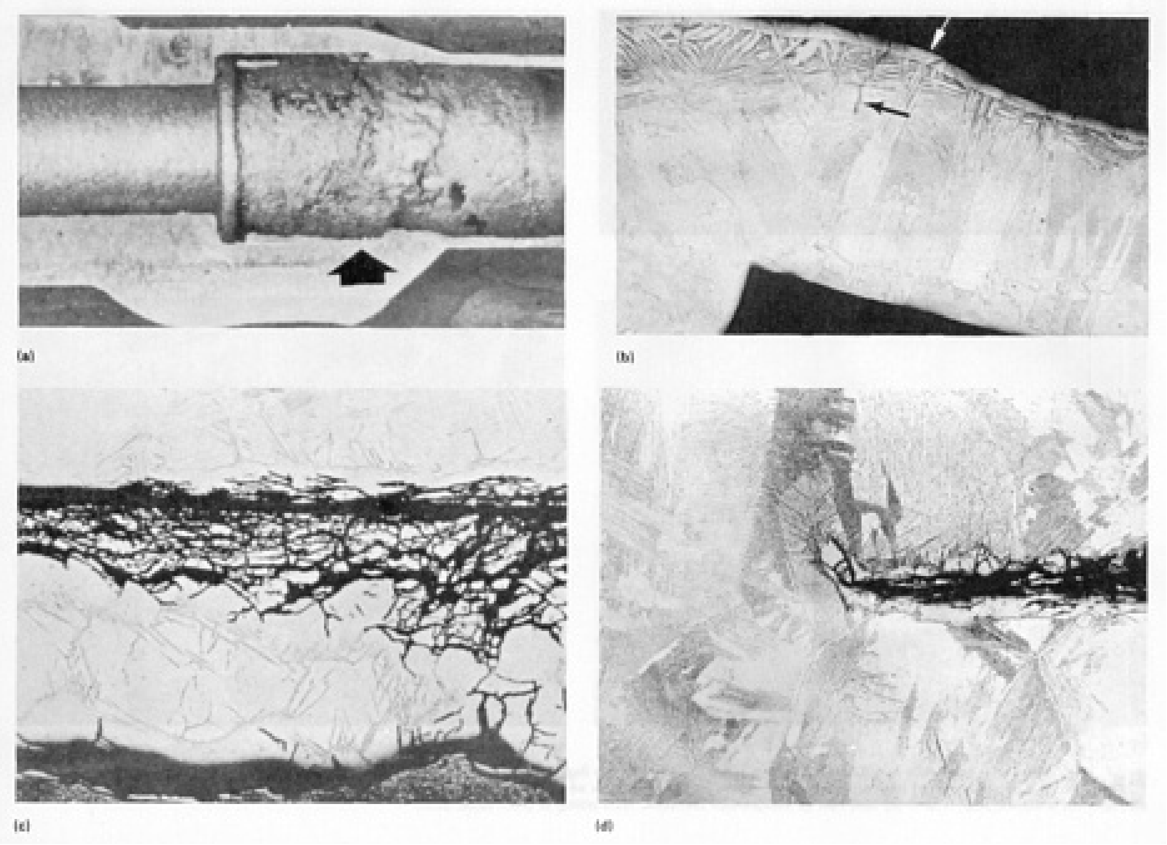

Fig. 28 Hydrogen embrittlement failure of A55 titanium tubing in a cryogenic hydrogen storage system on the Apollo program. (a) Tube with hydrided joint area (arrow). (b) Hydride layer on the inside diameter of a welded joint showing cracks. 105×. (c) Massive hydride layer in faying surface between welded tube and sleeve. 175×. (d) Hydrides discovered in tube joined to pressure vessel not in a direct hydrogen flow area. 85×

Investigation disclosed that hydride embrittlement occurred at the weld and that hydride layers were formed in discrete areas along the pure titanium tube. It was postulated that this purging flow of hydrogen, traveling at supersonic speeds, heated the inside of the tube and that turbulence in the weld area, perhaps associated with defects, stripped off the protective oxide.

Destructive evaluation was made of an existing pressure vessel at some 30 different welded connections. A few of these showed hydriding that was superficial in nature except for one tubular section outside the flow stream (Fig. 28d) where bending may have occurred. Corrective action consisted of changing all plumbing to type 304L stainless steel. Future spacecraft cryogenic systems, such as the space shuttle orbiter, used aluminum alloy 2219-T6 for pressure vessels.

Fuel Cell Nitrogen Pressure Vessel. The nitrogen pressure vessel in Apollo electrical power system fuel cells (Fig. 29) provides operating pressure for the KOH electrolyte. The pressure vessel, made of Ti-5Al-2.5Sn, would normally rupture above 59.3 MPa (8600 psi). Minimum system design pressure was 39.8 MPa (5780 psi). During proof pressure testing, one vessel failed (leaked) at 10.4 MPa (1500 psi). Investigation revealed that the vessel had been repair welded

locally in a dry box with insufficient gas coverage to prevent oxygen embrittlement of the weld. Metallographic examination also revealed concentrated hydride needles lining the edges of the repair bead and localized surface hydriding. This could not be explained by the welding process.

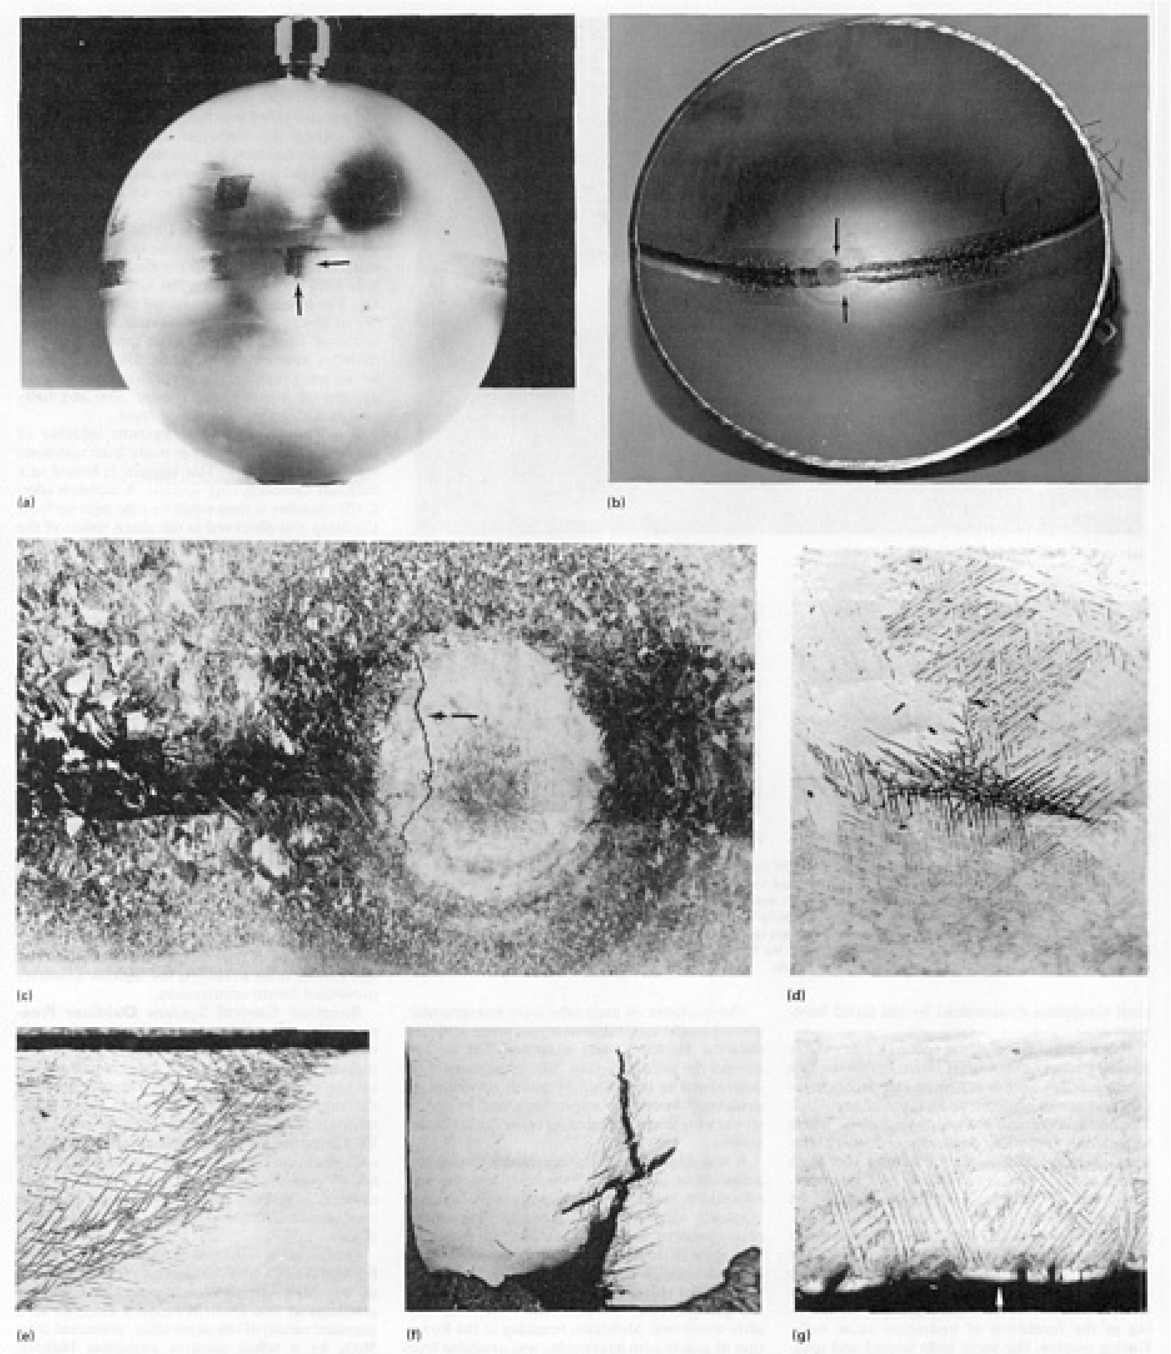

Fig. 29 Hydrogen embrittlement failure of a titanium pressure vessel for nitrogen storage in the Apollo fuel cells. (a) Pressure vessel made of Ti-5Al-2.5Sn showing weld repair (arrows). (b) Internal view showing crack in repair area. (c) Close-up view of crack in the repair. (d) and (e) Hydrides on the vessel outside diameter. (d) 325×. (e) 215×. (f) and (g) Hydrides on the pressure vessel inside diameter. Hydrogen came from a leaking furnace valve during weld stress relieving. (f) 165×. (g) 215×

Further investigation revealed the vessel was stress relieved after welding at approximately 595 °C (1100 °F) in a controlled-atmosphere furnace. Unfortunately, the furnace also had the capability of providing a hydrogen-reducing atmosphere. The investigation disclosed that a hydrogen valve near this part in the furnace was found to be leaking. This leakage was eventually very costly to the supplier because all of the Apollo parts were reevaluated and/or scrapped and the supplier had to investigate and reverify the quality of all other titanium parts processed in that furnace over the past

few years. Because the supplier also manufactured jet engines, intensive efforts were made to ensure the complete safety of the delivered hardware.

Launch Escape Tower Solid Rocket Motor Case. The launch escape motor was a solid rocket motor designed to pull the Apollo command module free of the Saturn V stack in the event of an aborted launch. The motor case was 660 mm (26 in.) in diameter and 3.8 m (12.5 ft) long. The motor case was made of 4335V modified low-alloy steel heat treated to 1445 MPa (210 ksi). It was welded longitudinally in the cylindrical section and circumferentially where the forged heads joined the cylinders. Sixty cases were initially ordered, and all passed the hydrostatic proof pressure test. Approximately 2 years later, six additional rocket motor cases were ordered. Two of these burst during the hydrostatic test.

An investigation revealed that two factors contributed to the failure. First, the manufacturer ran out of weld wire and substituted a higher-carbon wire (0.40% C versus 0.35% C) in weld repair areas. Second, because of government safety regulations, the manufacturer changed from proof testing with oil to testing with inhibited (0.2% sodium dichromate) water. Inhibited water *per se* does not prevent hydrogen embrittlement. As a result, the weld repair areas were highly susceptible to hydrogen embrittlement. Rupture of the existing surface oxide during proof testing permitted hydrogen embrittlement of the case, and the case rupture occurred in the area with the lowest tolerance to hydrogen, that is, the higher strength weld (Fig. 30). This susceptibility was confirmed in the laboratory with fracture mechanics test specimens.

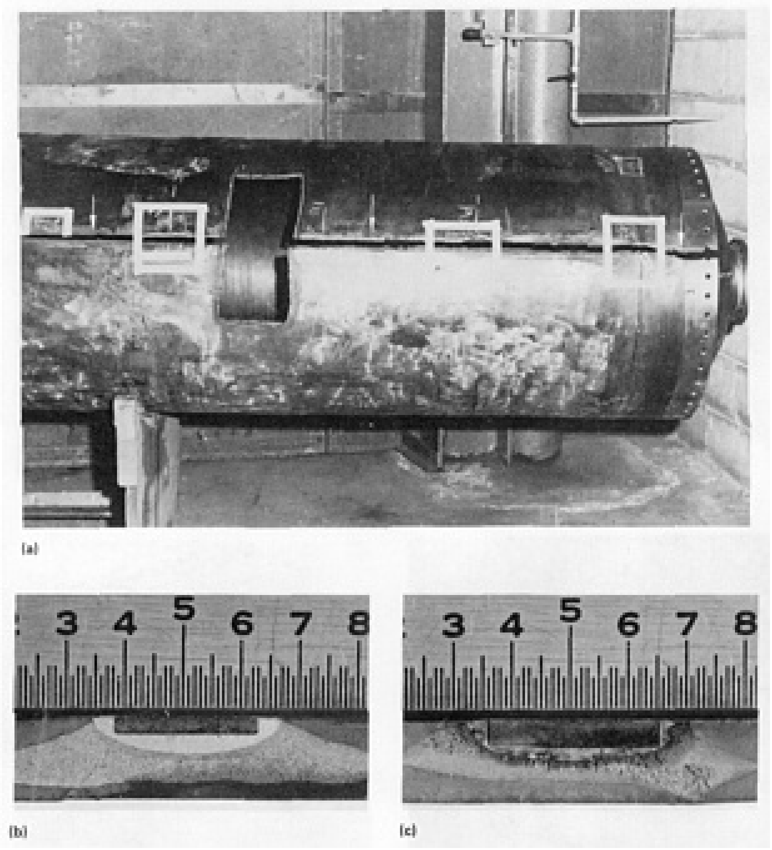

Fig. 30 Hydrogen embrittlement failure of a 4335V modified steel solid rocket motor case used in the Apollo launch escape tower. Steel is heat treated to 1445 MPa (210 ksi). The pressure test medium was inhibited distilled water. (a) Failed case with failure origin removed from longitudinal rupture along weld. (b) Notched toughness specimen from HAZ tested in air. K_{Ic} = 90 MPa$\sqrt{m}$ (82 ksi$\sqrt{in.}$). Specimen has electrically discharge machined notch and was fatigue cracked prior to toughness testing. (c) Notched toughness specimen from weld made in a similar fashion. K = 83.5 MPa$\sqrt{m}$ (76 ksi$\sqrt{in.}$) in air for 120 min. No flaw growth. K_i = 83.5 MPa$\sqrt{m}$ (76 ksi$\sqrt{in.}$) in inhibited water. The specimen failed in 53 min.

The literature had reported premature failure of high-strength steel pressure vessels in inhibited water in the early 1960s. The mechanism can be explained by Fig. 31, which shows that hydrogen-assisted crack growth is inhibited in the presence of oxygen but continues in an oxygen-free environment (Ref 23). Figure 31 also explains why hydrogen embrittlement seldom occurs when a high-strength steel is corroded in air, even though hydrogen is generated, but occurs in water tests of pressure vessels where the availability of oxygen is limited.

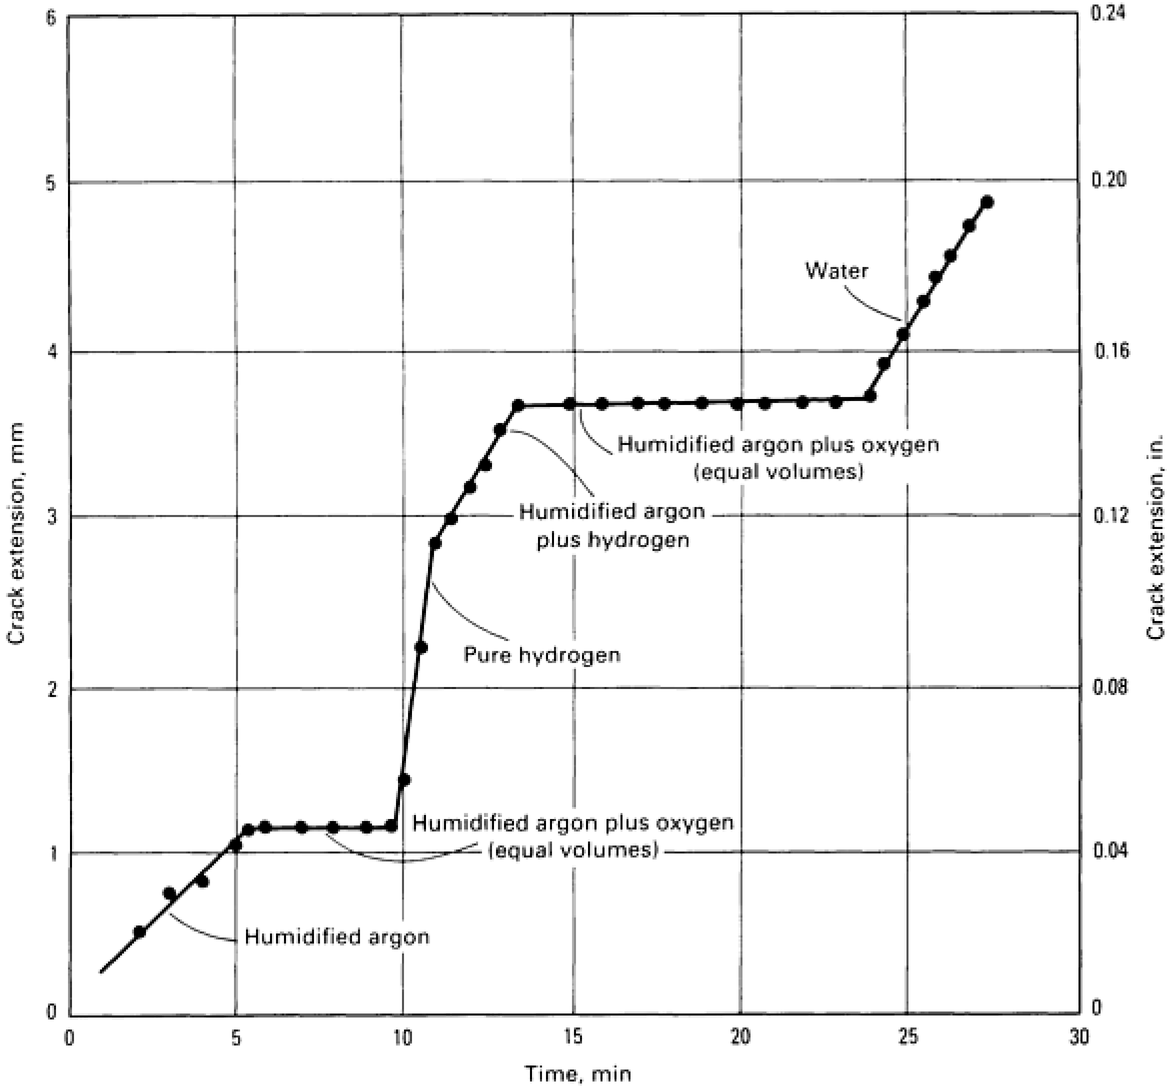

Fig. 31 Subcritical crack growth in H-11 steel (yield strength: 1585 MPa, or 230 ksi) in water, water vapor, hydrogen, and oxygen environments

Pressure Vessel Welds. During the Apollo program, pressure vessels made of Ti-6Al-4V, an α-β alloy, were welded with either Ti-6Al-4V wire or commercially pure titanium wire. The commercially pure wire was softer and more easily handled. One aerospace supplier reported that an explosion occurred in a Ti-6Al-4V helium pressure vessel and that the explosion resulted in the failure of other helium pressure vessels in the vicinity. The failed pressure vessels used multipass welding and commercially pure wire to join thick weld joints (>25 mm, or 1 in.).

Examination of the failed weld showed excessive hydride needle formation following the contour of the molten weld metal, essentially perpendicular to the transverse loading across the bead. Failure occurred because of the brittle hydride needles (Fig. 32). It was postulated that the high solubility for hydrogen of Ti-6Al-4V alloy compared to that of commercially pure titanium was the source of the hydrogen and that repeated weld cycles allowed diffusion of hydrogen to pure titanium followed by precipitation at the pure metal/Ti-6Al-4V interface. Theories of strain aging were also advanced, suggesting that hydrogen migrated to the highest strain areas.

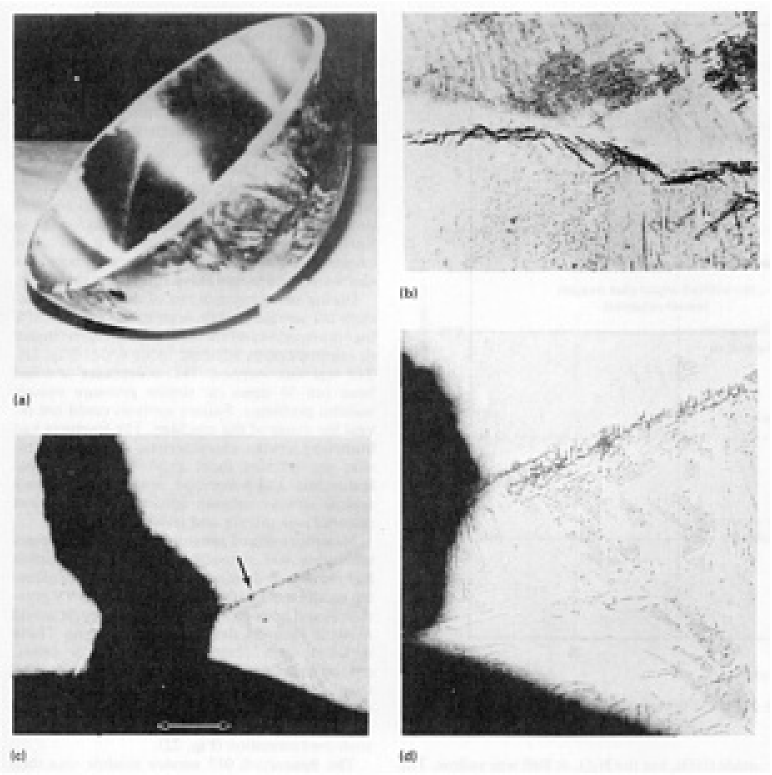

Fig. 32 Hydrogen embrittlement failure of a Ti-6Al-4V helium pressure vessel used on the Saturn IV B. Similar hydriding occurred in Apollo SPS pressure vessels. (a) Failed pressure vessel due to brittle hydride formation along weld bead made with commercially pure titanium. (b) Hydride at edge of pure metal weld bead in Ti-6Al-4V vessel shown in (a). 620×. (c) Section through a Ti-6Al-4V Apollo SPS pressure vessel welded with pure titanium on the root side. Coupon was stress cycled 200 times, then tested in tension to failure (lower arrow indicates direction of test loading). Hydride needles adjacent to the weld bead are shown. 45×. (d) Path of hydride needles changes direction and becomes parallel to load across weld. 70×

All of the solution-treated and aged Ti-6Al-4V pressure vessels on the Apollo command and service modules were welded with Ti-6Al-4V wire except for the final pass on the SPS fuel and oxidizer tanks. In this case, the root side of weld was back chipped, and a filler pass was made with commercially pure wire.

Specimens from SPS qualification tanks were examined and, in some cases, cycle tested. Hydride formation, although limited in nature, did follow the inside diameter bead contour. Because the pass was wide and shallow, the hydride path changed from perpendicular to the weld to a plane parallel to the surface. This undoubtedly explained why no problem had occurred with these pressure vessels. Existing SPS vessels were considered safe based on proof pressure, x-ray, and penetrant inspection.

In future programs, commercially pure titanium wire was not permitted for welding α-β titanium alloys. This experience pointed out that the migration and precipitation of hydrogen must be considered in α-rich titanium structural members that undergo thermal cycles.

Landing Gear Parts. The space shuttle orbiter landing gear is made principally from 300M steel heat treated to 1895 MPa (275 ksi). At this strength level, steel is highly susceptible to SCC and hydrogen embrittlement. Because of the critical orbiter weight requirements (see the discussion "Orbiter Landing Gear System" in this section), this alloy and temper were used despite objections from material and process engineers. Over a short period of time, three separate hydrogen embrittlement failures took place. Each pointed out processing deficiencies that had to be corrected immediately.

The first failure occurred the day before the initial rollout of the shuttle orbiter in September 1976. While the orbiter was resting on the landing gear in Palmdale, CA, a technician noticed the head of a bolt on the ground near the gear. A quick inspection revealed that it came from a 300M pin that retains the steering actuator. The pin, nut, and washer were still on

the spacecraft. The pin failed by delayed fracture under the low installation preload used with a shear fastener (170 MPa, or 25 ksi, tension) (Fig. 33).

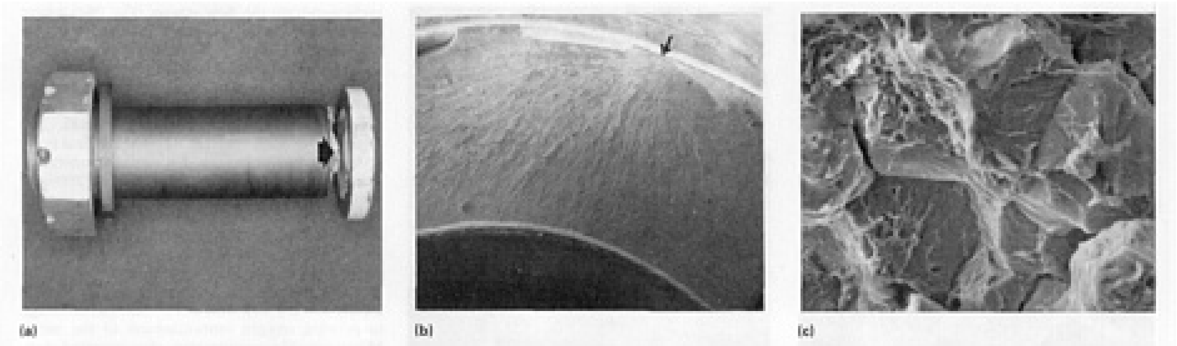

Fig. 33 Hydrogen embrittlement failure of a 300M steel orbiter nose landing gear steering collar pin. The pin was heat treated to a 1895-MPa (275-ksi) strength level. The part was plated with chromium and titanium-cadmium. (a) Pin showing location of failure. Actual size. (b) Failure origin (arrow). 9×. (c) Brittle intergranular fracture face characteristic of hydrogen embrittlement. Parts did not receive a hydrogen embrittlement relief bake due to processing error. 1380×

Metallurgical analyses revealed that cracks occurred in three locations at the radius of the head of the pin. An embrittled microstructure (rock candy in appearance) was located in these areas with no evidence of corrosion. A significant portion of the fracture face was characteristic of hydrogen embrittlement, although final failure was ductile under more rapid fracture. Investigation revealed this pin was part of a lot that had been reworked to correct a plating error. The pin had both chromium plating and titanium-cadmium plating on the part. Chromium was plated on the pin shank and head. Cadmium-titanium was plated on the head radius and internal hole. A review of the records at the vendor failed to disclose any evidence of a hydrogen embrittlement relief baking step.

Corrective action consisted of a reinspection and rebaking of all reworked parts. Future reworks required full manufacturing planning, not just a material review disposition.

The second part that failed was the lower drag brace of the main landing gear. It was also made of 300M steel at the same heat-treat level, had chromium-plated wear surfaces, and had cadmium-titanium plating on other surfaces for corrosion control. The brace failed under a 2-h sustained load of 950 MPa (138 ksi), or 50% of its ultimate tensile strength, during static load qualifications testing. Failure analysis again determined that crack propagation was by hydrogen. The initiation sites were arc burns on the part caused by accidental contact with a hand-held electrode used to ensure more uniform plating (Fig. 34). All parts that had been plated with a hand-held electrode had to be restripped and inspected. For these reworked parts and future parts requiring a hand-held electrode, the electrode was adequately protected by wrapping with nylon or other approved organic web fabrics. This incident was also an indication that baking in this heavy section was marginal for the removal of hydrogen. A complete review of baking procedures, times, and temperatures was made to ensure that no deficiencies existed.

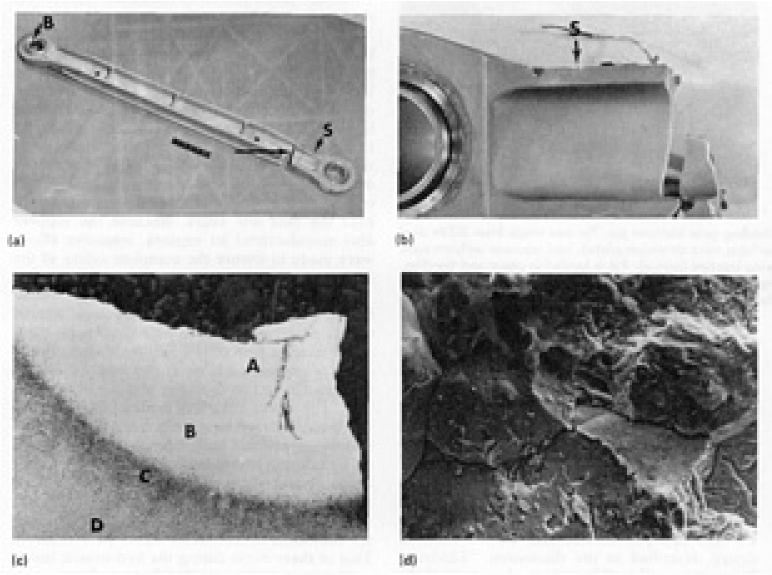

Fig. 34 Hydrogen embrittlement of an orbiter landing gear lower drag brace made of 300M steel. Steel was heat treated to 1895 MPa (275 ksi). The part was plated with titanium-cadmium. Wear surfaces were chromium plated. (a) Drag brace showing tensile failure that occurred at 50% of ultimate tensile strength during a qualification test. (b) Close-up of failure. (c) A section through the initiation site showing an arc burn. A, area melted by arc burn; B, untempered martensite; C, overtempered martensite; D, tempered martensite of the base material. 145×. (d) Fracture face away from initiation area showing intergranular failure characteristic of hydrogen embrittlement. 870×

The third part to fail was the trunnion pin of the nose landing gear. The pin failed again under static load and was made from 300M steel heat treated to the same levels as the other parts. This part was chromium plated on the shank area and had a titanium-cadmium plating applied to threads and to other surfaces requiring corrosion protection. The thread plating ranged in thickness from 5 to 7.5 μm (0.2 to 0.3 mil), while other corrosion protection plating was 12.5 to 17.5 μm (0.5 to 0.7 mil) thick.

Failure analysis disclosed the same grain-boundary fracture characteristic of hydrogen embrittlement--again with no corrosion on fracture faces. The part had a few local areas of untempered martensite from grinding burns (Fig. 35), and some areas had chromium plating as thick as 0.3 mm (12 mils). The drawings called for a nominal thickness of 0.06 mm (2.5 mil). Some cadmium plating solution had entered the fracture surface and had both plated and deposited salts. It was believed that overheating due to grinding resulted in untempered martensite, which cracked either before or upon immersion in the plating bath. Residual hydrogen left in the part after plating migrated to the crack areas when the parts were under sustained load, resulting in slow crack growth leading to failure. Fracture mechanics analyses were able to show that the initial flaw size would grow by subcritical crack growth to the final size (2.5 mm deep × 2.4 mm long, or 0.100 × 0.095 in.) that failed under load.

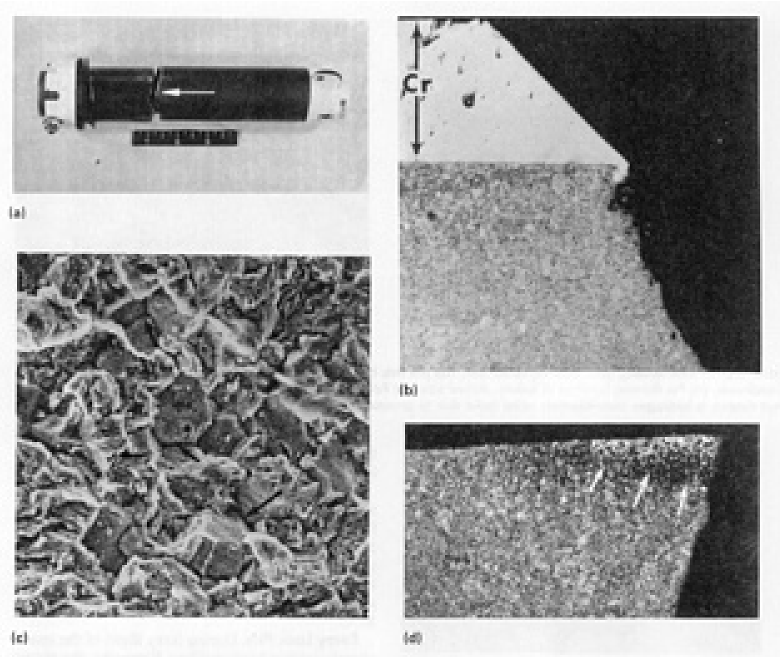

Fig. 35 Hydrogen embrittlement of an orbiter nose landing gear trunnion pin. Pin was made from 300M steel heat treated to 1895 MPa (275 ksi). Wear surfaces were chromium plated, and nonwear surfaces were plated with titanium-cadmium. (a) Failed trunnion pin showing fracture (arrow). Pin is loaded in shear and bending. $\frac{1}{5}$ ×. (b) Fracture surface and very thick chromium plating. 85×. (c) Fracture face showing intergranular failure propagated by hydrogen. 875×. (d) Localized grinding burn and untempered martensite (arrows) where cracking initiated. 95×

In this case, special controls had to be placed on grinding, including lubricants, pressures, speeds, and feeds. It is significant that all failures occurred during a 4- to 5-month period and that, since then (9 additional years), no subsequent failures have been noted.

High-Pressure Hydrogen Valve Seat. Early shuttle orbiter flights required high-pressure hydrogen valves for the fuel cell system. A solenoid valve, used successfully in the Apollo program for high-pressure helium in the reaction control system, was evaluated as a candidate valve for use with the high-pressure hydrogen. Testing consisted of exposing the valve to a 16.5-MPa (2400-psi) pressure for 24 h, followed by 200 actuation cycles at 2.4 MPa (350 psi). After hydrogen testing, the valve was disassembled for metallurgical examination. Hardness tests were performed and cross sections were made. A valve seat made of type 440A stainless steel was found to be cracked (Fig. 36).

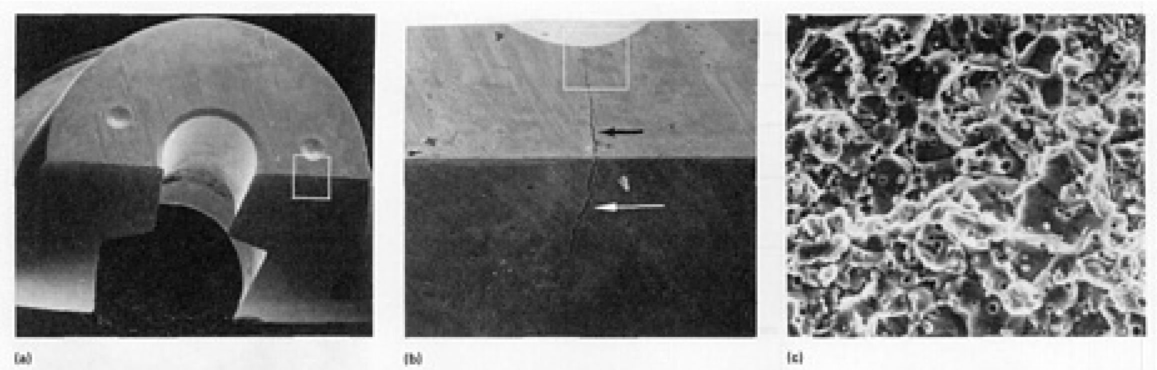

Fig. 36 Hydrogen embrittlement of a type 440A stainless steel valve seat from an orbiter solenoid latching valve. Seat is hardened to 52 HRC. (a) Sectioned valve seat showing area of cracking (inside box). 9×. (b) Cracking (arrows) appears to originate in hardness indentation. 75×. (c) Fracture surface of crack showing

intergranular nature of the failure. Failure was caused by hydrogen in etching solution and residual stress at the hardness indentation, not by previous high-pressure hydrogen exposure. 1440×

The crack originated from a hardness indentation, and concern was expressed regarding whether the hydrogen gaseous exposure or the metallographic examination caused the failure. Using other available valve seats, unexposed to gaseous hydrogen, it could be demonstrated that the combination of the hardness indentation and the acid etchant (a mixture of HNO_3, HCl, and water) was the cause of the failure. Again, hydrogen was a culprit, but this time it was not from high-pressure hydrogen gas but from metallographic preparation procedures. The valve was qualified for use.

A Belleville spring is a convex-concave washer that stores energy when flattened. It is widely used in aerospace in bungee applications. When a Belleville spring is compressed, very high tensile forces are put on its periphery. Because these springs are made of high-strength steel alloys, stress corrosion and hydrogen embrittlement become real concerns. Depending on the application, the springs are stacked in series, parallel, or series-parallel stackings (Fig. 37).

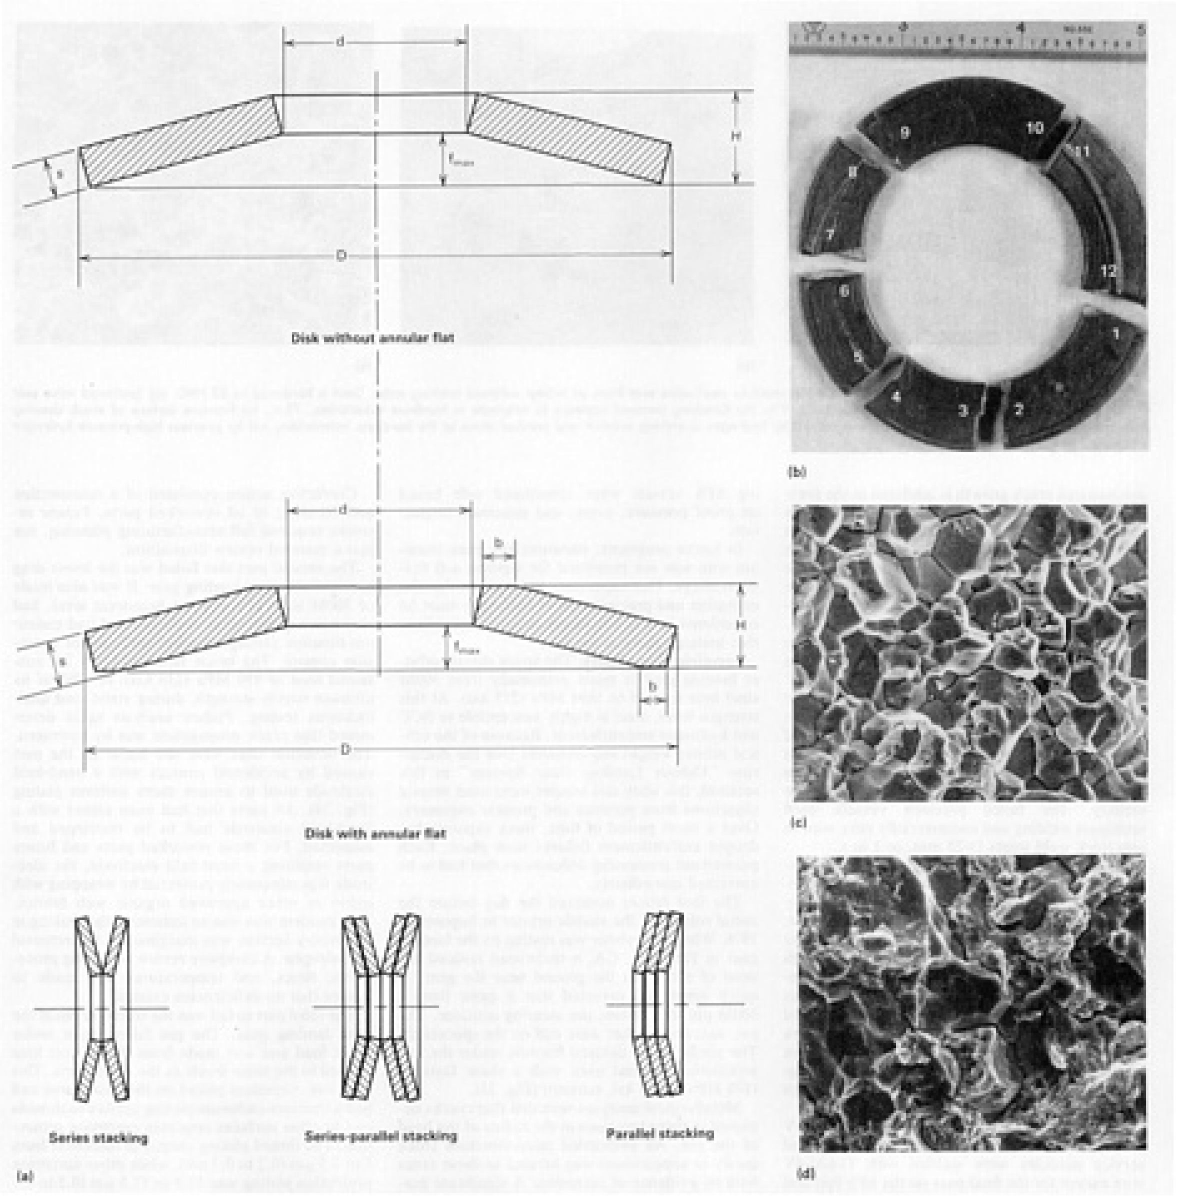

Fig. 37 Hydrogen embrittlement of alloy steel Belleville springs for the space shuttle orbiter program. (a) Illustration of spring design and stacking arrangements. (b) Belleville spring that failed in service. (c) Fracture face of a cadmium-plated Vascomax 300 maraging steel spring that failed from hydrogen embrittlement in saltwater immersion. 1080×. (d) Fracture face of cadmium-plated 6150 alloy steel Belleville spring that failed by hydrogen embrittlement due to inadequate baking. 1440×

The Belleville springs used on the space shuttle orbiter may be made from Vascomax 300 maraging steel or 6150 steel. The springs have been plated with cadmium. Cadmium plating is permitted because the springs are totally contained and will not be exposed to the space vacuum (see the discussion "Structural Joints and Fasteners" in this section). Testing has shown that cadmium-plated maraging steel springs will withstand 30 days of salt fog without failure, even with breaches in the cadmium plating, but the springs fail in a 30-day saltwater exposure because of hydrogen embrittlement as a result of cadmium cathodically protecting the steel.

On several occasions, Belleville springs made of cadmium-plated 6150 steel have failed within minutes after loading. In these cases, hydrogen embrittlement from the plating process is suspected. On one occasion, 40 springs were replaced in a bungee. When reloaded, 17 new springs failed within a short period of time. Repeated baking at 190 °C (375 °F) for 23 h has not completely solved the problem. The literature indicates that cadmium-plated springs should be baked at 260 °C (500 °F) for 1 h or at 230 °C (450 °F) for 4 h. The current approach used on the orbiter has been to use vacuum plating, thus avoiding any exposure to hydrogen pickup during electroplating.

Nickel-Tin-Plated Steel Parts. Three weeks before the first manned flight of the Apollo, a 4340 steel parachute fitting failed. Metallurgical examination of the fracture face revealed a rock candy intergranular fracture typical of hydrogen embrittlement. Investigation disclosed that the parachute system subcontractor specified a 3-h hydrogen embrittlement relief bake at 190 °C (375 °F) instead of the 23 h required by the Apollo contractor after application of the plated nickel-tin coating.

The nickel-tin coating had originally been developed to replace cadmium plating on fasteners because cadmium plating sublimes in the vacuum of space. The total coating is 5 to 10 μm (0.2 to 0.4 mil) thick and is excellent for close-tolerance threads. Investigation of the records at the plating shop, however, revealed that the plater performed no hydrogen relief bakeout, because the military specification for tin plating at that time did not require it. The plater ignored the drawing callouts.

Over 1000 different spacecraft part designs were analyzed to determine which parts needed to be inspected and/or replaced. Extensive testing was performed to find the threshold stress levels of parts that had not been baked. Efforts were concentrated on evaluating the highest strength, most highly loaded threaded parts first, because these have the least tolerance for hydrogen and the highest probability of failure. One such configuration is shown in Fig. 38. This part, made of low-alloy steel heat treated to 1380 MPa (200 ksi) tensile strength and nickel-tin plated, failed within 7 h at a stress of 69 MPa (100 ksi). Through inspections of critical parts, torque level verification, and associated testing, the safety of flight parts was ensured. No failure had been found on any flight safety critical parts.

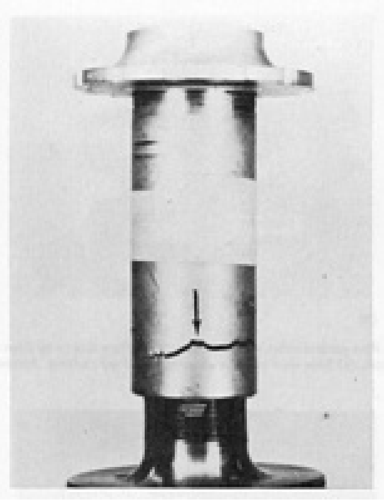

Fig. 38 Hydrogen embrittlement of a low-alloy steel Apollo test part plated with nickel-tin and tested under sustained load. Nickel-tin plating is 5 to 10 μm (0.2 to 0.4 mil) thick. No hydrogen embrittlement relief baking was used in the test part. The part was tested at 50% of its ultimate strength (1380 MPa, or 200 ksi) and failed in less than 7 h, beginning at external threads.

One may question why there were no previous part failures by hydrogen embrittlement given that the same plating procedures had been used for 3 to 4 years. A plausible explanation is that hydrogen will find its way out of steel over a period of time by diffusion through plated coatings. The nickel-tin coating was far more permeable to hydrogen than cadmium platings. Therefore, parts that did not encounter sustained tensile loads shortly after plating were eventually relieved of hydrogen. As it happened, a single supplier had plated nearly 9000 spacecraft parts by the time this problem surfaced. Many of these parts were already installed into the Apollo vehicles under production. Fortunately, the problem could be resolved without vehicle disassembly or scrapping of parts.

Oxygen Ignition

Oxygen is widely used in spacecraft operations as either liquid oxygen or gaseous oxygen. Liquid oxygen will react under certain impact conditions with nearly any metal. Metals such as titanium and magnesium are relatively easy to ignite, while aluminum and stainless steels require considerably more energy to ignite and are used in LOX tubing, valves, and pressure vessel designs. Inconel alloy 718 is one of the most resistant metals to LOX ignition and is widely used in orbiter LOX or GOX applications. In gaseous oxygen, both mechanical impact and pneumatic impact can cause ignition (see the discussion "Main Propulsion System" in this section). Organic materials also readily react with oxygen under impact conditions. When ignition occurs, the part is often so badly melted that no direct identification of the cause can be determined, and the causes of failure can only be inferred from detailed analyses of design and operating or test parameters.

Extravehicular Mobility Unit. A fire destroyed an extravehicular test unit and space suit at the NASA Johnson Spacecraft Center in Houston. Although the location of the ignition was pinpointed, the cause of the fire could never be positively identified. Particle impact, as well as design and manufacturing defects, could not be ruled out. Aluminum and 300-series stainless steel were used in the design. The aluminum was severely burned.

The oxygen flow control valve controls the flow of hot gaseous oxygen at 280 °C (540 °F) and at 31 MPa (4500 psi) to the external tank of the space shuttle system. Two explosions occurred during testing of this valve. In both cases, the valve was a victim of the explosion, not the cause. The first, in January 1977, took place 7 min into a flow test of the valve at a test facility. A facility check valve, which was acting as a shutoff valve against 31-MPa (4500-psi) oxygen, failed at ambient temperatures. The valve was made of type 316 stainless steel with a Stellite ball on the valve stem. The ensuing ignition damaged the stainless steel flow control valve (Fig. 39). The cause was suspected to be contamination in the system.

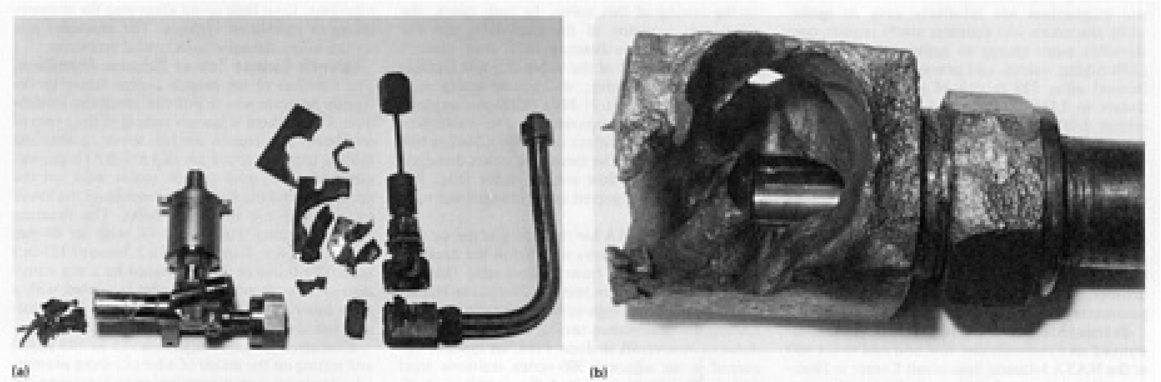

Fig. 39 Oxygen ignition of a type 316 stainless steel check valve that occurred during testing a shuttle orbiter LOX flow control valve. (a) The check valve (right) ignited during test at 31 MPa (4500 psi) oxygen pressure. Also shown is the LOX flow control valve (left). (b) Close-up of failed check valve

Concern by NASA for the safety of the orbiter LOX flow control valves resulted in the decision to make these valves from Inconel alloy 718; this decision was based on tests conducted at NASA White Sands using high-velocity particle impacts. During the acceptance testing of a valve for the *Atlantis* spacecraft in June 1984, an ignition occurred in an adjacent 300-series stainless steel fitting. The ignition melted the stainless steel, aluminum base plate, and part of the Inconel alloy 718 valve (Fig. 40). This failure was attributed to the ignition of a loose silicone rubber O-ring seal after approximately 600 s of flow at 195 °C (380 °F) and 27.6 MPa (4000 psi).

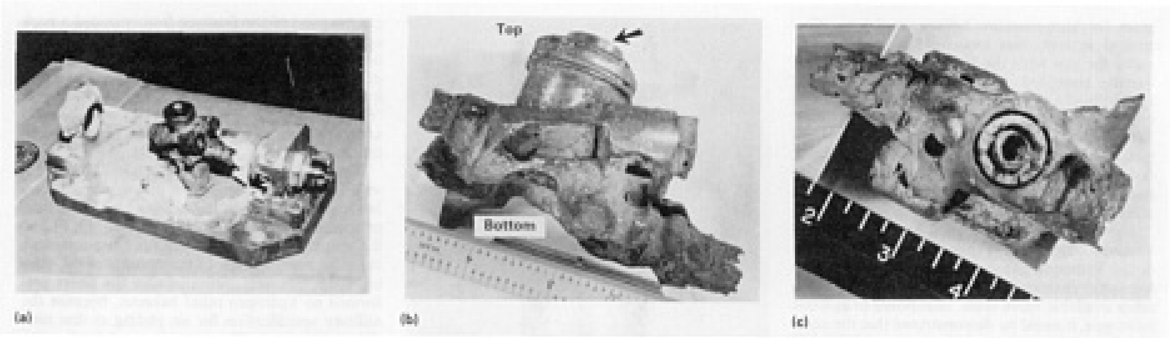

Fig. 40 Damage to an Inconel alloy 718 shuttle LOX flow control valve and aluminum test fixture due to ignition of a silicone O-ring seal in an austenitic stainless steel test fitting. (a) Test article and fixture after ignition. (b) Side view of valve showing localized melting. Arrow indicates area where solenoid screws on. (c) Bottom view of valve

High-Temperature Gaseous Reactions

High-temperature gaseous reactions occur during mill processing, heat treating, and surface hardening of metals. During heat treating, detrimental reactions with metals take the form of carburizing or decarburizing in steel, intergranular oxidation in nickel-base superalloys, and formation of an αcase on titanium alloys. Surface attack on aluminum alloys is cosmetic in nature and not particularly detrimental to its properties. To prevent these reactions, furnaces with inert, controlled, or vacuum atmospheres can be used, the part can be coated or protected, or the detrimental surfaces can be machined off, grit blasted, pickled, and so on.

During surface hardening, carburizing or nitriding atmospheres are used to achieve the desired surface hardnesses. These are normally well controlled by specifications and quality control sampling to prevent detrimental surfaces from being accepted.

High-temperature detrimental gas reactions become a major concern when they are unanticipated. There may be insufficient allowance on raw material to remove unacceptable layers. Reactions with hardware have occurred where parts, in final dimensions, have little or no allowance for property losses or embrittled surfaces. The examples presented below describe such typical problems.

Launch Escape Tower Tubular Members. The function of the launch escape tower in the Apollo program was to pull the command module free of the Saturn V launch system in the event of an abort. The launch escape tower, a titanium tubular truss structure about 3 m (10 ft) high, was attached to a solid rocket motor case on the upper end and the command module on the lower end through the tower leg bolts. The titanium tubing specified was Ti-6Al-4V with an 89-mm (3.5-in.) outside diameter and a 3.2-mm (0.125-in.) wall. The titanium was produced by a hot extrusion process in which the billet is coated with a glass layer, which not only lubricates the extrusion but also protects it from oxidation.

Excessive surface roughness (85 to 190 RHR) and pitting on the inside of a lot of tubing prompted a destructive microsectioning to determine the cause of the problem (Fig. 41). The inside surface was found to contain a brittle αcase and localized cracks indicative of a high-temperature reaction with oxygen (>705 °C, or 1300 °F). Because there was no practical way to rework the inside of the tubing at that time, the lot was scrapped. Future lots provided for adequate material removal on the tube inside diameter.

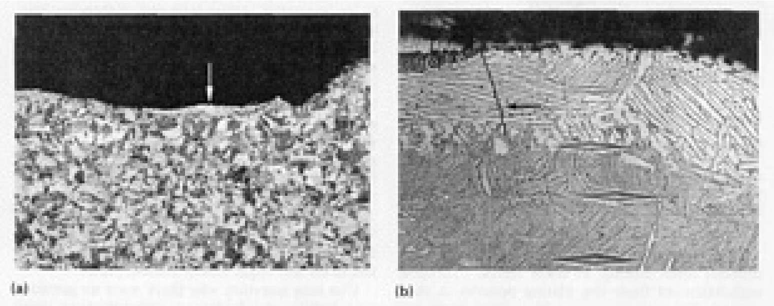

Fig. 41 Oxygen embrittlement of an extruded Ti-6Al-4V launch escape tower tube for the Apollo spacecraft. (a) Cross section of tube inside diameter showing pitting and αcase (arrow). 30×. (b) Cracking of the αcase (arrow). 260×. The glassy coating used to protect the part during processing was not continuous, resulting in high-temperature oxidation in air.

Reaction Control System Vernier Engine Chambers. The reaction control system on the space shuttle orbiter provides the rocket propulsion to change the attitude of the orbiter with regard to the sun or earth. The RCS vernier engine chamber, made of niobium alloy C 103, must function to 1315 °C (2400 °F). The chambers are protected with an R512A silicide coating. Localized failure of the coating was observed in a vernier RCS engine that had undergone an extensive number of firing cycles. In one case, failure occurred at a slight (75 μm, or 3 mil) mismatch between two machining cuts. This resulted in an offset in the coating, accelerating localized failure. To provide the greatest coating cyclic life capability, action was taken to ensure blending of all machine cuts, to use a dual coating thickness, and to ensure a minimum total coating thickness of 0.1 mm (4 mils).

The silicide coating used on the RCS engine chambers can also fail when exposed to a cyclic, low-temperature (650 to 815 °C, or 1200 to 1500 °F) oxidizing environment for extended periods. The low-temperature failure is caused by the thermal expansion mismatch between the silicide coating and the niobium alloy C 103 substrate. Cracks in the brittle coating fill with oxides, eventually causing spalling of the coating. Once the coating spalls, oxygen can reach the niobium alloy substrate. Oxidation of the niobium alloy at these temperatures is relatively slow, but as the substrate oxidizes, the adjacent coating is undermined. This results in more spalling, which enlarges the coating failure site (Fig. 42).

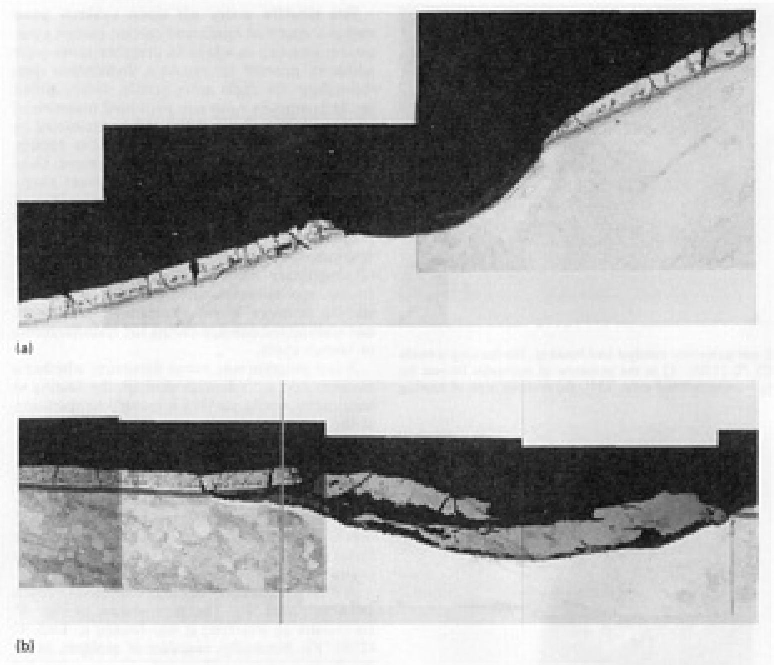

Fig. 42 Oxidation of a niobium alloy C 103 RCS engine chamber after cyclic temperature testing. The thermal expansion mismatch between the protective silicide coating and the niobium substrate caused the coating to spall. (a) Coating failure site and oxidation of the C 103 substrate after ~81,700 s and 267,000 cycles at 650 to 815 °C (1200 to 1500 °F). (b) As oxidation of the substrate progresses the adjacent coating fails. Here the coating is being lifted from the surface.

Orbital Maneuvering System Nozzle Extension. The orbital maneuvering system provides the rocket propulsion for orbit insertion, translation, rendezvous, and deorbit of the space shuttle orbiter. The conical OMS nozzle extension is approximately 1.3 m (50 in.) long and 1.2 m (46 in.) in diameter. It is a welded sheet metal structure made of niobium alloy FS-85, typically 1.5 mm (0.060 in.) thick, and has an R512E silicide coating to protect it from oxidation at temperatures to 1360 °C (2480 °F).

A nozzle was removed from the *Challenger* vehicle when cracks adjacent to the weld bead were found (Fig. 43). The fracture face showed brittle quasi-cleavage with some grain-boundary fractures rather than ductile dimpling. A hardness traverse indicated the fracture to be brittle. Because welding was performed in a controlled chamber to maximum oxygen levels of 2 ppm, no weld contamination during manufacturing was suspected. Inspection of the nozzle showed the coating had been breached and spalled in eyebrow-shaped areas as a result of the nozzle flexing under pressure. A redesigned, stiffer nozzle was already available for replacement; the failed lightweight nozzle represented an earlier design.

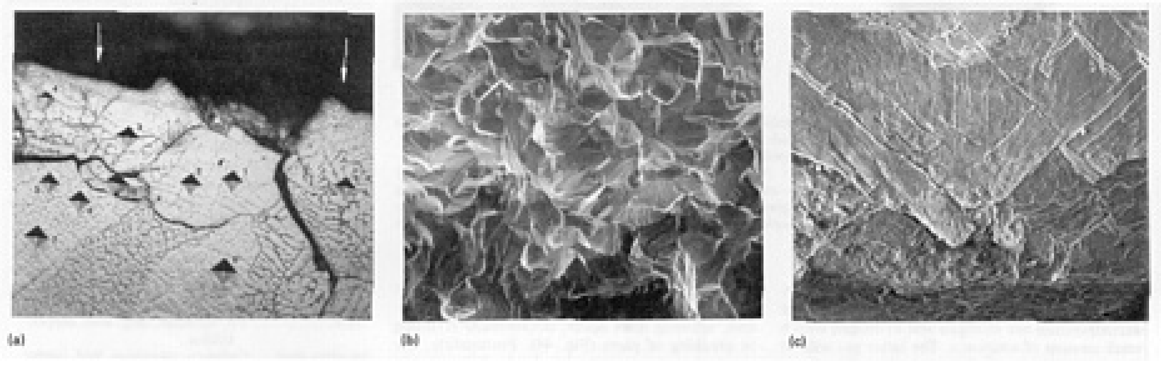

Fig. 43 High temperature oxidation embrittlement of a niobium orbiter OMS rocket nozzle extension due to mechanical damage to the silicide coating. (a) Fracture of FS-85 alloy showing that hardness increases near the failed edge. Hardness ranges from 67 HRC at location 4 to 46 HRC at location 8. 145×. (b) Fracture face

Auxiliary Power Unit Gas Generator Catalyst Bed. The auxiliary power unit of the space shuttle orbiter uses an iridium catalyst bed to decompose neat N_2H_4. The decomposed gases are then directed into a high-temperature turbine, which in turn drives hydraulic pumps for orbiter hydraulic pressure. The gases resulting from the decomposition are nitrogen and hydrogen with a small amount of ammonia. The latter gas will, at the temperatures of the catalyst (>930 °C, or >1700 °F), cause nitriding of the Hastelloy alloy B used to house the catalyst bed. Hastelloy alloy B was chosen for this application because of its relatively high resistance to nitriding. Nevertheless, nitriding does occur, occasionally resulting in cracking of parts (Fig. 44). Fortunately, the cracked parts are under low loads, failure is not critical, and no high-temperature coating is required.

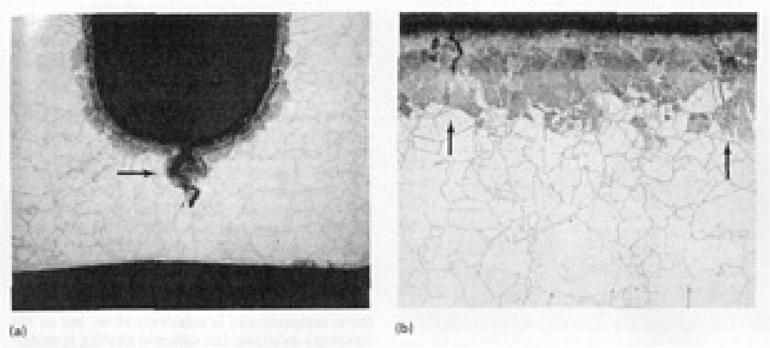

Fig. 44 High-temperature nitriding of an orbiter APU gas generator catalyst bed housing. The housing is made of Hastelloy alloy B and is in service to 925 °C (1700 °F) in the presence of ammonia formed by hydrazine decomposition. (a) Nitriding and crack originating from embrittled area. 25×. (b) Another area of housing showing nitriding and cracking. 40×

The shuttle entry air data system nose cap is a modified reinforced carbon-carbon composite nose cap in which 14 pressure ports were added to provide air pressure distribution data throughout the flight entry profile. Holes drilled in the composite nose cap permitted insertion of a niobium alloy C-103 plug that was connected on the internal side to thin-wall niobium tubing. These tubes terminate at pressure sensors. Concern was for the survival of the niobium plugs, because loss of a plug could result in ingestion of a stream of extremely hot plasma that could potentially damage the spacecraft. Although the niobium was coated with a VH109 silicide coating (a proprietary mixture of chromium, titanium, silicon, and hafnium), there was concern that the silicide coatings might experience inadvertent and undetected damage during the manufacturing or launch cycle.

A test program was run to determine whether a niobium port with damage through the coating to bare metal would survive a reentry temperature at the maximum oxygen partial pressure expected during the heating peak, thus ensuring fail-safe mission behavior (Fig. 45). Flaws were made in the coating of a size readily visible by inspection using a chisel point indenter. Each defect resulted in a coating spall area approximately 1 × 1.5 mm (0.040 × 0.060 in.). Penetration into the bare metal was approximately 0.25 × 0.5 × 0.75 mm (0.010 × 0.020 × 0.030 in.) deep.

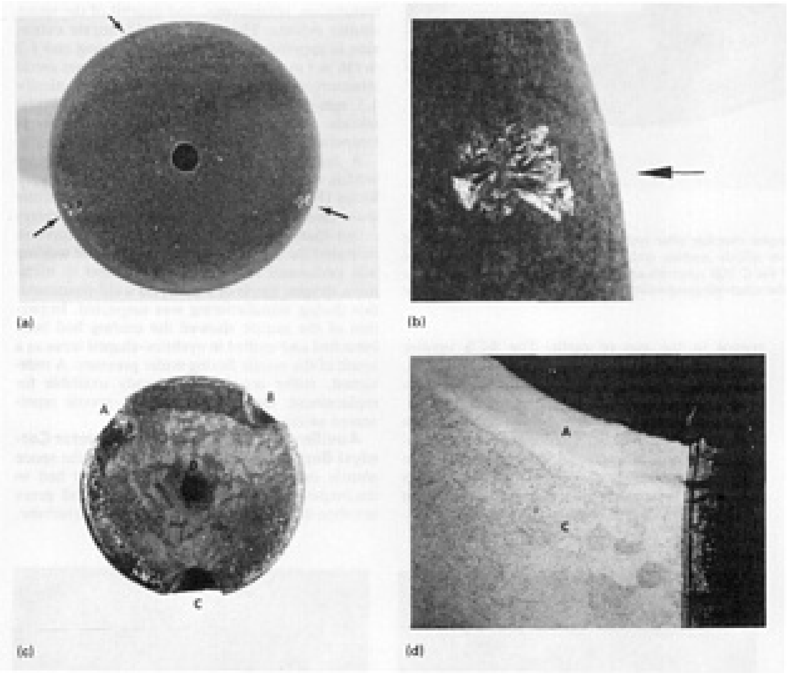

Fig. 45 High-temperature oxidation of a C 103 niobium alloy nose cap plug in the orbiter SEADS program. The plug is coated with a silicide coating, which was purposely damaged for testing to verify flight safety. (a) Three perforations (arrows) in the coating result in spalled areas of 1 × 1.5 mm (0.040 × 0.060 in.) each. 2×. (b) Enlargement showing base metal damage $\frac{1}{4}$ × $\frac{1}{2}$ × $\frac{3}{4}$ mm deep (0.010 × 0.020 × 0.030 in. deep). 15×. (c) Oxidation of niobium during one simulated entry cycle at a 1485-°C (2700-°F) peak temperature using 0.57-kPa (12-psi) oxygen partial pressure. Craters A, B, and C grew in damaged areas to 6.3 mm diameter × 2.5 mm deep ($\frac{1}{4}$ × 0.10 in.). 1.5×. (d) Embrittlement of crater surface in section A is 0.2 mm (7 mils) deep. Section C is undamaged base metal. 50×

A maximum reentry cycle is expected to reach 1430 °C (2600 °F). The part shown in Fig. 45 represents an overtest; it was heated to 1485 °C (2700 °F). Normally, reaction of niobium in air results in a canary yellow voluminous oxide, but flow characteristics caused the oxide to be blown free of the surface. Craters grew at damaged coating areas during this cycle to sizes of approximately 6.3 mm in diameter × 2.5 mm deep (0.25 × 0.10 in.), and some subsurface embrittlement was experienced. Niobium, used in the highest-temperature location on the space shuttle orbiter, showed that it is capable of surviving at least one reentry regime even if it has local coating damage.

Liquid-Metal Cracking

Liquid-metal cracking is cracking in a base metal that occurs in the presence of a liquid metal. Often, parts that crack are under stress. Intrusion of the liquid metal into grain boundaries often occurs, but in some cases, intrusion is difficult to detect. The term liquid-metal embrittlement is often used because liquid-metal cracking often causes embrittlement.

Liquid-metal cracking does not always lead to catastrophic failure of parts, as shown in the brazing example below, but it often totally destroys the structural integrity of the part. The major structural materials on a manned space vehicle are primarily made of alloys of aluminum, steel, stainless steel, titanium, and nickel. These are embrittled by liquid metals shown below:

Alloy	Liquid metals causing embrittlement
Aluminum	Mercury, indium, tin, zinc
Steel	Tin, cadmium, zinc, lead, copper, lithium
Stainless steel	Cadmium, aluminum, lead, copper
Titanium	Cadmium, mercury
Nickel	Zinc, cadmium, mercury

Most of these metals have a very low melting point. The lowest, mercury, is often used in switches, instruments (thermometers, manometers), and vapor arc lamps. Mercury is prohibited from use on the space shuttle orbiter to avoid contamination from spillage. Cadmium, due to its sublimation in space, is again highly restricted and is never permitted to exceed 120 °C (250 °F). This is well below the liquid-metal embrittlement temperatures of the plated steel. Zinc, except as an alloy constituent, is generally not used on manned spacecraft.

Many of the embrittling elements find their way into spacecraft usage in three families. First, these elements are used in low-temperature soldersfor electrical and avionics applications. These include lead-tin for electrically soldered connections and some indium-base solders for glass-to-metal seals. Second, these embrittling elements are used as silver solders for higher-strength applications. Most of these solders melt in the range of 605 to 800 °C (1125 to 1475 °F) and may contain copper, cadmium, zinc, lithium, and tin. These have caused liquid-metal cracking, especially with incompatible metals under stress. Particular attention is given to these applications. They can be quite troublesome where torch brazing techniques are used, because temperature control depends upon the skill of the operator. Third, many brazing alloys used on the space-craft for stainless steel plumbing systems contain copper. Many years of brazing experience with automated equipment has proved this to be acceptable (see the following discussion).

Brazed Plumbing Joints. Radiographic inspection of three brazed manifold tube joints for the shuttle orbiter revealed that the 21-6-9 stainless steel tubing had cracked. The tubing was 13 mm ($\frac{1}{2}$ in.) in diameter and was brazed by automatic equipment with Nicoro 80 braze alloy (81.5Au-16.5Cu-2Ni). Metallurgical examination showed that all brazed joint cracks were completely filled with the braze alloy. A review of all shuttle orbiter brazing up to this time indicated that eight of the 1165 joints (~0.5%) had similar braze-filled cracks. The cracks were both longitudinal and circumferential; they occurred in type 304L stainless steel, Inconel alloy 718, and 21-6-9 stainless steel in line sizes of 9.5, 13, and 19 mm ($\frac{3}{8}$, $\frac{1}{2}$, and $\frac{3}{4}$ in.) (Fig. 46). All cracks were completely under the braze union.

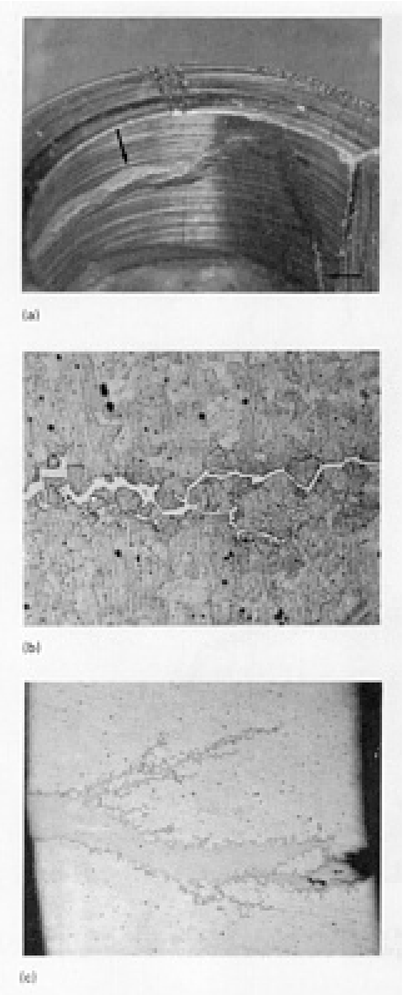

Fig. 46 Liquid-metal cracking of brazed plumbing lines and unions in the shuttle orbiter due to overheating. Brazing alloy is Nicoro 80 (81.5Au-16.5Cu-2Ni). (a) Braze-filled crack (arrows) on Inconel alloy 718 tube end. 5×. (b) and (c) Intrusion of brazing alloy into 21-6-9 stainless steel. (b) 130×. (c) 45×

During the Apollo program, 30 tube ends of 5500 braze joints in type 304L stainless steel showed the same indication. Extensive pressure testing of braze-filled cracked tube ends indicated that these tubes would burst in the tubular wall section rather than in the braze-filled crack under the union. These joints were also found to be satisfactory in thermal shock and vibration tests. Based upon this experience, tubes with braze-filled cracked ends, which remain totally under the braze union, are acceptable.

The cause of the problem is thought to be liquid-metal attack. The tube end may contain residual tensile stresses during its induction brazing or may contain small cracks that grow in contact with the braze metal. The fresh surface of the crack is readily wet by the braze alloy. Although the initial induction brazing heats the joint to approximately 980 °C (1800 °F), reheating a braze joint with the same induction brazing parameters increases the temperature because the braze alloy now conducts heat from the sleeve to the tube end more readily than in the initial braze, in which heat is transferred across the capillary gap to the tube by radiation. It is believed that temperatures in tube ends may exceed 1095 °C (2000 °F) during reheat cycles used to reflow braze or debraze.

Copper is known to be capable of causing liquid-metal embrittlement of stainless steels above 1095 °C (2000 °F). It is suspected that the high copper content of the braze alloy initiates the cracking when it occurs.

The OMS rocket engine combustion chamber is a regeneratively cooled, axial flow type chamber in which the fuel passes through passages in the chamber wall. The fuel acts as a coolant and at the same time is preheated before entering the firing chamber. The chamber is made from type 304L stainless steel. Its exterior is straddle milled to make longitudinal grooves, which are then closed into channels by electroless nickel plating.

The testing program for the space shuttle orbiter OMS engine combustion chamber requires the evaluation of engine combustion instability. This is simulated by igniting a small bomb in the combustion chamber during a firing sequence. (The niobium nozzle extension, normally bolted to the engine in service, is not attached during this test.) Immediately after one such instability test, a portion of the chamber was found to be cracked (Fig. 47).

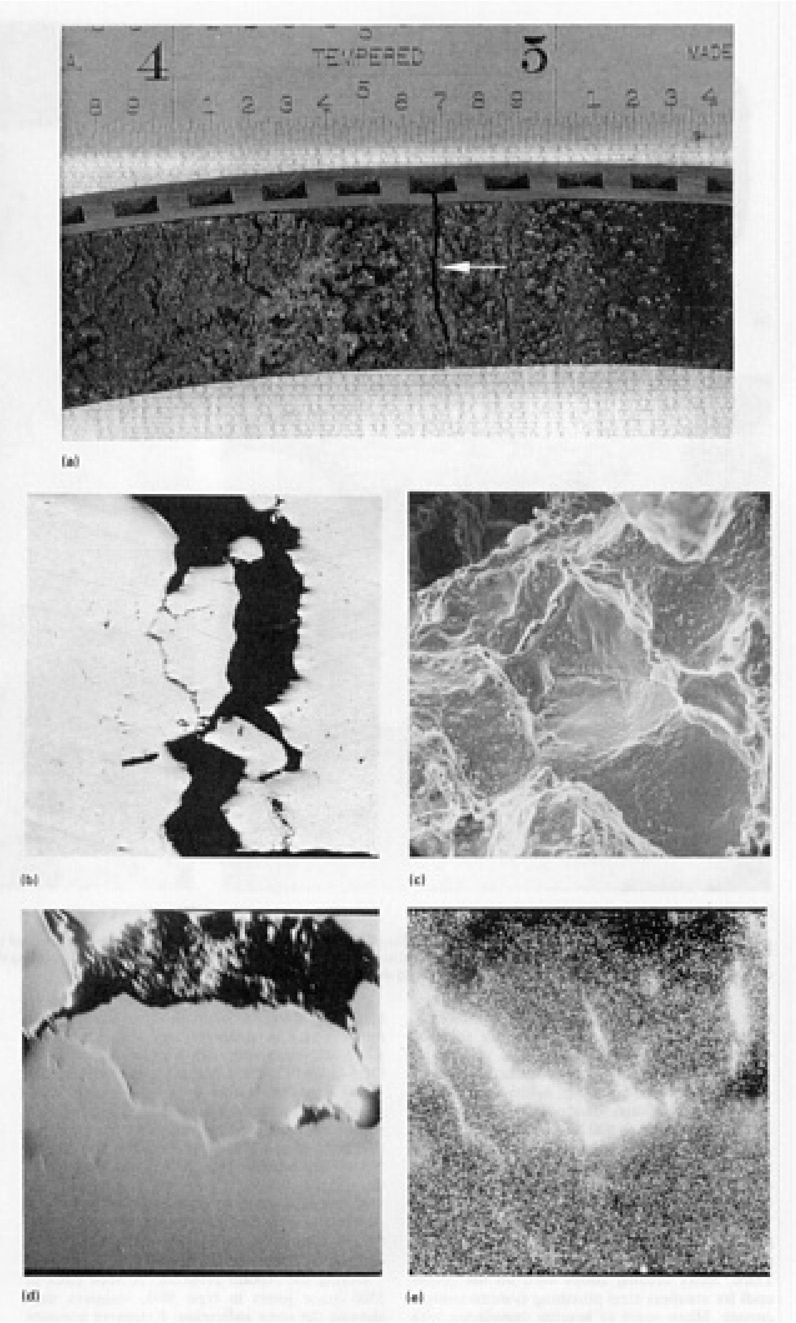

Fig. 47 Liquid-metal cracking of an orbiter OMS rocket chamber during testing. The chamber is regeneratively cooled and made from type 304L stainless steel. Copper wiring broke loose and melted inside the chamber during instability testing, resulting in liquid copper embrittlement. (a) Section of chamber showing a crack (arrow) in the fuel channel. (b) Crack cross section. 70×. (c) Fracture face of crack showing intergranular appearance. 355×. (d) Enlargement of copper-filled crack in (b). 125×. (e) Electron beam dot map of copper concentration in crack in (d). 125×

The cracked chamber and some bomb residue, scabbed onto the inner surface, were examined. The scab material contained copper, copper oxide, and calcium carbonate. The copper apparently came from copper wiring associated with the bomb. The source of the calcium could not be determined. Copper was found in crack areas and on crack faces and had penetrated the metal along grain boundaries.

Reaction Control System Chamber. The reaction control system is used to control the roll, pitch, and yaw movements of the space shuttle orbiter and employs an engine using a silicide-coated niobium alloy C 103 chamber. The hypergolic propellants N_2O_4 and hydrazine react within the chamber to provide engine thrust. Normally, chambers are internally film cooled by the flow of the hydrazine fuel along chamber walls and operate well below 1315 °C (2400 °F). Under conditions of engine combustion instability, loss of the protective film may result in wall temperatures exceeding 1535 °C (2800 °F), and chamber burnthrough may take place. To prevent any detrimental action to the surrounding spacecraft structure in the event of an instability and burnthrough, a wire sensing system on the chamber exterior will trigger shutoff of fuel and oxidizer valves.

During a test of the wire sensing system, a reaction control chamber was purposely modified to induce instability, and significant cracking of the chamber resulted. Cracking was associated with the melting of chromel-alumel thermocouple wires at temperatures slightly above 1425 °C (2600 °F). A test was set up in the laboratory on stressed coupons to simulate the suspected liquid-metal embrittlement failure.

The test specimen measured 25 × 75 × 1.4 mm (1 × 3 × 0.056 in.), was coated with a silicide coating (75Si-2Cr-5Ti), and was subjected to elastic bending stresses. Fine thermocouple wires were then placed on the niobium surface. Figure 48(a) shows the extent of surface attack that occurred instantaneously as wires were melted. Figures 48(b) and 48(c) show cross sections of liquid-metal embrittlement caused by melting the alumel (95Ni, Al, Si, Mn) and the chromel (90Ni-10Cr) thermocouples, respectively. This example illustrates that even protective ceramic coatings can be breached during liquid-metal attack.

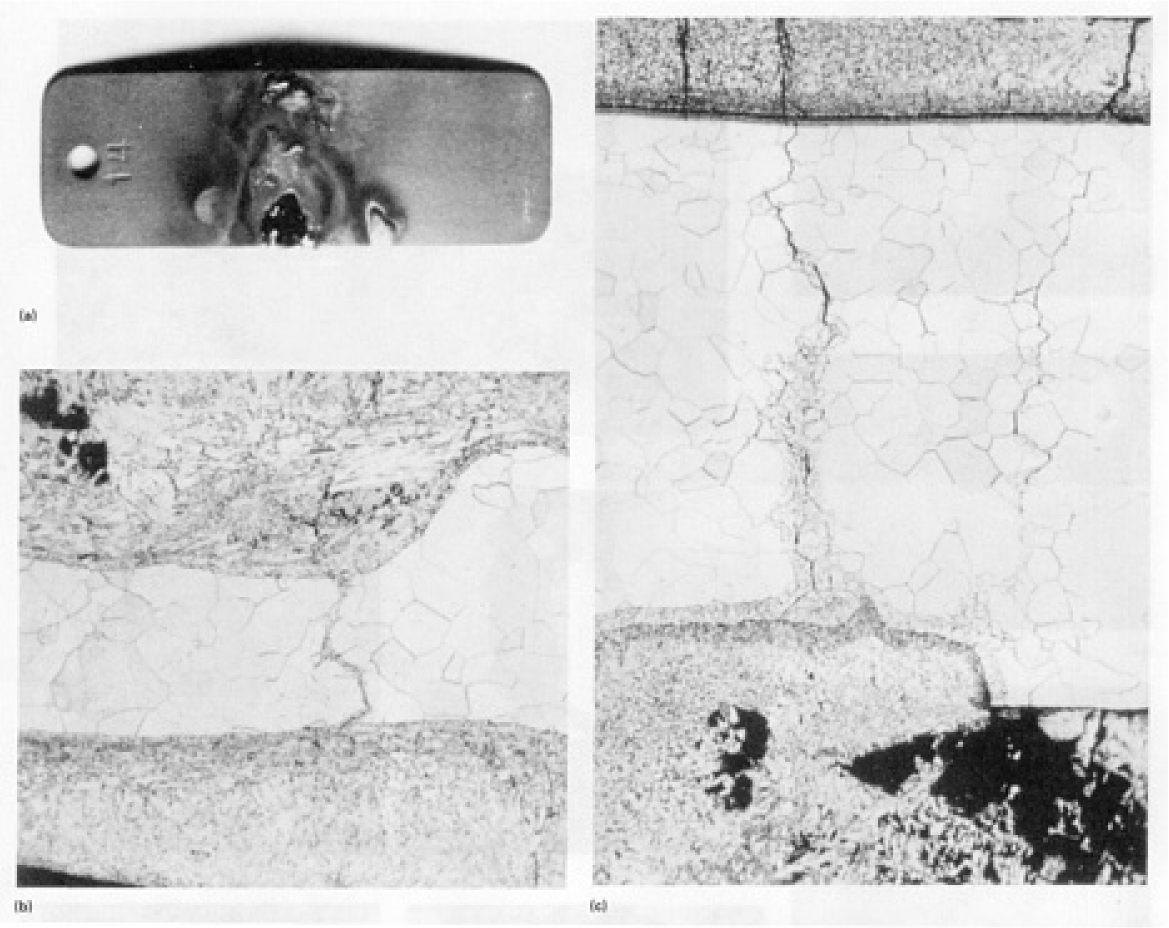

Fig. 48 Liquid-metal embrittlement of a niobium alloy C 103 test coupon intended to simulate embrittlement of a C 103 shuttle RCS nozzle. The coupon, with a silicide coating, was stressed, and fine chromel and alumel wires were melted on its surface. The resulting coating damage is shown in (a). (b) Cross section showing damage caused by liquid alumel. 100×. (c) Cross section showing damage from liquid chromel. 100×

Precipitation of Corrosion Products

To function properly, a valve for a manned spacecraft must be free of corrosion products. Some spacecraft valves, in a full-open position, only move 0.25 mm (10 mils) off the valve seat. Some have sealing lands only 125 μm (5 mils) wide. One of the cases of valve failures is the clogging that occurs from flow-decay products, that is, precipitation of dissolved metals as complex salts.

Reaction Control System Quick Disconnect. After servicing of the forward reaction control system on the space shuttle orbiter in preparation for the second launch, a quick disconnect failed, spilling nitrogen tetroxide on the spacecraft *Columbia.* The N_2O_4 attacked the epoxy amine primer and resulted in the loosening or loss of about 100 tiles. It also entered the spacecraft, exposing structure to corrosion and electrical wiring to possible damage. Examination of the quick disconnect revealed deposition of complex iron nitrate compounds on its moving surfaces, causing jamming of the disconnect in an open position.

Nitrogen tetroxide is commonly handled and stored in steel containers. In the process, iron dissolves into the N_2O_4, and because it is present at concentrations of only a few parts per million, the integrity of the storage lines and containers are not jeopardized. Under certain conditions of temperature and pressure, however, the iron will precipitate out as complex salts or form gels that cause valves to malfunction. Figures 49(a) and 49(b) show the solubility of iron in N_2O_4 as a function of water content, temperature, and NO content. At 20 °C (70 °F), the solubility of iron is 5.5 ppm when the NO content is 2.5% and water is 0.12%. If the temperature were to cool to 10 °C (50 °F) after the spacecraft was loaded with this iron-saturated N_2O_4, only 2.6 ppm would remain soluble. The rest could precipitate out. A quick glance at the curves will show that under these conditions, a pickup of moisture by N_2O_4 (or loss) drastically decreases solubility, as does lowering the temperature and losing NO, a somewhat more volatile constituent.

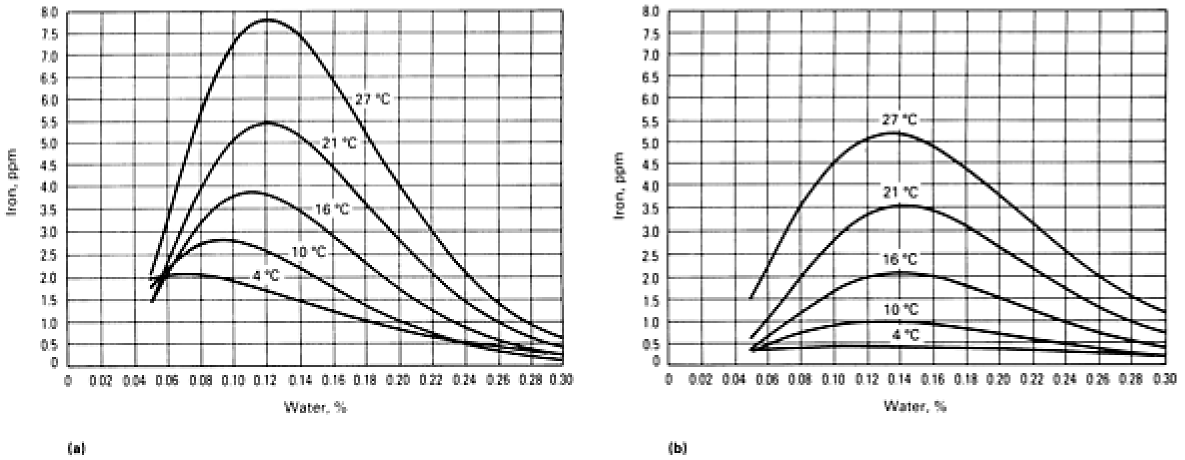

Fig. 49 Solubility of iron in N_2O_4 as a function of water, temperature, and NO content. (a) Solubility curves at 2.5% NO. (b) Solubility curves at 1.25% NO

The failure of the quick disconnect delayed the launch of the second flight by more than a month for repair of the thermal protection system and evaluation and/or repair of other spacecraft problems created by the spillage. These problems were minimized in future launches by the use of chillers and filters to process N_2O_4 prior to its loading. Furthermore, samples are being taken at the spacecraft interface to verify that iron levels are below 2 ppm.

The AC motor relief valves are used to control the flow of propellants (fuel and oxidizer) to the RCS engines. Flow decay products from nitrogen tetroxide caused an AC motor relief valve to fail to open at the specified pressure in an orbiter reaction control system test program. The flow decay products are shown on the poppet in Fig. 50.

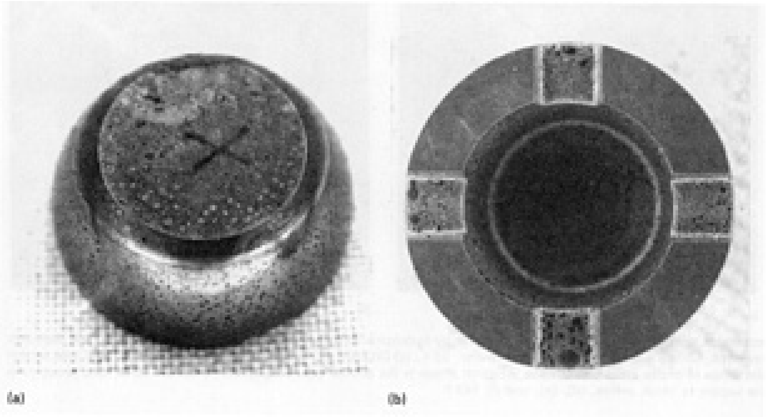

Fig. 50 Failure of an orbiter RCS AC motor relief valve from flow-decay products in N_2O_4 testing. (a) Front side of poppet. The round spots are deposits which caused the valve to malfunction. (b) Back side of poppet showing similar surface deposits.

Reaction Control System Helium Regulator Sensor Tubes. In the reaction control system of the space shuttle orbiter, helium is used to expel propellants to the RCS rocket engines and vernier rocket engines. The helium regulator valve, which controls this function, uses a sensor that has a fine orifice (0.18 mm, or 7 mils, in diameter) through which helium passes. The pressure drop in this flow channel is a measure of the helium demand of the system. Because the hole is only about twice the diameter of a human hair, it is essential that no contamination, flow decay, or corrosion products restrict its flow.

One would expect a helium system to be totally free of corrosion or precipitation products. However, it must be recognized that molecular diffusion permits fuels and propellants to backstream into helium components. Figure 51 shows a result of contamination in the sensor passage as a combination of entrapped cleaning solution and reaction of this product with hydrazine. The tube passage, on one of the shuttle flights, resulted in the sluggish response of the valve to the system demand. Laboratory testing indicates that repeated wetting and drying with hydrazine vapors alone can cause plugging of this passage with decomposition products. Experience has shown that the roughness of the walls of the hole probably contributed to iron dissolution and subsequent precipitation of complex iron hydrazine salts. Fortunately, the valve can be checked out adequately prior to flight. Studies were underway in 1986 to determine what design or processing changes could be made to minimize this problem.

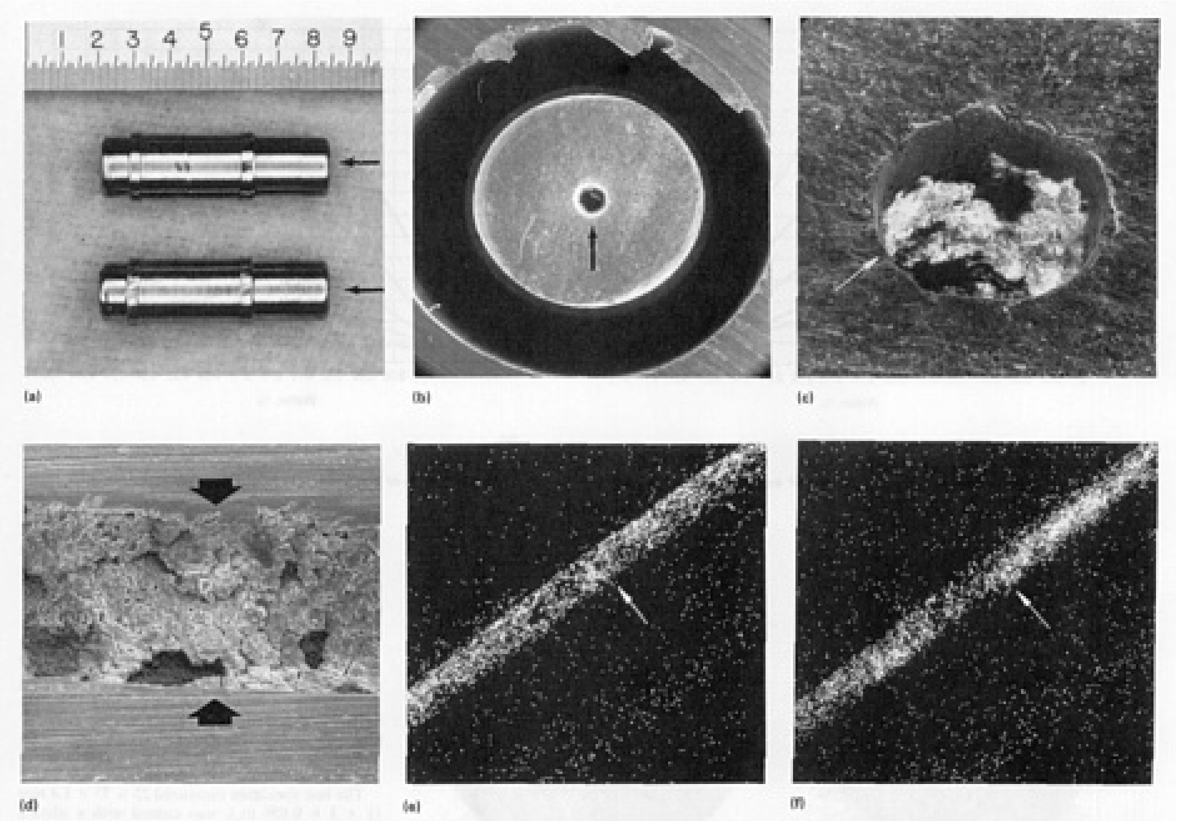

Fig. 51 Failure of an orbiter RCS helium regulator valve due to contamination of the sensor orifice by hydrazine salts. (a) Sensor orifice assembly made from austenitic stainless steel. (b) Orifice shown with screen removed. Orifice is 0.18 mm (7 mils) in diameter. 35 ×. (c) Deposits of hydrazine salts (arrow). 300×. (d) Cross section through orifice showing salt deposits. (e) and (f) Electron dot maps of orifice cross section. The diagonal streak is the orifice. (e) Phosphorus. (f) Sulfur. Sulfur and phosphorus came from soap contaminants. These reacted with hydrazine vapors to block orifice. (d), (e), and (f) 145×

The APU injector tube of the space shuttle orbiter is made of Hastelloy alloy B. It is the conduit for liquid hydrazine to the catalyst bed in which the hydrazine decomposes to nitrogen, hydrogen, and some NH_3 gases. As the hydrazine approaches the catalyst bed, it is heated by the catalyst bed heater to about 650 °C (1200 °F). Metals dissolved in hydrazine, especially iron and molybdenum complex salts, precipitate on these walls when hydrazine vaporizes, as shown in Fig. 52. This precipitation is insufficient to restrict flow in this application. If precipitation of this nature were to occur on moving valve parts, it could result in valve leakage, sluggish response, or jamming.

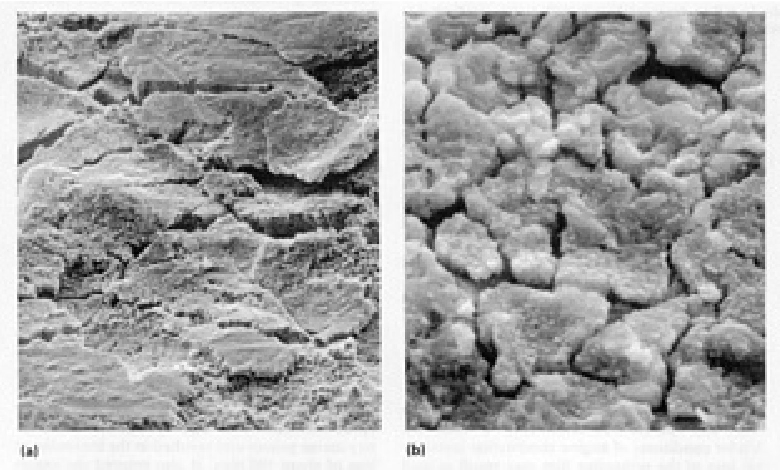

Fig. 52 Encrustation of hydrazine salts in Hastelloy alloy B orbiter APU gas generator injector tubes. (a) and (b) Deposits occurring in sections of tubes above the 375 °C (700 °F) temperature range. Both 415×

Atomic Oxygen in Low Earth Orbit

Atmospheres in low earth orbit principally consist of atoms and/or molecules of oxygen, nitrogen, argon, helium, and hydrogen (Fig. 53a). Although the densities of these constituents are low at typical spacecraft altitudes of 300 to 500 km (185 to 310 miles), the orbital velocity of the spacecraft results in flux densities of 10^{13} to 10^{15} atoms/cm^2 · s. The interactions with the spacecraft produce drag effects that can limit orbital life in lower earth orbits as well as cause changes in the optical (thermal control) and physical properties of coatings and polymers by reflection, adsorption, or chemical reactions.

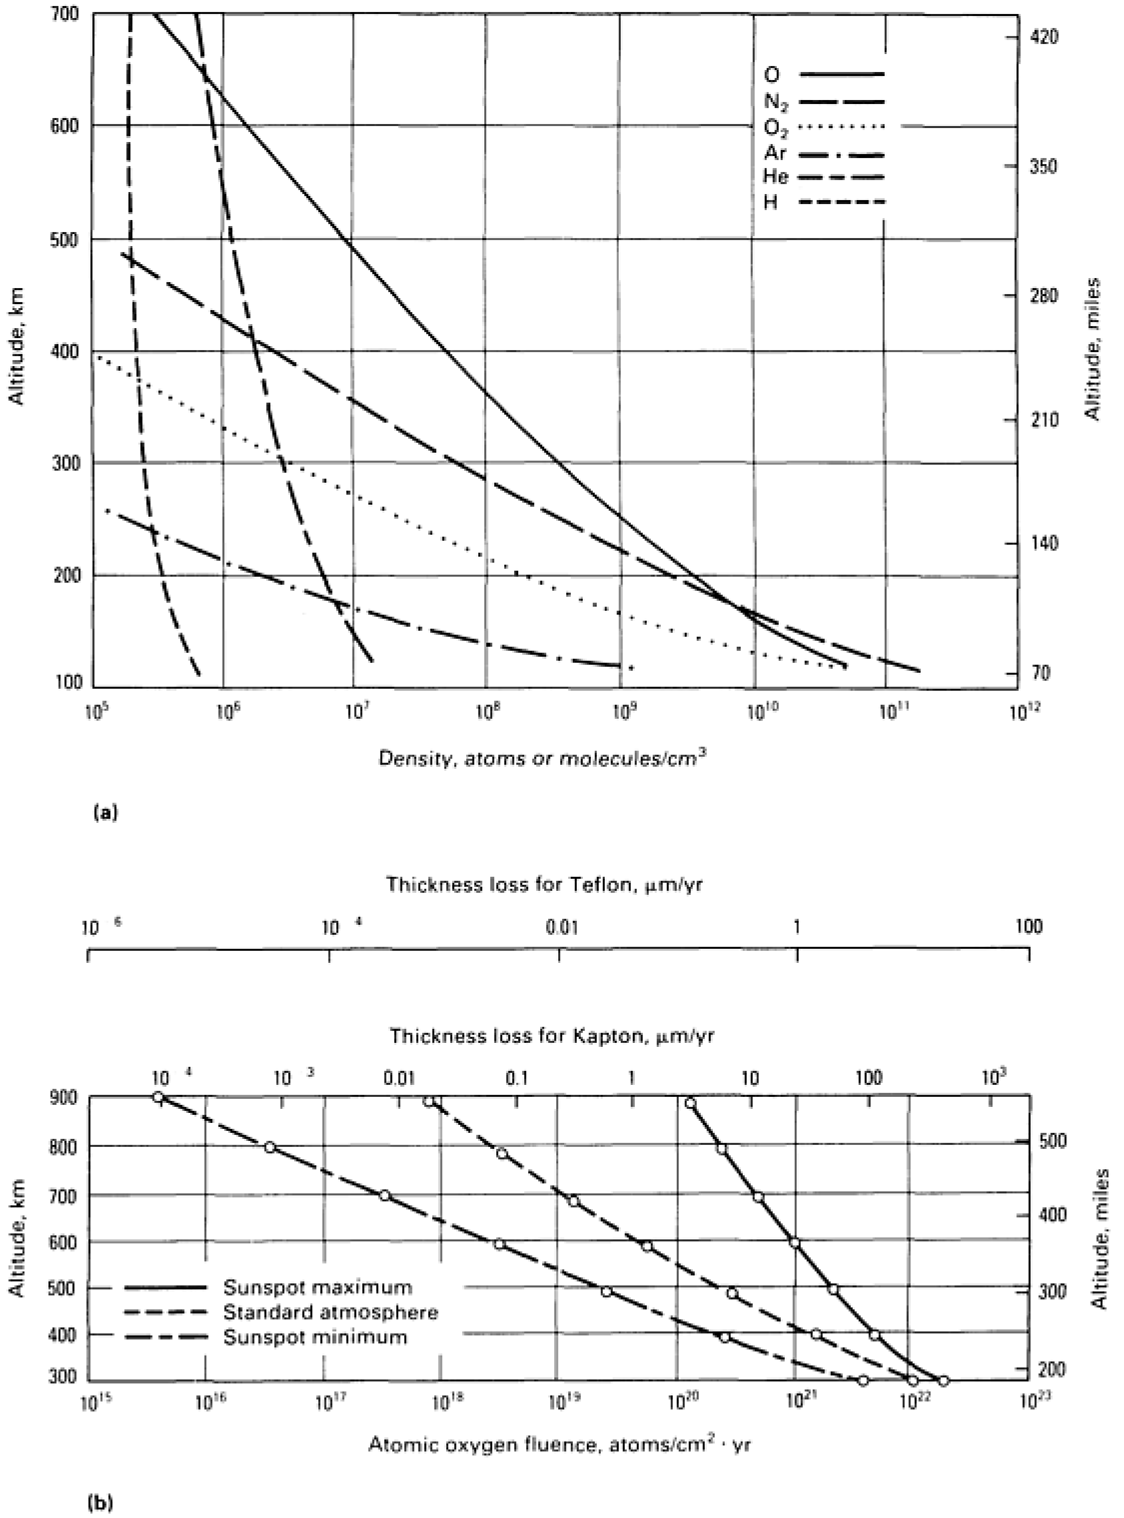

Fig. 53 Atmospheric composition (a) as a function of altitude. Source: Ref 24. (b) Effect of solar (sunspot) activity and atomic oxygen flux on thickness loss of Kapton- and Teflon-covered solar inertial facing surfaces (two sides exposed). Source: Ref 25

In the altitude range of approximately 200 to 650 km (125 to 400 miles), the atmosphere consists primarily of atomic oxygen. The interaction of materials with atomic oxygen, which has impacting energy levels of 5 eV, can produce significant surface changes in some materials. The effect of atomic oxygen depends on the fluence (or total flux of atoms per unit area), the impact angle, and the material impacted. The greatest damage occurs to surfaces moving in the

direction of flight. The flux level of atomic oxygen depends on solar activity and is related to the 11-year solar (sun spot) cycles, as shown in Fig. 53(b).

Atomic oxygen degrades organic materials by breaking atomic bonds, by oxidation, and by causing loss of volatile species. This degradation takes the form of surface erosion. In the case of organic polymers, losses of 0.2 to 0.35 mm (8 to 14 mils) could be expected on a space station every solar cycle (11 years), depending on the orientation. Silicone polymers and perfluorinated polymers are approximately 50 times more resistant to surface loss than organic polymers. Only two metals show significant reaction--silver and osmium. Silver oxidizes readily, and expected surface losses, based on Shuttle SPS-8 tests (Ref 26), could exceed 0.2 mm/yr (8 mils/yr). Osmium reacts to form OsO_4, a volatile gas; this reaction also results in significant losses. All other metals are nonreactive except for copper, which forms a superficial protective oxide film and undergoes essentially no changes in properties or dimensions.

To prevent detrimental damage due to atomic oxygen, proper materials selection and the use of coatings are often acceptable approaches. Some metals appear resistant in thicknesses as thin as 15 nm.

Atomic Oxygen Degradation of Polymeric Insulation Films. The first shuttle flight resulted in surface roughening of the Kapton (polyimide) thermal control blankets used in the cargo bay areas. The surfaces of the film, which were normally glossy and amber in color, changed to a flat, translucent yellow appearance that resulted from microscopic roughening of these surfaces. Areas shielded by other parts showed no changes. From an analysis of the data and environments, it was concluded that atomic oxygen was the responsible active species causing this surface reaction/erosion. Subsequently, panels of test materials were exposed on racks in the shuttle cargo bay on the fifth and eighth flights to study the extent of degradation and to determine material reaction efficiencies.

Samples of polyurethane paint before and after 40 h of exposure in the velocity direction on the eighth orbiter flight are shown in Fig. 54(a) and 54(b). Samples of Kapton H polyimide film before and after 4 years of exposure on a satellite in low earth orbit are shown in Fig. 54(c) and 54(d). Figure 54(e) shows the surface of a 0.05-mm (2-mil) thick sheet of FEP teflon coated with 100 nm of Inconel over 150 nm of silver and exposed to atomic oxygen and ultraviolet radiation in low earth orbit for 4 years. The metal coating appears to be completely stripped from the surface.

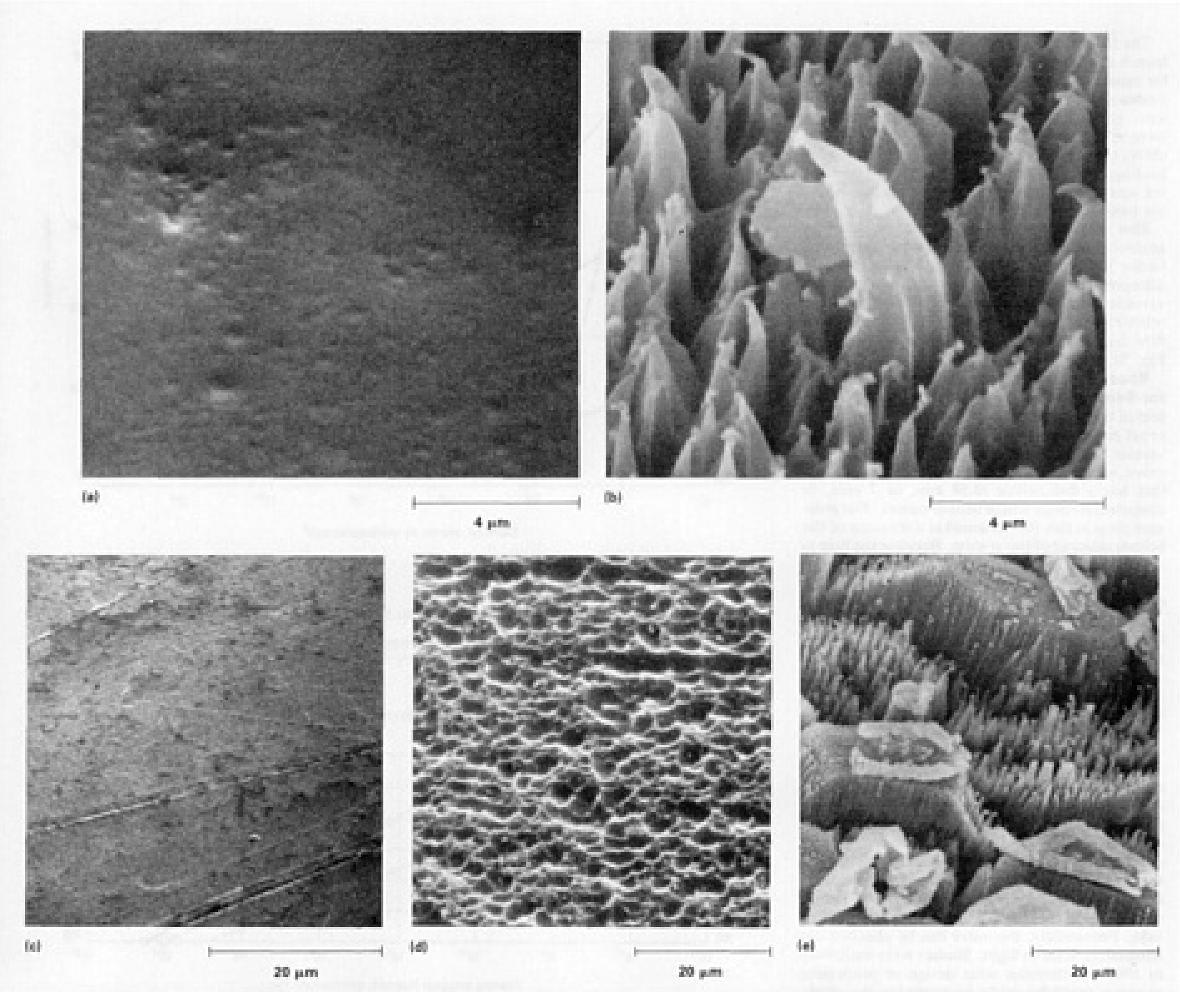

Fig. 54 Atomic oxygen degradation of materials in low earth orbit. (a) and (b) Polyurethane paint before (a) and after (b) 40 h of low earth orbit exposure in the velocity direction on the eighth shuttle flight. Both 14,000×. (c) and (d) Sample of Kapton H (polyimide) film before (c) and after (d) approximately 4 years of exposure on a satellite in low earth orbit. (e) Surface of a metallized Teflon film after about 4 years of exposure on a satellite in low earth orbit. The surface had been coated with 100 nm of vapor-deposited Inconel alloy over 150 nm of vapor-deposited silver. Both metals appear to have been completely eroded away. Corrosion of Space Boosters and Space Satellites

Douglas B. Franklin, George C. Marshall Space Flight Center, National Aeronautics and Space Administration

The selection of corrosion prevention systems for space boosters and satellites requires the consideration of many different criteria related to the expected operating environments and various functional requirements. Both boosters and satellites may be exposed to a seacoast environment for prolonged periods as well as to various propellants and operating fluids. Satellites are also exposed to the high vacuum and solar radiation of space, and their external coating must provide controlled values for solar absorption and emittance to ensure proper temperature control. Boosters, on the other hand, often have severe cryogenic and elevated temperature exposures.

The need for lightweight structures, coupled with the low factors of safety used in component design, result in the use of materials selected more for strength than corrosion resistance. This creates a high potential for stress-corrosion failure and makes the effects of surface corrosion very significant. When the high reliability requirements for spacecraft are added to these considerations, it places a very demanding performance requirement on the corrosion protection system used. No reuse was planned in earlier space booster programs, but for the space shuttle, economy demands the reuse of most of the major components. Perhaps the most demanding environmental exposure is the solid rocket booster, which must survive periodic immersion in seawater for several days as well as damage to protective coatings resulting from towing and recovery operations (Fig. 55). The boosters must be capable of up to 20 reuses.

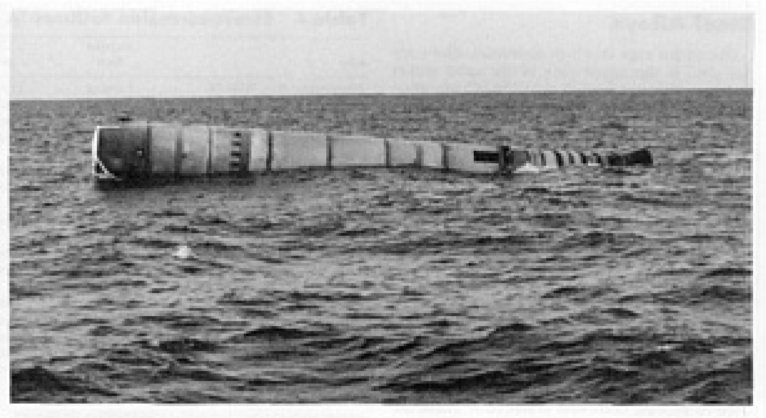

Fig. 55 Ocean recovery of a shuttle solid rocket booster

Aluminum Alloys

The primary structural materials used for many of the propulsion components in the space shuttle transportation system (Fig. 56) are high-strength aluminum alloys. This includes aluminum alloy 2219 for welded structures (such as the propellant tankage) and aluminum alloys 7075 and 2024 for structures where mechanical joining methods can be used. The protective system used on aluminum surfaces where exterior exposure is the primary concern consists of a chemical conversion coating (MIL-C-5541) to promote paint adhesion, followed by a chromate-inhibited epoxy primer 0.025 mm (1 mil) thick (Ref 27) and an epoxy topcoat 0.025 to 0.045 mm (1.0 to 1.8 mils) thick (Ref 28).

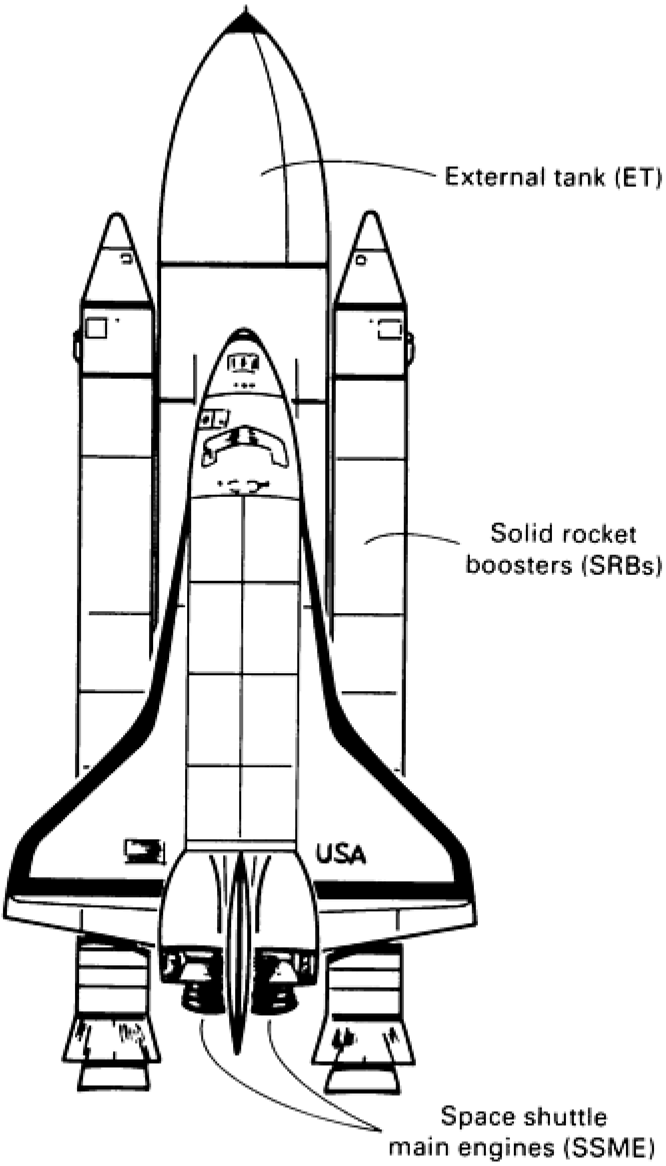

Fig. 56 Major propulsion components of the space shuttle transportation system

This system is used on the upper and lower skirt structures of the solid rocket boosters that are recovered from the ocean and reused. With some modification, it also is used on the external tank (Fig. 56) and provides a good base for bonding thermal insulation to provide protection from aerodynamic heating and heat from rocket exhaust plumes. To obtain good paint adhesion, it has been found to be extremely important to maintain surface cleanliness between each processing step, particularly after application of the chemical conversion coating. In addition, strict compliance with the recommendations of the paint manufacturer for drying times and application procedures is required. To ensure adequate quality control, the coatings are applied and tested to the requirements of MIL-F-18264.

Where immersion in seawater and component reuse without refurbishment are required, all faying surfaces must be completely sealed (wet lay-up) with a polysulfide sealant meeting the requirements of MIL-S-8802. It is very important that there are no open gaps or voids not completely filled by the sealant, because seawater can be forced into these areas during recovery and will cause a serious corrosion problem. Fasteners should also be installed with wet sealant, and fastener heads must be completely oversealed. These procedures cannot be followed where electrical bonding is required. For these areas, jumper cables are used with the contact surfaces bare. The connection is then completely oversealed with polysulfide sealant.

Another area requiring special consideration for protection is under the polyurethane foam insulation used on the external tank exterior to prevent excessive cryogenic propellant boil-off (liquid hydrogen and oxygen) during launch preparation and flight. Because of the need for good cryogenic adhesive properties, the paint system previously described cannot be used. It was also found that the bonding primer originally selected to promote adhesion between the tank surface and the spray foam would not adequately protect the aluminum alloy 2219 surface during extended storage, shipping, and launch preparations, particularly where multiple exposures to cryogenic temperatures are involved. After laboratory tests, the material finally selected for this purpose consists of an epoxy bonding primer with an increased amount of strontium chromate pigment (Ref 29). This primer provides improved corrosion protection under the foam insulation without any significant degradation of cryogenic adhesive properties.

Steel Alloys

One major area in which aluminum alloys are not used is the motor case of the solid rocket booster. This application uses D6AC low-alloy steel heat treated to an ultimate tensile strength of 1340 to 1550 MPa (195 to 225 ksi). The paint system selected for corrosion protection is a sacrificial zinc-rich epoxy-polyamide primer 0.038 to 0.063 mm (1.5 to 2.5 mils) thick (Ref 30) and an epoxy-polyamide topcoat 0.038 to 0.063 mm (1.5 to 2.5 mils) thick (Ref 31). The steel surfaces are gritblasted to white metal (Steel Structures Painting Council Specification SSPC-SP6) prior to painting. Although this system provides good protection to steel surfaces for prolonged periods of time, the paint is removed (by gritblasting) and reapplied after each flight because of magnetic-particle inspection requirements imposed on the motor case surfaces.

There are a few areas in which paint cannot be used to provide corrosion protection. These are the areas where the solid rocket booster motor case segments are joined and where the skirt segments join the motor case segments. The material used to provide protection here is a heavy-duty calcium-base grease with special corrosion inhibitors for use in seawater (Ref 32). The grease is carefully applied to all bare areas during assembly and is removed and reapplied after each flight. The grease protects the surfaces during storage and preflight operations and provides excellent protection for several days of ocean exposure during recovery of the segments and until joint refurbishing operations can be initiated, which can be several weeks later. The grease can also be applied diluted with trichloroethane or other solvents to provide protection to bare motor case segments during initial shipment by rail from the manufacturer as well as after the paint is stripped from used motor cases during refurbishment.

Graphite/Epoxy Motor Case

A graphite/epoxy motor case that provides significant weight savings for the SRBs is under development. Because of structural considerations and design requirements, D6AC steel adapter rings are used to join the motor case segments. To prevent galvanic corrosion on the D6AC rings, the exterior surfaces of the graphite/epoxy are coated with the epoxy-polyamide topcoat discussed previously, and the machined joint area is sealed with a nonconductive sealant. This minimizes the cathode surface area and reduces the galvanic current. The D6AC rings are protected as described in the previous paragraphs.

Electrical Cables

One area of the solid rocket booster that has been very difficult to protect is the electrical cables and connectors. Because seawater contacting the ends of the stranded electrical wiring will quickly permeate through the wire and prohibit any reuse capability, electrical cables are enclosed in a watertight jacket of a polyether-based urethane plastic. This requires bonding of the jacket to the connector at each end of the cable, as shown in Fig. 57. In addition, the stainless steel connectors have a watertight O-ring seal to prevent the intrusion of seawater. To provide additional protection against inadvertent leakage, the connector pins are coated with a film of heavy-duty calcium grease (Ref 32) prior to assembly. The female connector sockets are designed so that the grease film is wiped off during insertion of the male pins and necessary electrical continuity through the connector is maintained.

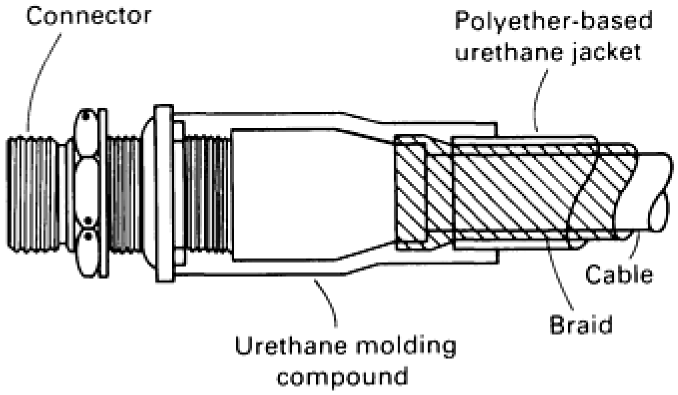

Fig. 57 Schematic showing electrical cable with watertight jacket

Cathodic Protection

Carbon fiber reinforced phenolic ablators are used to line the solid rocket motor nozzles. These materials appeared to aggravate corrosion in the solid rocket booster aft skirt during immersion in the ocean. Sacrificial zinc anodes (MIL-A-18001) were therefore added to provide additional protection. This includes zinc anodes for several individual aluminum components, the use of zinc for several nonstructural components, and the use of flame sprayed zinc on several aluminum components. In addition, zinc anodes are attached at various locations by divers prior to towing the solid rocket boosters back to land for refurbishment. These anodes have reduced significantly the galvanic attack of the aluminum surfaces in the aft skirt of the solid rocket booster.

Other Alloys

Other alloys used for space booster systems include type 304 stainless steel, type 321 stainless steel (for welded components), Inconel alloy 718, titanium alloys Ti-6Al-4V and Ti-3Al-2.5V, and MP35N nickel-cobalt alloy. Although these alloys are inherently corrosion resistant, special treatments are usually required to ensure that exposed surfaces are passivated to reduce possible pitting problems. Surfaces exposed to seawater during solid rocket booster recovery are flushed with potable water (200 ppm chloride max), washed with a nonionic detergent (0.5% solution at 57 °C, or 135 °F), flushed again with potable water, and rinsed with deionized water until residual surface chlorides are below 50 ppm. Components are refurbished as necessary after each flight to ensure that their integrity is not compromised.

Control of Stress Corrosion

One other area that is carefully considered in design is the control of stress corrosion, particularly because of the widespread use of high-strength alloys that generally have poor resistance to stress corrosion. Several stress-corrosion failures have occurred in earlier programs, many of which resulted in significant program impact.

Table 4 lists these failures. As shown in Table 4, most of the failures have occurred in high-strength aluminum alloys and in the precipitation-hardening stainless steels in the seacoast environment. There have also been instances in which unique environments were not adequately considered. For example, stress-corrosion failure of a beryllium copper spring occurred because it was not recognized that a small amount of hydrazine could leak past an O-ring, thus exposing the spring to ammonia, a decomposition product of hydrazine.

Table 4 Stress-corrosion failures in space boosters

Alloy	Material form	Failure occurrence	Component name	Program
Aluminum alloy 7079-T6	Forging	Prelaunch	LOX dome	Saturn IB
AM-355 stainless steel	Bar	Prelaunch	Flared tubing sleeve	Saturn I
17-7PH stainless steel	Sheet	Prelaunch	Wave spring	Saturn IB
Aluminum alloy 7079-T6	Forging	Manufacture	Prevalve control support link	Saturn V
Aluminum alloy 7075-T6	Plate	Test	Splice angle	Saturn V
Aluminum alloy 7075-T6	Bar	Assembly	Prevalve control piston cylinder	Saturn IB
Aluminum alloy 2024-T4	Bar	Test	Oxidizer check valve body	Saturn IB
17-7PH stainless steel	Sheet	Test	Actuator spring	Saturn V
17-7PH stainless steel	Sheet	Test	Prevalve Belleville spring	Saturn V
Aluminum alloy 7178-T6	Forging	Storage	Upper E-beam	Saturn IB
7079-T652	Forging	Storage	Rear spar	Saturn IB
7079-T6	Forging	Test	Hold-down fitting	Saturn IB
7079-T6	Forging	Test	Actuator body	Saturn V

Figure 58 shows an actual stress-corrosion failure that occurred in an aluminum alloy 7079-T6 forging used as a main housing in a hydraulic actuator. The failure occurred at the forging parting plane and was caused by excessive moisture in the hydraulic oil, residual stress from heat treating, and the interference fit of a small check valve that was press fit into the forging at the parting line. The failure was found during acceptance testing of the part prior to installation.

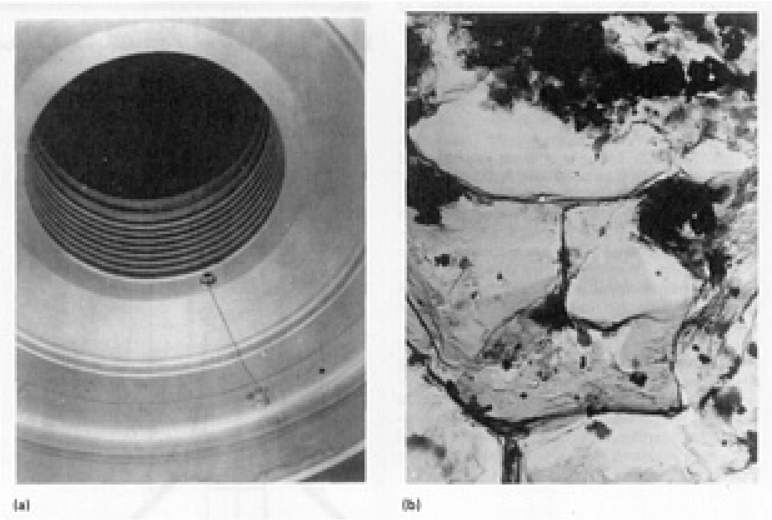

Fig. 58 Stress-corrosion failure of 7079-T6 aluminum forging. (a) Failed housing. (b) Fractograph of failure

An example of stress-corrosion failure in 17-7PH RH950 stainless steel Belleville washers is shown in Fig. 59. The washers were used as a Belleville spring (a stack of 54 washers) in a valve actuator. Failure resulted from exposure to a humid atmosphere (water was trapped in the actuator housing) and the installation stresses caused by the preload on the spring stack.

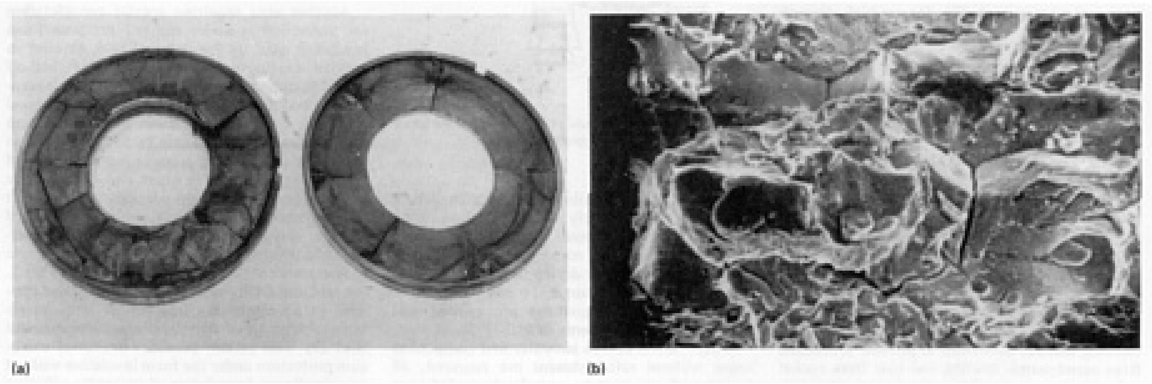

Fig. 59 Stress-corrosion failure of 17-7PH RH950 stainless steel valve actuator Belleville spring. (a) Failed spring washers. (b) SEM of fracture surface. 2000×

The best method for controlling stress corrosion is to select, where possible, materials that are highly resistant to stress corrosion. To this end, guidelines (MSFC-SPEC-522) have been prepared to aid the designer in the selection of materials for use in space booster and satellite systems. Tables 5, 6, and 7 list alloys grouped to show their comparative stress-corrosion resistance when exposed to a seacoast environment. The materials listed in Table 5 are considered resistant to stress corrosion in a seacoast atmosphere and can be used without restrictions.

Table 5 Alloys with high resistance to SCC

Alloy	Condition
Ferrous alloys	
Carbon steel (1000 series)	Below 1240 MPa (180 ksi) ultimate tensile strength
Low-alloy steel (4130, 4340, D6AC, etc.)	Below 1240 MPa (180 ksi) ultimate tensile strength

(a) For copper alloys, number under "Condition" indicates percentage of cold work.

The materials listed in Tables 6 and 7 should not be used unless specific evaluation and justification are made for each specific application. This requires a careful consideration of various factors in addition to the susceptibility of the material to stress corrosion. This includes exposure conditions, protective treatments used, and sustained tensile stresses that may be present. It is extremely important to consider all sources of stress; not only operational stresses but also residual stresses and stresses that may be induced into the part during assembly must be considered. Residual stresses can be the result of machining, forming, and heat-treating processes, while assembly stresses can result from improper fit-up tolerances, overtorquing, press fits, high-interference fasteners, and welding. A more detailed discussion of these factors can be found in MSFC-SPEC-552.

Special Environmental Effects

In addition to ordinary atmospheric environmental effects, corrosion control procedures for space boosters and satellites must take into account other special environmental factors. Many of these are related to propellant compatibility.

Oxygen. Most organic materials are not compatible with oxygen systems and can ignite under service conditions. Because of a lack of compatibility with liquid oxygen and stringent cleanliness requirements, organic coatings are not used on aluminum propellant tank (external tank) interiors. Corrosion on these surfaces (aluminum alloy 2219-T87) is prevented by use of a chemical conversion coating (MIL-C-5541). In addition, rigorous drying procedures are required after conversion coating and tank cleaning (usually done in one continuous process), and the humidity inside the tanks is controlled to below 60% relative humidity during storage and purged to -12 °C (10 °F) dew point before shipping to the launch site.

The primary metallic materials not considered acceptable in oxygen systems are tin, magnesium, and titanium alloys. Their use may result in catastrophic impact ignition. Tin is particularly reactive, and it has been found that copper alloys with a tin content as low as 2% can react when impacted in liquid oxygen. All materials used in oxygen systems are selected to meet the requirements of NASA Handbook NHB 8060.1 at the temperature and pressure that will be encountered during use.

Hydrogen. Propellant compatibility is also of concern in hydrogen systems, particularly at the high pressures--up to 48 MPa (7000 psi)--found in the space shuttle main engine (SSME). Table 8 shows the effect of exposure to high-pressure hydrogen on the notched strength ratio of several metal alloys. One technique that has been used to protect alloys susceptible to hydrogen embrittlement is to copper plate the exposed surfaces. A 0.13-mm (5-mil) thick coating of electroplated copper has been used for protecting Inconel alloy 718 in several SSME components. Gold plating that is

0.13 mm (5 mils) thick has also been used for this purpose on Waspaloy alloy turbine disks. For these coatings to be effective, very careful procedures are required to ensure that coating adhesion and integrity are of the highest quality.

Table 8 Relative resistance to hydrogen embrittlement of various alloys in high-pressure hydrogen at room temperature

(a) Ratio of notched strength in hydrogen to notched strength in helium

Hydrazine and Nitrogen Tetroxide. Several other propellants are encountered in space booster and satellite systems that present unique compatibility problems. The two most common are hydrazine and nitrogen tetroxide. The major concern with hydrazine systems is not corrosive attack but the decomposition of hydrazine, which can result in failure due to a large volumetric change. For nitrogen tetroxide systems, most metallic materials are resistant when the N_2O_4 is dry. However, because moisture can easily contaminate such systems (resulting in the formation of nitric acid), the primary materials of construction are those that also have high resistance to nitric acid, such as the aluminum alloys, stainless steels, and titanium alloys.

Corrosion Control for Satellites

The criteria for selection of coatings for satellite systems are usually related to their thermal control properties and resistance to the effects of the space environment. Properties can vary widely depending upon the specific requirements needed. Figure 60 illustrates the variation in types of coatings and surface treatments that may be used.

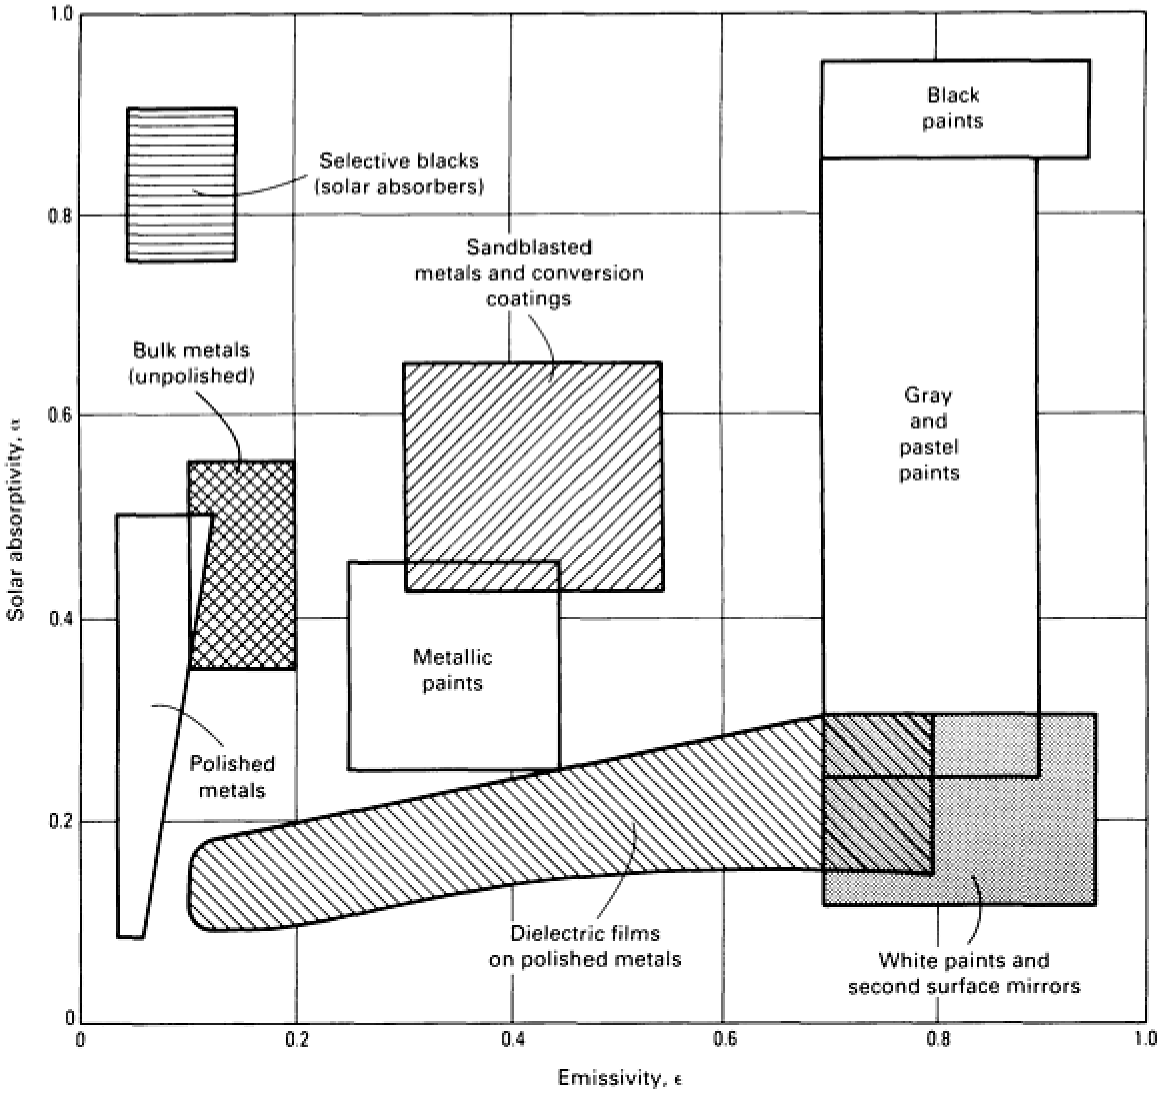

Fig. 60 Chart showing the range in optical properties for several types of coatings and surfaces

Corrosion protection properties are usually of secondary importance. Consequently, the environmental exposure conditions, particularly during manufacture and storage, must be carefully controlled to prevent corrosion and to prevent the deterioration of critical surfaces from contamination. This means stringent controls on packaging of individual components, humidity control during component assembly, and environmental control during storage of completed assemblies. Because most systems are assembled in a clean room to prevent surface contamination, keeping the relative

humidity below 70% should prevent most corrosion problems during the assembly process. For storage purposes, particularly long-term storage, environmental conditions should be regulated so that the maximum relative humidity is below 60% and preferably below 50%. Storage in uncontrolled environments is not permitted.

Corrosion in the Electronics Industry

Jack D. Guttenplan, Rockwell International Corporation

Introduction

THE EFFECTS OF CORROSION on material degradation and component performance in the electronics industry have long been recognized. Recent studies have shown that corrosion is becoming as even more significant factor in the reliability of electrical and electronic equipment. This has occurred because of the following trends:

- Designs requiring high component density and faster signal processing, resulting in smaller components with closer spacings and thinner metallic sections.
- New requirements for low-resistance, electrically stable grounding paths and electrical bonds to protect against stray electromagnetic radiation.
- The exposure of electronics to more severe environments

The effects of environment and corrosion on the reliability of electronic equipment became very evident during the Vietnam War. Military electronics were not designed to resist the effects of the hot, humid environment and the monsoon rains to which they were exposed, and high failure rates resulted. Other examples of severe environments to which military electronic equipment are exposed include avionic systems in ship-based naval aircraft (Ref 1) and guidance systems on nuclear submarines (Ref 2).

The problem of corrosion of electronic equipment, however, is not unique to the military. It exists throughout commercial and military applications worldwide and can occur in various severity levels of indoor and outdoor environments.

Frequently, minute amounts of contaminants or corrosion products can cause serious degradation or complete failure. Thin films of oxidation or corrosion products, invisible to the eye, can result in noise or resistance buildup in electrical

contacts and subsequent system failure. Extremely low levels of moisture and corrosive contaminants have been known to cause corrosion problems with printed circuit boards, encapsulated integrated circuits, nichrome-film resistors, electrical connectors, other discrete devices, and a wide range of plated components.

Studies have been initiated to determine both the nature of field environments and to develop laboratory test methods applicable to various classes of operating environments. These studies have shown that parts per billion levels of selected pollutants are sufficient under proper conditions of temperature and humidity to accelerate corrosion reactions in electronic equipment (Ref 3). Corrosion can occur during manufacturing, storage, shipping, and service. Moisture and such corrosive agents as chlorides, fluorides, hydrogen sulfide (H_2S), sulfur dioxide (SO_2), nitrogen compounds such as ammonia (NH_3), and other airborne contaminants are the major culprits (Ref 4). The sources of these corrosives have been the subject of intensive investigation. Some sources that have been identified include soldier flux residues, residual electroplating or other processing chemicals, sulfur from storage container materials, vaporized contaminants from adhesives, reactive substances in plastic materials and glass, environmental acid deposition, and a wide range of reactive airborne contaminants.

Most of the same principles and mechanisms apply in the corrosion of electronic equipment as in, for example, the corrosion of a large structure. However, the interaction among electrical, metallurgical, and environmental conditions, together with severe dimensional constraints, can lead to a unique set of corrosion problems for electronic systems. These problems will be discussed briefly in the following sections.

Corrosion Problems and Preventive Methods

Moisture Intrusion Into Black Boxes. Many manufacturers of electronic equipment have resorted to sealed black boxes to prevent corrosion. However, moisture intrusion remains a major factor in electronic equipment failures. The optimal way to exclude moisture is to make the box hermetic (airtight) by fusion. Even if the box is hermetic, materials inside the box must be baked out to eliminate outgassing of moisture, and the box should be evacuated and pressurized with a dry inert gas. This procedure will provide confidence of low relative humidity throughout the service life.

However, the equipment for internal maintenance/testing and the increasing number of through-wall electrical input/output connections make fusion impractical in many cases. Designers must select other approaches for sealing boxes. Elastomers (rubber compounds) in the form of gaskets and O-rings are commonly used to seal lids and other points of entry. However, water vapor will eventually permeate through any elastomeric sealant and thus increase internal humidity. Designers need to predict the long-term entry of water vapor through these seals. Desiccants can postpone an increase in relative humidity, but the rate of moisture influx must still be estimated.

A recent study provided data on the moisture vapor transmission rates for typical elastomeric sealants and illustrations on the use of these data in calculating the rates of moisture influx into sealed boxes (Ref 5, 6). It was concluded that a butyl rubber compound was the best sealant against water vapor permeation, with ethylene propylene rubber a less desirable alternative. In an example using butyl rubber gaskets to seal a box, the calculations showed that, starting at 0% relative humidity inside and 90% relative humidity on the exterior, the time to reach 50% relative humidity at 40 °C (100 °F) inside the box was 7 years. With a proper desiccant in the box, the time was extended to 20 years. Using the same example, it can be calculated that the time for a silicone rubber gasket (without desiccant) would be 3 weeks and that the time for an ethylene propylene rubber gasket would be 1.9 years (see Ref 5 for the particular rubber compounds used.)

An additional conclusion of this study was that in order to have high confidence that corrosion will not be a problem inside a sealed black box the relative humidity should be maintained at 40% or less at room temperature (Ref 6). Also, to prevent condensation, care must be taken to keep the internal temperature of the box from dropping below the dew point. This study did not address gross leakage of moisture due to improperly designed or sealed seals and defective materials or the incompatibility of sealant materials with environmental fluids.

One of the standard methods of cooling an electronic enclosure is the use of force ventilation, with air generally drawn from the atmosphere surrounding the equipment enclosure. In sites with aggressive atmospheres, this type of cooling will greatly accelerate corrosion because the circulating contaminated air comes in intimate contact with sensitive electronics. Unless the outside environment is benign, the introduction of outside air into an electronic equipment cabinet should be eliminated or limited to the lower rate possible (Ref 7).

For equipment that is neither sealed nor pressurized, corrosion protection should be designed for worst-case conditions on the assumption that moisture will get in. Corrosion can be minimized by:

- Providing low point drains so that water cannot collect
- Encapsulating components so that moisture cannot reach them
- Conformal coating printed circuit boards for protection against moisture and contaminants
- Mounting printed circuit boards vertically and well above the bottom of the housing to prevent moisture and debris from collecting on the boards
- Locating edge connectors on the vertical sides, not the bottom, of the printed circuit board so that moisture and debris will not collect in the mated connectors and degrade the contacts
- Locating feed-through connectors on the sides of the box, not on the bottom, for similar reasons
- Designing cabling to lead down and away from connectors and providing drip loops where possible
- Avoiding hygroscopic materials that will hold or wick up moisture
- Avoiding materials that emit corrosive vapors
- Using a volatile corrosion inhibitor that is carefully selected to protect those metals of concern in a particular application

Dissimilar-Metal Corrosion. Electronic design is unique in the wide variety of metals used because of particular physical and electrical properties. Some of the more common metals and their uses in an electronic system are given in Table 1. These metals are combined to form a myriad of dissimilar-metal couples in electronic equipment. In the presence of moisture (an electrolyte), destructive galvanic corrosion can take place (see the section "Galvanic Corrosion" of the article "General Corrosion" in this Volume).

Table 1 Metals and alloys commonly used in electronic systems

Metal	Uses
Gold	Electrical connector contacts, printed circuit board edge connectors, leaf-type relays, miniature coaxial connectors, semiconductor leads, and microminiature and hybrid circuits
Silver	Protective coating on relay contacts, wave guide interiors, wire, high-frequency cavities, EMI/EMP shields, and EMI gaskets
Magnesium alloys	Radar antenna dishes and lightweight structures, such as chassis, supports, and frames
Iron, steel, and ferrous alloys	Component leads, magnetic shields, magnetic coatings on memory disks, transformers, brackets, racks, hermetic electrical connector shells, and fastener hardware
Aluminum alloys	Equipment housings, chassis, mounting racks, supports, frames, electrical connector shells, and printed circuit board heat sinks
Copper and copper alloys	Wire, printed circuit board circuitry and heat sinks, component leads, terminals, bus bars, nuts and bolts, and radio frequently gaskets
Cadmium plating	Sacrificial protective coating on ferrous fastener hardware and on electrical connectors
Nickel plating	Barrier-type layer between copper and gold in electrical contacts, for corrosion protection on electrical connectors, printed circuit board heat sinks, electrical bonds in EMI applications, and for compatibility in dissimilar-metal junctions
Tin plating	For corrosion protection, solderability, and compatibility between dissimilar metals, on electrical connectors, radio frequency shields, filters, small enclosures, component leads, and automatic switching devices
Solder and solder plating	For joining, solderability, and corrosion protection
Beryllium	Inertial guidance instruments

Source: Ref 8

The principles of galvanic corrosion are discussed elsewhere in this Volume, and will not be dealt with in this article. To minimize the effects of galvanic corrosion in electronic equipment, the joining of dissimilar metals as defined in MILSTD-889 should be avoided wherever possible. Where similar metals cannot be used because of design requirements, one or more of the following steps should be taken:

- Design the couple so that the area of the more noble metal (cathode) is appreciably smaller than the area of the more active metal (anode). Decrease the cathode area by painting or coating
- Plate the cathode (and/or anode) with a compatible metal
- Interpose a compatible metallic washer or gasket between the dissimilar metals
- Interpose a nonabsorbing, insulative washer, gasket, or coupling between the joined metals

- Paint the faying surfaces prior to joining
- Seal the interfaces to preclude entrance of moisture
- Place the electronics in a hermetically sealed enclosure and pressurize with an inert gas. If impossible to hermetically seal, used elastomeric seals and maintain relative humidity below 40% at room temperature (see the section "Moisture Intrusion Into Black Boxes" in this article)
- Where electrical bonding is required, follow the guidelines discussed in the section "Electromagnetic Interference (EMI)" of this article.

The prolific use of noble (more cathodic) metal platings on anodic substrates as corrosion barriers for electronic components is a related problem. Where the plating is excessively thin (porous), is cracked due to flexure or differential thermal expansion, or suffers mechanical damage, then the anodic base metal is exposed. In the presence of moisture, accelerated galvanic corrosion will occur. This corrosion is particularly severe because of the unfavorable area relationship (large cathode-to-anode area ratio). Care must be taken to ensure that minimum thicknesses of plating necessary to eliminate porosity are specified on engineering drawings and are enforced by quality control testing. Reflowing of tin and solder coatings helps to eliminate porosity. Where flexure of the plating is anticipated, for example, on component leads, a low-stress ductile plating should be used. In this example, a solder plate would be preferred to the more brittle electroless nickel plate.

Electromagnetic Interference (EMI). Even the most reliable electronic circuits and components are susceptible to malfunction due to interference from natural and man-made electromagnetic emissions. Filtering, shielding, and grounding are three ways to minimize these effects, known as electromagnetic interference, and to keep the equipment itself from being a source of interference to other electronics (Ref 9).

Shielding and grounding involve surrounding the electronics with a conductive shield or envelope grounded back to the main structural section or airframe. This requirement has resulted in an increasing number of electrically bonded interfaces and grounding paths in which low direct current (dc) resistance must be maintained. Extensive use of the light (active) metals for housings and chassis in electronic systems, together with the inability to use insulating-type coatings at electrically bonded interfaces, has compounded the difficulties of corrosion control. Normal corrosion rates, accelerated by galvanic action where dissimilar metals must be bonded, can lead to an increase in electrical resistance due to oxide and corrosion product formation. This will result in the eventual loss of EMI protection.

Protective treatments for electrically bonded interfaces must satisfy the conflicting requirements of corrosion control while maintaining good electrical continuity. Several methods are helpful in meeting these requirements, including plated metals, chemical conversion films, metal-to-metal contacts sealed with an organic moisture barrier, water-displacing ultrathin-film corrosion-preventive compounds as specified in MIL-C-81309, and combinations of the above.

The use of MIL-C-5541, Class 3, chemical conversion films for the protection of aluminum in electrically bonded interfaces has been investigated for aerospace electronic equipment (Ref 10). These Class 3 films combine good corrosion resistance (that is, they must pass 168 h of exposure to 5% salt spray test per ASTM B 117) with low electrical resistance, a specified in MIL-C-81706.

The effects of temperature, mechanical action, and aging on Class 3 chemical film properties have also been evaluated (Ref 10). All three effects are important because they could influence the reliability of EMI protection. High temperatures are known to degrade the corrosion resistance of chemical films. Scratches or abrasion could expose base metal and degrade corrosion protection. Finally, long storage and service life requirements of 10 years or more for military hardware, much of which is without inspection, make the effects of aging an important consideration. Electrical resistance must remain stable to meet the requirements for radio frequency junctions specified in MIL-B-5087, "Bonding, Electrical, and Lightning Protection for Aerospace Systems." The requirement is a maximum dc resistance of 0.0025 Ω/junction. Three principal conclusions were reached in this investigation.

First, Class 3 chemical films of MIL-C-5541 will withstand temperatures to 65 °C (150 °F) for extended periods of time without loss of properties. The maximum exposure without serious degradation is a few hours at 95 °C (200 °F). Thermal treatments or processing that exceed this exposure cannot be tolerated.

Second, scratches up to 1.6 mm ($\frac{1}{16}$ in.) wide and mechanical abrasion where the chemical film is not completely removed pose no threat. Apparently, hexavalent chromium (Cr^{6+}) leaching slowly out of the film acts as a corrosion inhibitor to protect bare aluminum.

Finally, preliminary aging results indicate that the properties of chemical films remain stable at both low (20% relative humidity) and high (cycling temperature humidity per MIL-STD-202, Method 106) humidities after 1 year and 2 years of exposure. The low-humidity test represented exposure inside a sealed black box, but 10 days of exposure to the high humidity is a standard accelerated corrosion test for electronic systems.

These results indicate that MIL-C-5541, Class 3, chemical films are an excellent choice for the protection of aluminum in electrical bonding applications. Galvanic effects are nonexistent, as they are with noble metal platings; the chemical films are easily repaired; and the properties remain stable. Where aluminum is joined to more noble metals (for example, nickel, stainless steel, or silver), sealing of the interface with an organic sealant will be required.

A recent trend in commercial electronic system is the movement away from metal and toward plastic enclosures (Ref 11). Metals are excellent shielding materials, while plastics are transparent to electromagnetic signals. Two approaches are being used to impart metal shielding properties to plastics. One is to incorporate conductive fillers in molded plastics, and the other approach is to apply metallized surface coatings to the interior surfaces of plastic enclosures. Both techniques have some major problems that are currently being addressed.

System-Generated Electromagnetic Pulse. A problem related to EMI protection is protection against system-generated electromagnetic pulse. This is a new requirement for military hardware. Secondary electrons emitted from an irradiated metal and accelerated out through the double layer at the metal surface at high velocity are capable of harming electronic circuits or components that they might contact. To prevent this, a gas fill should be used inside of a sealed black box that will slow down or absorb electrons, and a low atomic number (low-*Z*) coating must be applied to the inside surfaces of the box to reduce the electron emission efficiency of those surfaces. The low-*Z* coating is defined as a coating containing less than 1% by mass of elements of atomic number (*Z*) greater than 9. The thickness and the coverage requirements for the low-*Z* coating will vary, depending on the atmosphere/lack of atmosphere within the box. In many cases, a clear epoxy polyamide coating 0.025 to 0.1 mm (1 to 4 mils) thick has been used for this purpose. The low-*Z* coating can substitute for a corrosion-preventive coating on interior surfaces.

Flux Residues. The main functions of a soldering flux are to remove oxides, tarnish films, and other impurities from the surfaces of metals being soldered and to exclude atmosphere from the surfaces faces during soldering to prevent the formation of new oxides. A soldering flux should also lower the surface tension of the molten solder, allowing the solder to flow readily and adhere to more of the base metal surfaces (Ref 12).

In the case of liquid-type soldering fluxes, many organic and inorganic materials provide excellent fluxing action, but most of these materials leave extremely corrosive residues after cooling (Ref 13). Corrosive flux residues that attack and consume the solder alloy and base metals can weaken or embrittle the soldered connections. They can also increase the electrical resistance of the connections or open them entirely. On the other hand, conductive corrosive residues can pick up moisture from the atmosphere and can lower insulation resistance and form conductive paths, causing current leakage or short circuits. Nonconductive corrosion products, especially those carried by fumes, can cause damage by building up on electrical contact surfaces.

The fluxes used for electronic soldering can be divided into two categories: the solvent-soluble, or rosin types and the water-soluble types. In general, the water-soluble fluxes and their residues are much more active than the rosin fluxes and residues, but mild water-soluble fluxes and highly activated rosin fluxes are available. Inorganic zinc chloride-hydrochloric acid ($ZnCl_2$-HCl) type fluxes are included in the water-soluble category, but their highly corrosive nature and the difficulty in removing the residues preclude their use in electronic soldering.

Water white rosin, a widely used soldering flux material, leaves essentially noncorrosive, nonconductive, and nonhygroscopic residues. Because rosin is a very weak organic acid, its practical ability to clean a metal oxide surface is limited. To increase the ability of rosin fluxes to clean oxide surfaces, activating agents are added to produce rosin mildly activated (RMA) and rosin activated (RA) fluxes. For RMA fluxes, and activator may be any of a number of amines, organic acids, amides, or halogen-containing materials (Ref 14). Because RMA fluxes must be noncorrosive, as specified in military specification MIL-F-14256, only a small, limited amount of these materials may be added. The activating agents for RA fluxes are usually amine-neutralized HCl or occasionally a halogen-substituted organic material. These proprietary materials are water soluble and are the primary active constituents of the organic chloride type fluxes. When

heated, these activators decompose and liberate HCl. This liberated acid, unlike rosin, not only reduces the metal oxide but readily attacks the cleaned metal surface as well as the surface of the solder.

The organic chloride type fluxes are the most active fluxes used in soldering electronic assemblies. The active components are usually amine hydrochlorides (or hydrobromides) combined with water-soluble organic acids. Glutamic acid hydrochloride is an example. Fast and efficient removal of the residues is necessary to prevent initiation of corrosion.

Water-soluble chloride-free fluxes have gained some popularity. The active components of these fluxes are water-soluble organic acids. The residues are similar to those of the organic chloride type fluxes, but they eliminate the possibility of chloride ion (Cl^-) entering the corrosion cycle. If left on the board too long, they may discolor the solder surface. A water rinse is usually sufficient for flux removal. If polymerization occurs during soldering, alkaline cleaners may facilitate removal.

In a study performed for the U.S. Army Electronics Command, it was determined that the single largest factor causing corrosion of printed circuit board assemblies was flux residues (Ref 15). To prevent this form of corrosive attack, the lowest acid content flux possible should be used for soldering (Ref 8). In addition, cleaning processes should be employed that are tailored to the type of flux used and will completely remove all residues.

Component Lead Materials/Finishes. High reliability in the operation of moisture-sensitive microelectronic devices is often achieved by packaging these devices in hermetically sealed containers. This generally limits the electrical feed-through leads to low coefficient of expansion materials such as Kovar, Dumet, and Alloy 42 because of the need to form a seal with glass. These low-expansion materials, however, rate very poorly for solderability. They are finished, therefore, with a metal that is selected for its solderability and compatibility with internal wire bonding and die-bonding operations. The commonly used lead materials are difficult to plate, and many solderable finishes cannot be plated directly onto these materials. Gold is predominantly used because it can be plated directly on Kovar, has good solderability, is corrosion resistant, and is compatible with bonding operations. Tin and tin alloy electroplated finishes are also used in many cases for solderability and corrosion control.

Although gold itself is quite inert, severe galvanic actin can occur on gold-plated Kovar if the coating is not pore free (Ref 16). A potential difference of approximately 0.6 V can be generated by the dissimilar-metal couple of gold to Kovar (Ref 17), and the area relationships are poor (large cathode-to-anode area ratio), resulting in accelerated attack of the Kovar base material.

Tin or tin-lead solder coatings, on the other hand, are preferable for corrosion control because they are close to Kovar in the electromotive series and because the potential difference is low (0.02 V) (Ref 17). Quite often, gold-plated component leads are pretinned, that is, immersed in the solder pot to give a solder coating. Studies have shown that gold coatings as thick as 7.5 μm (300 μin.) completely dissolve in molten solder to give a solder-Kovar bond. On most metals, 2.5 μm (100 μin.) of gold is sufficient for solderability. Greater thicknesses are of little value because the gold simply dissolves in the molten solder. The pretinning procedure effectively eliminates the galvanic-corrosion problem.

Other corrosion-sensitive areas for component leads are the lead-glass interface at the lead egress from the container and lead bends, which are susceptible to stress-corrosion cracking. When the glass is fused during the sealing process, a meniscus is formed, resulting in a thin coating of glass extending out on the lead material. The lead is then gold plated up to this meniscus. The thin coating of glass can be cracked or broken away during plating and subsequent handling, packaging, lead bending, and soldering, leaving bare lead material. This site is very susceptible to corrosive attack because of the galvanic couple formed between the more noble material finish and the base metal.

Stress-corrosion failures of leads have been observed for both transistor cans and integrated circuit packages when stress and moisture were combined (Ref 16, 18). Tensile stresses arise from lead bending during installation or even by differential thermal expansion in a rigid mounting because of the low expansion of Kovar alloy and the high expansion of the rigid circuit board. The practice of pretinning and organic conformal coating has been an effective solution to both of the above corrosion-sensitive areas.

Special care must be taken in the pretinning of leads on nonhermetic devices, particularly nichrome-film resistors. Thermal stress from the solder-dipping process can damage epoxy-to-metal end seals and allow the entry of fluxes, chlorinated solvents, and moisture. The nichrome film is susceptible to corrosion in the presence of moisture and a chloride contaminant; corrosion (electrolysis) can become rapid if a bias is imposed. The temperature of the solder, the residence time in the solder, and the proximity of molten solder to the body of the resistor are critical parameters that

must be regulated. A solder temperature of no higher than 260 °C (500 °F), a residence time of 5 s, and immersion to no closer than 0.64 mm (0.025 in.) from the body are recommended. The use of heat-sinking lead holders, the elimination of fluxes more aggressive than RMA fluxes, and the minimal use of trichloroethane and water rinses were also recommended (Ref 19).

Organic Outgassing Products. Many organic materials commonly used in electronic equipment can cause corrosion damage by the outgassing of vapors, particularly within nonbreathing enclosures. Potentially corrosive materials include adhesives, resins, plastics, elastomers, sealants, and organic finishes (Ref 18). Reference 20 describes corrosive vapors (hydrogen chloride) given off by polyvinyl chloride insulation on wiring. Other examples of materials that might cause damage inside of closed compartments include:

- Acetic acid from acid condensation cured room-temperature vulcanized (RTV) silicone sealant
- Sulfur compounds from polysulfide sealants and paper or cardboard used for packaging.
- Phenolic constituents from molded phenolic resins
- Ammoniacal vapors from molded resins
- Esters or organic acid vapors from plasticized resins
- Organic acids (generally acetic) from raw wood used in packing cases.
- Sulfurous or acidic vapors from cushioning materials used for packaging
- Amine catalysts from epoxy materials.

Damage from outgassing can be minimized by the following techniques (Ref 21):

- Organic materials should be thoroughly cured before assembly, especially acid-activated plastics
- Polyvinyl chloride should not be used in closed compartments
- Where practical, the use of neoprene, phenolic, polysulfide, and vinyl should be avoided in closed areas
- Where possible, materials should be given a bake to outgas moisture
- Cadmium should not be used in closed compartments

This last point refers to the fact that cadmium is very susceptible to attack by corrosive outgassing products in confined spaces. The use of cadmium is banned in this application by federal and military specifications and standards, such as QQ-P-416, MIL-S-5002, and MIL-STD-1250.

Metal Whiskers. Certain metals, including tin, zinc, cadmium, and silver, are subject to the growth of metallic filaments known as whiskers, Given sufficient time and the proper conditions, these filaments can grow long enough to short out adjacent circuitry and cause failures. High voltage quickly burns off the whiskers, but the low voltages characteristic of much electronic equipment cannot (Ref 22).

Whiskers are of particular interest in the case of tin because of the wide use of tin plate on miniature electronic equipment. The exact mechanism of whisker growth is not known. It appears to be related to metallurgical imperfections in these metals (Ref 18). In the case of tin, the most prevalent hypothesis states that whiskers grow because of strains set up in the tin plate during the plating process, especially if various organics required for the process are co-deposited (Ref 23). The growth of whiskers is slightly enhanced by elevated temperature and humidity. Whisker growth is greatly accelerated in the presence of high stresses. Other empirical data on tin whisker formation include (Ref 23):

- Bright tin in which organics are co-deposited has a propensity to produce whiskers, as opposed to a matte tin process
- Use of high current densities during plating has a tendency to induce stresses in tin plate that produce whiskers
- Thin tin-plated coatings (<1.3 μm, or 50 μin.) have more of a propensity toward whisker growth than tin plating of 2.5 μm (100 μin.) or more
- Baking after tin plating has helped to produce surfaces that are free of whiskers

Whisker growth can be minimized by the use of thicker coatings, preferably fused or hot dipped, or by stress relief if the coating is electro-deposited. Apparently, thin barrier coating are not effective in eliminating whisker growth. Consideration should be given to adequate spacing, positive barriers of insulating material, and maintaining a low level of humidity in the equipment. Finally, the co-deposition of small amounts of lead, in the case of tin, has been found to eliminate whisker growth (Ref 18). This is further clarified in Ref 24. The addition of 1.5% Pb to the tin coating (or reflowing) has been shown to eliminate whisker formations on tin-plated contacts.

Silver migration is a form of electrolysis in which silver ions dissolve from one conductor in a circuit and, under the impetus of a direct current and in the presence of moisture, migrate across an insulator to a second conductor. The rate of migration is affected by the magnitude of the potential difference, the humidity, the type of substrate, and the contamination present on the substrate. It is postulated that the silver is oxidized and that the resulting silver cations are carried in an electrolyte film to the negative conductor, where they are reduced back to metallic silver. Upon drying, silver will be found on the insulator, giving low insulation resistance or even conductivity.

Silver migration is minimized by using conformal coatings, by maintaining humidity at a level that precludes condensation, by using non-hygroscopic insulation, by removing contaminants, and by maintaining the spacing between conductors at different voltage potentials as wide as possible. Where practicable, gold, platinum, or tin-lead coatings are recommended for use instead of silver (Ref 18, 21).

Brittle Intermetallics. Gold has an extremely high rate of dissolution in molten 60-40 tin-lead solder, leading to the formation of the intermetallic compound $AuSn_4$ (Ref 25). Being extremely brittle, $AuSn_4$ can give to severe embrittlement in a solder joint. Several investigators in this field have studied the effect of gold coatings on joint strength on the basis that all coatings are converted to $AuSn_4$. The critical composition of the intermetallic compounds in a solder joint that causes embrittlement appears to be about 0.6% Au.

When the solder bath becomes saturated with gold, the suspended intermetallic material gives rise to grittiness in the appearance of the joint. However, embrittlement is the main problem, particularly if a device is to be exposed to thermal cycling. In the solder pot, a level of as low as 0.02% and as high as 0.2% Au has been reported to be the critical amount of gold contamination (Ref 26).

As mentioned previously, gold-plated leads are usually pretinned, thus dissolving the gold and giving a solder-to-base metal bond. Multiple dips are often specified to ensure complete removal of the gold. If it is necessary to solder over gold, care should be taken to minimize the formation of the brittle gold-tin intermetallic by one or more of the following methods (Ref 21):

- Use of extremely pure (99.99%+) gold
- Use of thin gold plate
- Use of minimum soldering time at minimum temperature

The soldered joints should be protected with a conformal coating. In addition, the gold content of the solder pot should be maintained below 0.2%.

Gold-Aluminum. The failure of gold-aluminum thermocompression bonds in integrated circuit devices due to electrical opens or intermittencies was initially attributed to a phenomenon known as purple plague (Ref 27). However, this turned out to be somewhat of a misnomer. Purple plague is defined as a brittle gold-aluminum compound formed in the presence of silicon (Ref 21). The gold-aluminum equilibrium diagram shows that five intermetallic compounds can be formed. Only one of these, $AuAl_2$, in the aluminum-rich phase, appears purple in the crystalline form.

An in-depth study of the cause of these thermocompression bond failures found no purple $AuAl_2$ formation (Ref 28). The study concluded that the failures occurred in the gold-rich phase because of the formation of Au_4Al_2 and Au_2Al. The failure mechanism postulated was the formation and transformation of these brittle intermetallics accompanied by the formation of strained interfaces. This was caused by the mismatch of atomic lattices and changes is volume, inducing stresses into the thermocompression bond. The strained interfaces thus formed are susceptible to fracture in the hard, brittle intermetallic phases. Methods of preventing this type of failure include the use of a third metal as a diffusion barrier and/or thermal treatments that will minimize or eliminate formation of intermetallics.

Electrical Contacts. One of the more severe corrosion problems unique to electronic systems is the degradation of electrical contacts. The reliability of modern systems is increasingly governed more by the reliability of interconnections than by active solid-state devices. This is due in part to the low connector contact forces and low voltages used in modern circuits and therefore to the sensitivity to very small amounts of corrosion products and other contaminants.

Contact corrosion is dependent on the materials with which the contact is plated. Nonnoble contact finishes, with tin as the major example, are susceptible to oxide formation that can result in a gradual increase in contact resistance. The dominant failure mechanism for tin-plated contacts is fretting corrosion (Ref 29, 30), a repetitive oxidation of contact points due to small-amplitude contact movement. The potential for fretting corrosion can be minimized by providing mechanically stable contacts, usually through high contact force, or by the use of a contact lubricant specifically formulated to be effective against fretting corrosion.

Noble metal finishes, of which gold is the major choice, do not react with the environment, but because of economic and other reasons, the plating is generally thin and has pores in which galvanic corrosion can occur. Corrosion of and migration of corrosion products from the copper alloy spring materials used in electrical contacts can lead to contact degradation in certain environments, particularly those containing chlorides and sulfides. In moisture-laden rooms, in which the relative humidity can reach 90%, a galvanic reaction takes place between the gold and copper at the pores; corrosion products form and gradually creep over the gold surface, resulting in poor or intermittent contact. Even where moisture is controlled at lower levels, high concentrations of sulfides in the environment can give the same effect. At one time, silver was used as an underplating for gold. In this case, the presence of sulfides caused rapid degradation of the contacts (Ref 2). At higher temperatures, solid-state diffusion of copper to the surface of the thin gold layer and subsequent reaction with the environment can cause increases in contact resistance.

Nickel barrier plating of the contact spring is effective in minimizing these aspects of copper corrosion. Housing design can also be effective in restricting the access of the environment to the contact interface or contact spring (see the section "Moisture Intrusion Into Black Boxes" in this article). A chromate conversion coating was developed and applied successfully to the cleaning and refurbishment of electrical contacts on submarines (Ref 2).

Design Considerations

The following are guidelines that should be considered for corrosion prevention and control in the design of electronic equipment. Some of these guidelines can be used in addition to the methods of corrosion prevention and control described previously in this article.

General. Methods for minimizing or preventing corrosion should be considered at the beginning of the design stage. Corrosion engineers, as well as electronics and radiation-hardening engineers, should be consulted, and designs should be based on the assumption that moisture will be present in the intended application.

Black Box Design. Hermetic (fusion) sealing should be used whenever possible. Butyl rubber O-rings and gaskets should be used for environmental sealing if butyl rubber is compatible with environmental fluids. Black boxes should be pressurized with dry inert gas, and a warning signal to indicate loss of pressure should be used. Electrical bonding or grounding interfaces and EMI gaskets should be sealed against moisture or fluid intrusion. Low point drains should be designed into nonhermetic and nonpressurized equipment. The introduction of outside air into electronic enclosures for cooling should be minimized or eliminated, and printed circuit boards should be mounted vertically and conformal coated in accordance with MIL-I-46058. Edge connectors should be located on vertical sides of printed circuit boards, drip loops should be used on electrical cables, and feed-through connectors should be located on the sides of the housing.

Materials Selection. Metals should be used in their most corrosion-resistant form (heat treatment, surface treatment, passivation, and so on) with the least amount of residual stressing possible. Hygroscopic materials should be avoided, as should RTV materials that contain acetic acid and cushioning materials that can deteriorate (revert), such as ester-type polyurethanes. Silver, cadmium, or bright tin plating should not be used on the inside of containers. To avoid whiskers, tin plate should be matte rather than deposited with organic brighteners. Formation of tin whiskers can also be avoided by fusing or alloying the tin plate. Silver or silver plating on circuit conductors or electrical contacts should be avoided. Funginert materials should be used, as should low-outgassing materials or bakeout materials, prior to sealing of the black box. Guidelines in MIL-STD-1250 and MIL-STD-454 should be followed.

Dissimilar Metals. If it can be avoided, dissimilar metals as defined in MIL-STD-889 should not be used in contact with each other. If such use cannot be avoided, plate with a metal (or metals) that will reduce the potential difference of

the couple to 0.25 V or less, interpose a compatible metallic washer or gasket, interpose an insulative washer, gasket or coupling, or paint the faying surface. All interfaces should be sealed, anode-to-cathode area ratios should be maintained as large as possible, the cathodic (more noble) material should be painted, and dissimilar-metal inserts or fasteners should be installed by the wet primer method. Magnesium should never be mated to a metal more noble than aluminum, and it must be remembered that graphite, graphite composites, graphite lubricants, and graphite-silver-, or copper-filled conductive paint or EMI gaskets acts as a noble metal in dissimilar-metal contact. These materials should not be coupled with aluminum or any structural metal.

Finishes. All aluminum, unless it is plated, should be coated with a chemical film in accordance with MIL-C-5541 or anodized in accordance with MIL-A-8625. If conductivity is required, aluminum can be coated with a MIL-C-5541, Class 3, film or plated. Nickel barrier plating should be used under gold plating. Where a more noble metal plating is used on an active base metal, any pore or defect in the plating will be a site for galvanic corrosion with a very poor area ratio; proper thickness, handling, and processing should be ensured and a barrier plating used if necessary. Adequate dimensional tolerances must be allowed for protective coatings, and paint should be applied wherever possible. A complete paint system consisting of a conversion coating, primer, and topcoat in accordance with MIL-S-5002, MIL-F-7179, and MIL-F-18264 should be used. When coating the cathodic member of a dissimilar-metal couple, a paint resistant to alkaline attack (not an alkyd-base paint) should be used. High-strength materials, if plated, should be baked to minimize susceptibility to hydrogen embrittlement, and all stainless steel components should be passivated in accordance with federal specification QQ-P-35.

Joining. Low-carbon (for example, type 304L and type 316L) or stabilized (type 321 and type 347) austenitic stainless steels should be used in welded structures to minimize susceptibility to sensitization and intergranular attack. Joints of dip-brazed aluminum structures should be thoroughly cleaned and then vacuum impregnated in accordance with MIL-I-6869, Class 2 and MIL-STD-276; all light metal castings should also be vacuum impregnated. Machining into a dip-brazed joint should be avoided. Solder fluxes with the lowest possible acid content should be used, and joints should be rigorously cleaned and tested for ionic contamination after soldering. In the thermocompression bonding of gold wire to aluminum metallization on semiconductor devices, a barrier plate or thermal treatment should be used to prevent the formation of brittle gold-aluminum intermetallics.

Maintainability. It should be remembered that metals can corrode during fabrication and storage and before assembly; protection is required. Cooling systems that remove moisture and particulate matter should be used for completed assemblies, and filters and traps should be cleaned or replaced regularly. For closed containers, desiccant systems with visual indicators should be employed. The temperature inside a sealed black box should never be allowed to drop below the dew point.

Case Histories and Failures of Electronics and Communications Equipment

Eddie White, George Slenski, and Bill Dobbs, Electronic Failure Analysis Group, Air Force Wright Aeronautical Laboratories

---

Introduction

THE ELECTRONIC FAILURE ANALYSIS GROUP of the Air Force Wright Aeronautical Laboratories' Materials Laboratory has investigated a large number of electronic and electrical failures. It has been established that about 83% of these failures are caused by materials and manufacturing process defects. Also, it has been verified that about 20% of the failures are caused by corrosion problems.

Several different testing and analysis techniques will be presented to identify ways of investigating corrosion problems in electronic failures. These brief discussion are intended only as introductions to the techniques; more information is available in the literature on the technique. Following this, a number of case histories of electronic failures associated with corrosion problems will be presented with recommended corrective actions. All of the corrective actions interrupt the electrochemical circuit required for corrosion to occur (anode, cathode, and electrolyte to conduct electricity between the anode and the cathode). Corrective actions consist of removing the electrolyte, insulating the anode, or removing the cathode. This usually results in a significant cost savings for the customer and a marked improvement in the reliability of the equipment.

Analysis Techniques

The penetration of moisture contaminants into electronic systems has many detrimental effects, including corrosion. In most electronic systems, dimensions have been minimized for faster signal processing and higher density. This means that most metallizations are thin, or small in cross-sectional area, and that the individual metallizations are close together. In such systems, trace amounts of moisture and contamination may cause system failure. If the aluminum metallized surface of an integrated circuit is contaminated and if moisture is present, a slight amount of corrosion may result in an open circuit. Corrosion of 1 pg of aluminum is sufficient to open an integrated circuit conductor. This extreme sensitivity requires special caution when dealing with corrosion in electronic systems.

Environmental Testing

Failure modes in electronic components and systems can be identified and related to field failures with environmental testing techniques. The four techniques commonly used are thermal and humidity cycling, humidity testing, salt fog tests, and combined environments reliability testing.

The thermal and humidity cycling test, sometimes called the moisture resistance test, is performed for the purposes of evaluating in an accelerated manner the resistance of component parts and constituent materials to the deteriorative effects of high humidity and heat conditions. Most degradation results directly or indirectly from the absorption of moisture vapor or films by vulnerable insulating materials and from the surface wetting of metals and insulation. These phenomena produce many deleterious effects, including corrosion, physical distortion and decomposition of organic materials, leaching out and spending of constituents of materials, and detrimental changes in electrical properties.

This test derives its effectiveness from its use of temperature cycling, which provides the alternate periods of condensation and drying essential to the development of the corrosion processes and produces a breathing action of moisture into partially sealed containers. Increased effectiveness is also obtained by the use of a high temperature, which intensifies the effect of humidity. Provision is made for the application of a polarizing voltage across insulation to investigate the possibility of electrolysis, which can promote eventual dielectric breakdown. Results obtained with this test are reproducible and have been confirmed by investigation of field failures. This test has proved to be reliable for indicating those parts that are not suitable for use in high-temperature and humid environments. Figure 1 shows a typical 24-h temperature and humidity cycle.

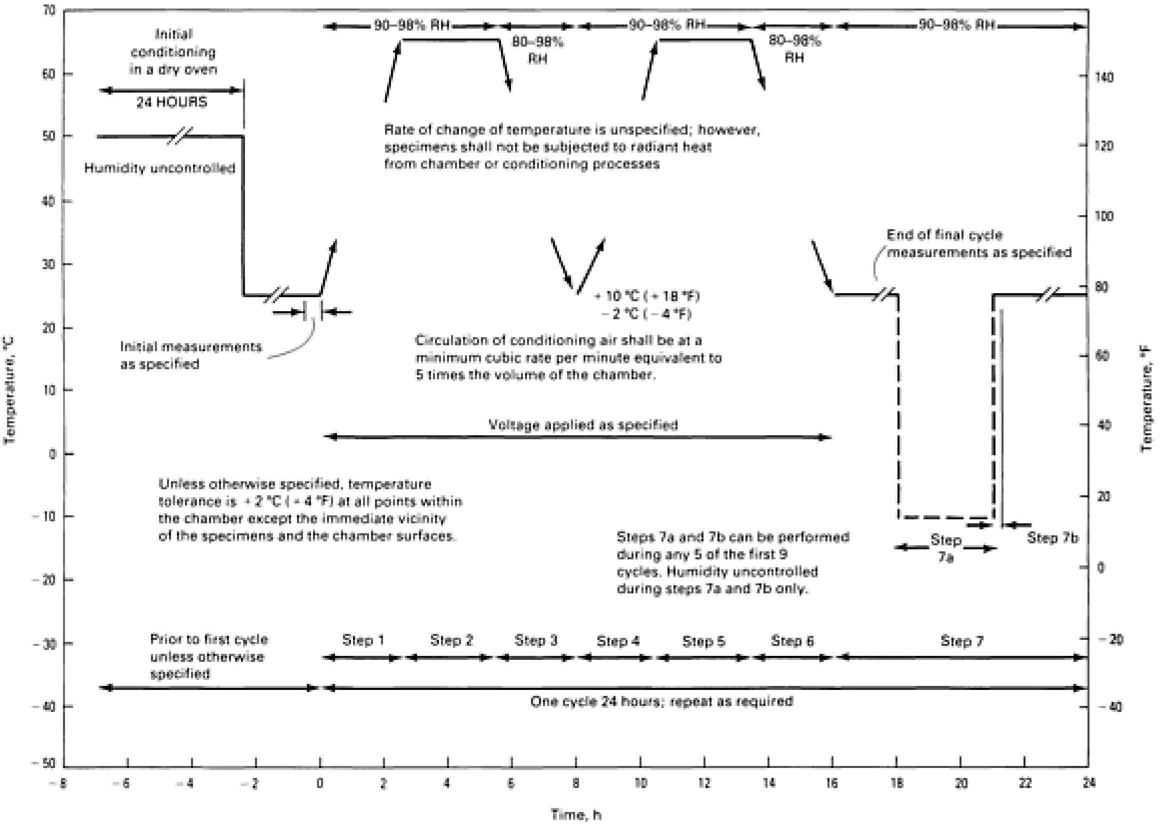

Fig. 1 Graphic representation of thermal and humidity cycling test

The humidity test requires that specimens be placed in a chamber and exposed to a relative humidity of 90 to 95% and a temperature of 40 °C (100 °F) for a selected period of time. This test is performed to evaluate the properties of materials used in components as they are influenced by the absorption and diffusion of moisture. This is an accelerated test that is accomplished by the continuous exposure of the specimen to high relative humidity at an elevated temperature. These conditions impose a vapor pressure on the material under test that constitutes the force behind the moisture migration and penetration. Hygroscopic materials are sensitive to moisture and deteriorate rapidly under humid conditions. Absorption of moisture by many materials results in swelling, which destroys their functional utility and causes loss of physical strength as well as changes in other important mechanical properties. Insulating materials that absorb moisture may suffer degradation of their electrical properties. This test is useful in determining the moisture absorption of insulating materials.

The salt fog test requires that the specimen be placed in a chamber in which air is circulated through a 5% sodium chloride (NaCl) solution maintained at 30 °C (85 °F). The relative humidity of the air should be 95 to 98% when released from the salt solution. The salt fog test, in which specimens are subjected to a fine mist of salt solution, has several useful purposes: however, this test has been erroneously considered by many as an all-purpose accelerated corrosion test that, when passed, will guarantee samples to be satisfactory under any corrosive condition. Experience has shown that there is seldom a direct relationship between resistance to salt fog corrosion and resistance to corrosion in other media, even in so-called marine environments. However, some idea of the relative service life and behavior of different samples of a similar material can be gained by means of the salt fog test, provided accumulated data from correlated field service tests and laboratory salt fog tests show that such a relationship exists. Such correlation tests are also necessary to show the degree of acceleration, if any, produced by the laboratory test.

The salt fog test is generally considered unreliable for comparing the general corrosion resistance different kinds of metals or for predicting their comparative service life. The salt fog test has received its widest acceptance as a test for evaluating the uniformity of protective coatings. In this connection, the test is useful for evaluating different lots of the same product. When used to check the porosity of metallic coatings, the test is more dependable when applied to coatings which are cathodic, rather than anodic, toward the base metal.

Combined Environments Reliability Testing (CERT). The purpose of this test is to identify failures that temperature, humidity, vibration, and altitude can induce in electronic equipment either individually or in any combination. Studies have shown that thermal effects, vibration, humidity, and, in certain cases, altitude have the greatest effect on the life of avionics in the operational environment. It has been suggested that these four factors account for 88% of all the environmentally induced failures in the field. Temperature, humidity, vibration, and altitude can interact to produce failures in electronic equipment mounted inside of an aircraft in synergistic ways that are not apparent when stressed independently.

The system under test is placed inside a chamber in which the four stresses may be applied. A temperature and humidity cycle similar to that shown in Fig. 1 is combined with vibration and altitude cycles to provide the final stress cycle that the equipment experiences. The equipment is electrically tested during environmental stress testing so that failures may be identified. This testing procedure is a very effective tool for identifying system deficiencies; the correction of these deficiencies enhances the reliability of avionic equipment.

Chemical Analysis Techniques

Infrared, visible, and ultraviolet spectroscopies are used for the qualitative and quantitative analysis of organic compounds and alloys. These methods are based on the fact that within any molecule the atoms vibrate with a few definite, sharply defined frequencies characteristic of that molecule. When a sample is placed in a beam of infrared radiation, it adsorbs energy at those frequencies characteristic of the molecule and transmits all other frequencies. The resulting pattern, known as an infrared spectrum, is thus a fingerprint that is characteristic of the compound. The intensity of an absorption band is a known, reproducible function of the amount of material in the sample beam. Therefore, measurement of the absorption intensity yields quantitative values of the materials present in a sample. However, the instrument slit width plays an important part in quantitative analysis, and better techniques are available. More information on infrared spectroscopy is available in the article "Infrared Spectroscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Ultraviolet and visible spectroscopies provide useful information that complements the infrared analysis. An ultraviolet or visible light of variable wavelength is selectively passed through a sample solution. When absorbance occurs in the ultraviolet or visible range, it indicates that electrons in the sample molecules are undergoing transition from the normal bonding molecular orbitals to higher-energy antibonding orbitals. The absorbances at these wavelengths indicate the presence of conjugated double-bond systems. The intensity of absorbance is proportional to the concentration of the molecules. The article "Ultraviolet/ Visible Absorption Spectroscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook* contains detailed information on the theory and use of this technique.

Raman Spectroscopy. Raman scattering relates to the change of frequency observed when a monochromatic light beam is scattered by polyatomic molecules. The Raman spectrum characterizes the scattering medium and is independent of the incident radiation frequency. It corresponds to the frequencies of the atom oscillations in polyatomic structures. The principal utility of Raman spectroscopy is in dealing with highly symmetrical molecules or chromophores (functional groups that produce color) within a molecule. Raman spectra can be used to characterize and identify chemical species (inorganic, organic, and biological molecule) and precisely determine their structures in all phases of matter. Thus, vibrational Raman spectra can be regarded as unique fingerprints and often contain information on the local molecular environment. Detailed information on Raman spectroscopy can be obtained in the article "Raman Spectroscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

X-Ray Diffraction. X-rays are electromagnetic radiation and, like visible light, can be diffracted. When a crystal is placed in a collimated x-ray beam, it behaves as a three-dimensional grating that produces a diffraction pattern. The wavelength, λ, of the incident radiation is related to the interplanar grating spacing, *d,* of the crystal by the equation known as Bragg's law:

$$n\lambda = 2d \sin \theta \qquad \textbf{(Eq 1)}$$

where *n* is an integer (the order of diffraction), and θ is the angle of incidence. Equation 1 founded the science of x-ray diffraction and determines the crystal parameter, *d,* when λ is known and θ, or 2θ, is measured. This technique can be used to identify elements by their crystal structure and their relative degree of crystallinity (see the article "X-Ray Powder Diffraction" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*).

Atomic Absorption Spectroscopy (AAS) is known as a very specific technique for the quantitative analysis of organic and inorganic materials for metals in nanogram to picogram levels. In this technique, a sample solution is atomized in a flame or furnace in which the ground-state metal atoms are excited to a higher-energy state in the presence of specific wavelengths of light. By measuring the amount of light absorbed, a quantitative determination of the amount of the element present in the sample can be made.

With the use of a furnace, atomic absorption spectroscopy (FAAS) has enhanced the capability for determining hard-to-analyze elements, such as boron, lead, aluminum, chromium, bismuth, and molybdenum, at trace levels. Although flame AAS is a convenient and fast technique, FAAS is extremely efficient for the measurement of low concentrations. A small sample volume is required for complete analysis, and solid samples can be directly analyzed with no sample preparation. More information on AAS is available in the article "Atomic Absorption Spectrometry" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*

Emission spectroscopy is the technique used for the simultaneous analysis of all metallic elements in a sample. Metal atoms of ground-state energy are excited by thermal energy (in the form of arc or a spark) to higher-energy states. These atoms then undergo transitions back to the ground state, accompanied by the emission of energy in the form of light and at discrete wavelengths. Each metal atom can undergo many different transitions, the sum of which is the characteristic emission spectrum for that element.

The spectra of all metals in the sample are superimposed, resolved into the component wavelengths by the grating and optics of the instrument, and recorded as lines on photographic plates. After processing, the plates are read on a densitometer, and an element is identified from the wavelength of its emission lines. This technique is most useful for the qualitative and semiquantitative analysis of metals. Emission spectroscopy is more versatile than atomic absorption in that several element can be identified simultaneously. Quantitative analysis with this method is very time consuming, but once the elements are identified, quantitative analysis can be performed with atomic absorption (flame or furnace) and inductively coupled plasma emission spectroscopic methods. More information on emission spectroscopy is available in the article "Optical Emission Spectroscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Gas and Liquid Chromatography. Gas chromatography (GC) is basically a technique for quantitative separating components in a mixture of organic compounds. The components are partitioned between two phases, an inert moving gas, and a stationary liquid film. The liquid film is supported in a long column through which the vaporized sample and gas move. The separation depends on the affinity each component has for the stationary phase. The compounds with the least affinity will emerge from the column first, while those with more affinity will emerge after some time interval. Upon leaving the column, the component passes through a detector, and its presence is indicated by a peak on a recorder. The identity of the peak can be determined by comparison with standards, and the concentration of the component is derived from the peak area. In order to analyze a sample by GC, it must have some vapor pressure below about 35 °C (95 °F). The article "Gas Chromatography/Mass Spectrometry" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*contains detailed information on this technique.

Modern high-performance liquid chromatography (HPLC) has become an extremely powerful technique for separating mixtures into their components. With HPLC, compounds of poor thermal stability and low volatility that cannot be separated by gas chromatography can often be separated for either qualitative or quantitative analysis. The components of a sample move through the column at different rates, and the amount of information that can be derived depends on the type of detector used. The standard technique of retention time comparison with known standards is practiced. In this technique, fractions of a sample can be collected in solution and can be analyzed by any other analytical technique. Other detectors can also be interfaced with this technique to diversify its applications. More information on HPLC can be obtained in the article "Liquid Chromatography" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*

Mass spectroscopy is used to analyze samples according to their mass. This technique is ideal for isotope and molecular weight indentification. The sample is vaporized, and the atoms or molecules are then ionized by a directed electron beam. The ionized beam is accelerated through a magnetic field, then detected by an ion collector. The resulting information from this process is a plot of the ion mass to charge ratio versus the ion relative abundance. Identification of the constituents of a sample that can be vaporized is readily aided by mass spectroscopy (see the article "Spark Source Mass Spectrometry" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*

Wet chemistry and microelemental analysis techniques are used to investigate the chemistry of materials in the following ways:

- Quantitative elemental (composition) analysis
- Qualitative identification of material type
- Qualitative detection of component moieties
- Check on quantitative instrumental methods
- Isolation and characterization of inclusions and phases
- Determination of oxidation state

Modern instrumental techniques for quantitative elemental analysis are capable of determining large numbers of sample constituents in very short periods of time. Even so, wet chemical analysis remains important for several reasons. First, small samples of almost any shape can be used. Second, chemical results average over the entire sample, while most spectrographic techniques analyze small areas of the sample surface. Third, some spectrographic techniques are sensitive to the thermal and mechanical treatment of the sample, while wet chemistry is free of these problems. Fourth, and perhaps most significant, wet chemistry provides the calibration for nearly all spectrographic techniques. More information on wet chemical analysis is available in the article "Classical Wet Analytical Chemistry" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*

Electron Optics

Scanning Electron Microscopy (SEM). The scanning electron microscope, like the transmission electron microscope, uses electronics to form a magnified image of the specimen. Unlike the transmission electron microscope, however, the electron beam of the scanning electron microscope does not penetrate the specimen. The electron beam incident on the specimen is rastered (similar to the television scan) across the object. The detector records either the secondary or the backscattered electrons emitted from the top side of the sample, near where the electron beam strikes it. The sample does not have to be thin, but it must be reasonably conductive so that it does not charge and deflect the electron beam. Nonconductive specimens are coated with a thin layer of gold, chromium, or carbon before SEM examination. Integrated circuits can be examined in the scanning electron microscope while bias is applied to the integrated circuit. A great deal can be learned about a device from this technique. Detailed information on the theory and applications of SEM is available in the article "Scanning Electron Microscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*

Transmission Electron Microscopy (TEM). The transmission electron microscope is a device that form magnified images by means of electrons. The electrons are usually accelerated to 50 keV or above. The microscope magnifies in several stages by means of electromagnetic or electrostatic lenses. Transmission electron microscopes at higher energies (several MeV) have resolutions of a few angstroms. The specimen must be cut into a very thin sample so that the electron beam can penetrate it. After the beam penetrates the sample, a photograph of the sample is taken and kept as a permanent record. The microscope can be adjusted so that an electron diffraction pattern from the sample is obtained. This provides information about the crystallographic structure of the sample. The transmission electron microscope usually provides the highest resolution image that can be obtained from a specimen. The article "Analytical Transmission Electron Microscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook* provides detailed information on all aspects of TEM.

Characteristic x-ray analysis is frequently done in the scanning electron microscope, and it identifies the elemental constituents in the sample. The electron beam in the microscope is directed on the specimen, and the incident electrons knock electrons free form the bound atomic states of the atoms. As other free electrons drop into these empty bound states, they emit photons or x-rays with energies that are characteristic of that particular element. The emitted x-rays are compared to standards for the identification of the element. This technique permits the elemental analysis of microminiature samples and is discussed in detail in the article "Electron Probe X-Ray Microanalysis" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*

Package Moisture Content Analysis

The moisture content of sealed packages can be analyzed by mass spectroscopy. The package is maintained at a temperature above the dew point when punctured. The gases from the package are directed into the mass spectrometer,

which measures the relative amount of moisture in the gases. This type of analysis is important in assessing the potential for corrosion inside hermetically sealed packages. The article "Gas Analysis by Mass Spectrometry" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook* contains information on this technique.

Surface Analysis

Auger spectroscopy is used to study the sample surface to a depth of about 0.5 to 2 nm (5 to 20 Å). When the sample surface is bombarded with electrons in the energy range of 20 to 2500 eV, Auger electrons are emitted from the surface with characteristic energies that are determined by the elements constituting the sample. When the emitted Auger electron energies are identified, the elements in the sample are also determined. Depth profiling can be accomplished by sputtering the sample surface at a controlled rate with an ionized gas. More information on this technique is available in the article "Auger Electron Spectroscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*

Electron spectroscopy for chemical analysis (ESCA), also known as x-ray photoelectron spectroscopy (XPS), uses the photoelectric effect to study th electronic structure of surfaces as well as the chemical identity of the surface components. With this technique, the excitation source is the x-ray; therefore, disturbance of the sample surface is minimized. The ejected electrons possess energies that are characteristic of given elements, but these energies are also dependent on the chemical environment of the element so that some information is obtained about the surface chemistry. The depth of surface examined may be as deep as 10 nm (100 Å) for organic materials. Detailed information on this technique is available in the article "X-Ray Photoelectron Spectroscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*

Secondary ion mass spectroscopy (SIMS) bombards the sample surface with selected ions, usually argon, at designated energies, generally less than 1 keV. As a result of this ion bombardment, secondary ions are sputtered off the sample surface. The secondary ions are collected and analyzed with a mass spectrometer. The technique usually provides detection sensitivity of 1 ppb or better with minimal sample surface damage and can be used for depth profiling (see the article "Secondary Ion Mass Spectroscopy" in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*).

Ion scattering spectroscopy (ISS) requires that the excitation beam be an ion source, similar to SIMS, and that the sample surface atoms scatter the incident ions through binary collisions. The scattered primary beam is then energy analyzed. This measured intensity is plotted versus the ratio of the scattered energy divided by the initial energy. Scattering peaks in the plotted curve correspond to elements in the sample surface. These peaks are calibrated against known elements for identification. The article "Low-Energy Ion-Scattering Spectroscopy" in Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook* contains more information on this technique.

Examples of Electronic and Electrical Corrosion

The following are a few representative examples of corrosion-induced failures of electronic devices. The analysis techniques discussed above were used to identify the corrosion mechanism.

Circuit Breakers. Numerous aircraft circuit breakers (Fig. 2) were identified as failed because their contact resistance when closed was considered too high. A number of circuit breakers from several different manufacturers were tested in the laboratory to determine the cause of the high resistance. The circuit break contacts were identified as either tungsten/silver or cadmium/silver mixtures. Nine circuit breakers were exposed to a 10-day humidity test (40 °C, or 100 °F, and 95% relative humidity). A destructive physical analysis of the parts found a small amount of corrosion on the tungsten/silver contacts. Because of this, a 20-day humidity test (49 °C, or 120 °F, and 95% relative humidity) was conducted on two contacts that had been cross sectioned. After the 20-day test, the tungsten/silver contacts were severely corroded, while the cadmium/silver contacts exhibited very little corrosion (Fig. 3).

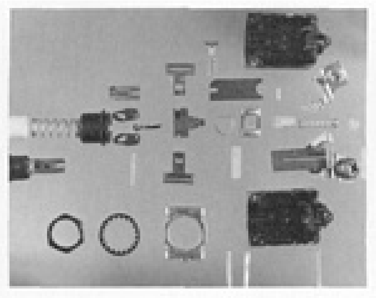

Fig. 2 Exploded view of an aircraft circuit breaker

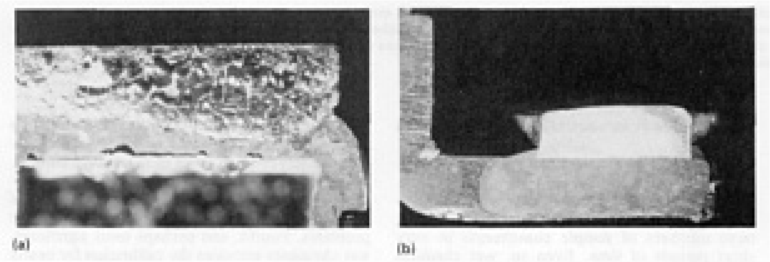

Fig. 3 Cross sections of circuit breaker contacts after 20-day humidity test. The tungsten/silver contact (a) is severely corroded, while the cadmium/silver contact (b) shows little corrosion.

A 48-h salt fog test (35 °C, or 95 °F, 5% NaCl, pH 6.5 to 7.2) was conducted on seven of the circuit breakers. Two of the circuit breakers failed. This was caused by salt condensation on the contacts (Fig. 4).

Fig. 4 Failed circuit breaker contact after 48-h salt fog test

The results of the analysis indicate that the tungsten/silver contacts corrode much more severely than the cadmium/silver contacts. Braze fluxes used to joint the contacts to the copper arm may contribute to corrosion. The contacts in all circuit breakers are improved by the mechanical wiping action of opening and closing the contacts several times. This should be done at periodic intervals. If the conduction of large currents is not required, the cadmium/silver contacts show superior resistance to corrosion.

Antenna Marker Beacon. A corroded antenna marker beacon (Fig. 5) was removed from an aircraft so that the source of corrosion could be determined. The beacon was x-rayed, and corrosion sites were visible in the radiograph (Fig. 5b). The antenna was opened and found to contain a polyamide foam (Fig. 5c). The antenna blade was removed from the foam (Fig. 5d) and observed to be corroded also. Both the housing and blade were found to be aluminum. The housing was

found to be plated with electroless nickel (Fig. 5e), and the blade was plated with a copper strike followed with a tin plate (Fig. 5f).

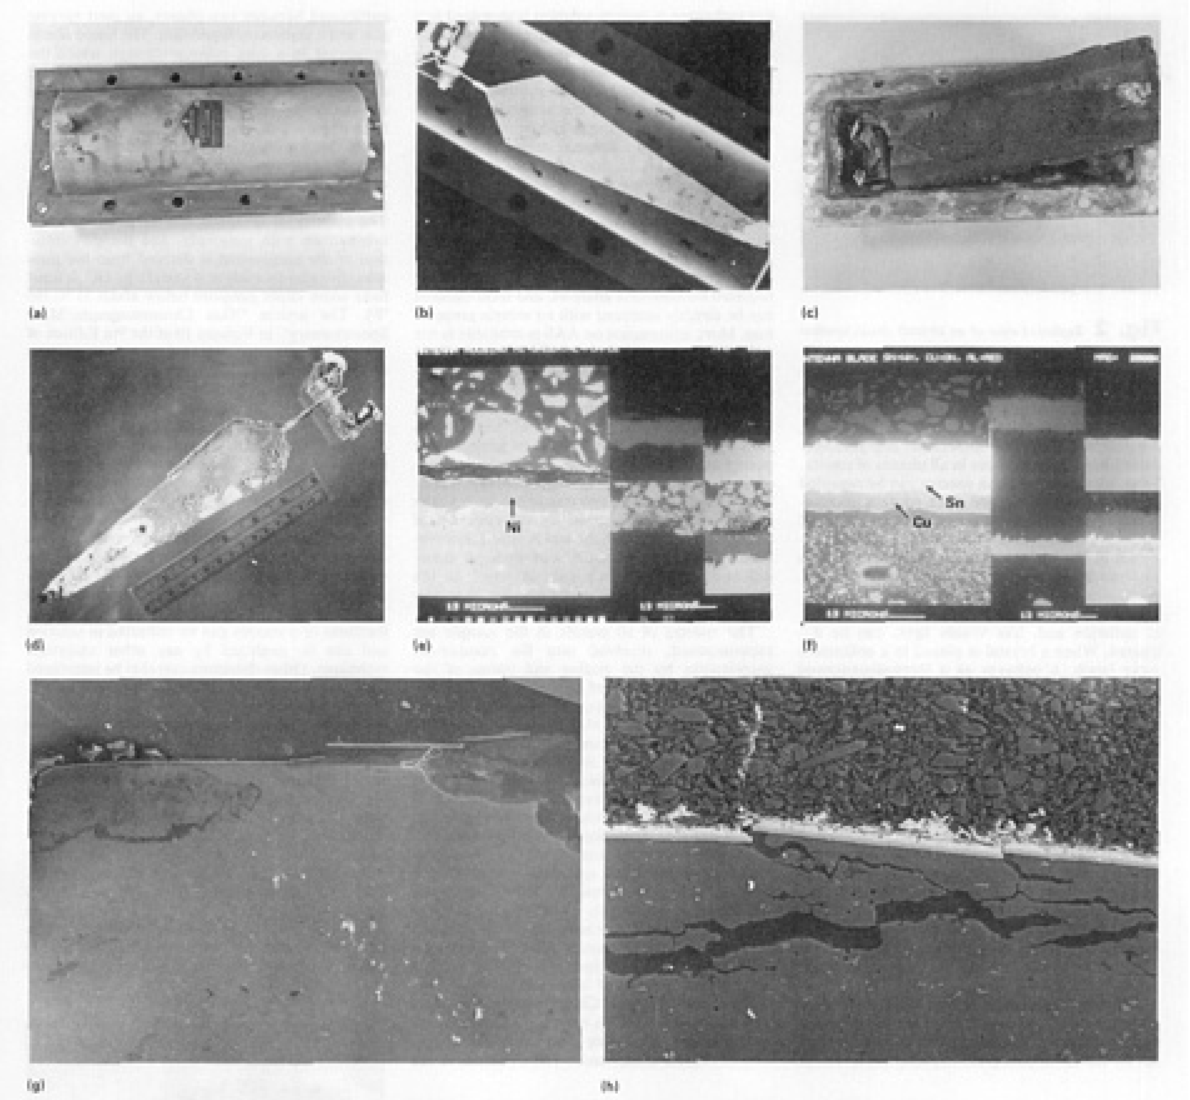

Fig. 5 Aircraft antenna marker beacon (a) that failed by corrosion. (b) X-ray radiograph of beacon showing areas of corrosion. (c) Polyamide foam inside the beacon. (d) Corroded aluminum antenna blade removed from housing. (e) X-ray map showing thickness of nickel plate (arrow) on aluminum beacon housing. (f) X-ray map showing the thickness of copper/tin plate (arrows) on aluminum antenna blade. (g) SEM micrograph of nickel plate on beacon housing showing areas of lifted plating. 50×. (h) SEM micrograph of copper/tin plate on aluminum antenna blade showing areas of lifted plating. 185×

It is believed that both the nickel plate and the copper/tin plate were porous. This permitted the penetration of moisture to the plating and aluminum interface. The presence of moisture and the anodic relationship of aluminum to nickel or tin resulted in a galvanic cell that caused pitting corrosion in the aluminum (Fig. 5g and h). These plating systems were used to maintain a high electrical surface conductance on the aluminum components. The corrosion resulted in non-conductive surfaces that affected the electrical performance of the antenna. It was recommended that, instead of plating the aluminum, a chromate conversion coating be used.

Printed wiring boards are subject to failure if a highly reactive soldering flux is used or if the flux is not completely removed after the soldering operation.

Flux Contamination on Dual In-line Packages. A printed circuit board (Fig. 6a) was removed from an aircraft because of short circuits on the board. Blue-green corrosion products appeared around and under dual in-line packages on

the board (Fig. 6b). Copper chloride was detected in the corrosion residue by characteristic x-ray analysis in the scanning electron microscope. Chlorides are a common contamination resulting from active solder fluxes and poor cleaning processes. It was recommended that a rosin-type solder flux be used and that a board cleanliness test be performed after cleaning.

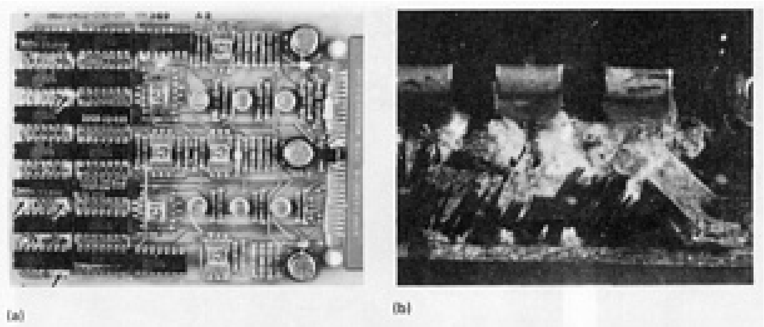

Fig. 6 Component side of failed printed circuit board (a) showing flux contamination (arrows). (b) Close-up of one of the dual in-line packages shown in (a). Leads are shorted out by flux contamination (arrow).

Corroded Conductor Traces on a Ground-Base Radar System. A ground-base radar system was removed from a 9-month storage for testing. All electrical systems failed because of short circuits in many of the multilayer printed circuit boards. Upon examination, the circuit boards appeared to have corroded conductor traces. Contamination and corrosion products had migrated to regions between conductor traces so that the traces were shorted out (Fig. 7). It was established by characteristic x-ray analysis that the contamination resulted from solder flux. A different cleaning procedure was recommended.

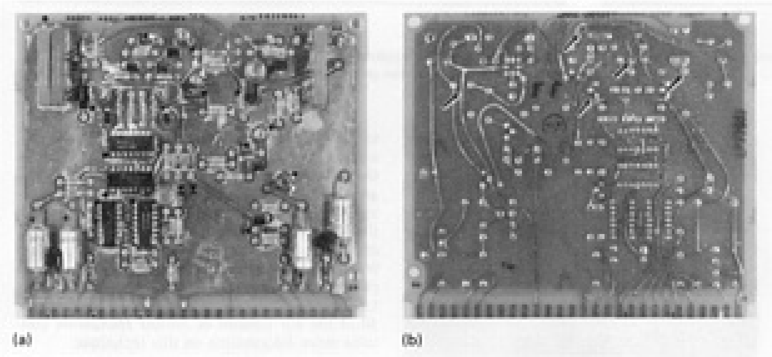

Fig. 7 Component side of failed printed circuit board (a) from a ground-base radar system showing corroded conductors. (b) Back side of board shown in (a); note corrosion an conductors (arrows) and while areas of mealing on the board.

Flux on Board Components. Components from a printed circuit board have also been found to be contaminated with solder fluxes. Figure 8 shows a corroded diode taken from a board. Inadequate removal of flux residues was determined to be the cause of this problem.

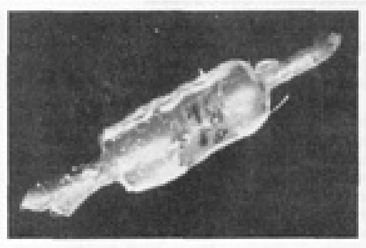

Fig. 8 Corroded diode removed from a failed printed circuit board

Water-Soluble Flux. The use of a highly reactive solder flux may sometimes have unexpected consequences. Of course, the reactive flux makes the soldering procedure easier. Components or boards that have poor solderability may sometimes be used, or some other device defects may be overcome; however, the reactive flux usually contaminates some parts of the electronic system so that is eventually causes more problems than it may solve.

A reactive water-soluble flux was used on a number of printed circuit boards because some of the component leads exhibited poor solderability. The flux had a high chlorine content. During the soldering operation, some of these chlorides were absorbed in the epoxy/fiberglass board surface. After soldering, the boards were cleaned and conformally coated, which trapped the flux near the surface of the board. The board cross section and an x-ray dot map of this area are shown in Fig. 9. This chlorine may eventually affect the copper conductors in the board because the conformal coating will absorb moisture, which could result in the formation of HCl. Without the reactive water-soluble flux, this chloride surface contamination does not occur. If the components to be soldered are handled properly, the soldering operation can be accomplished with less reactive fluxes. This is the best procedure.

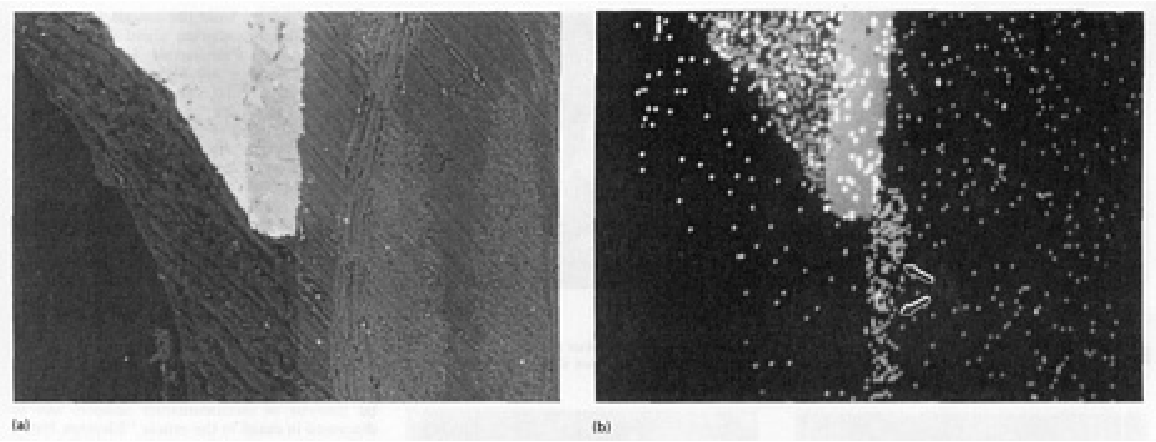

Fig. 9 Cross section (a) of printed circuit board contaminated by chlorine from a highly reactive water-soluble soldering flux. Left to right: void, conformal coating, solder, copper, and the epoxy/fiberglass board matrix. 130×. (b) X-ray dot map showing chlorine contamination (arrow) in the area shown in (a). The light dots indicate the presence of chlorine.

Vacuum Tubes. Triode amplifier tubes were failing because of severe corrosion of the exterior and interior of the tubes (Fig. 10). It was determined that the contaminant was a chloride and that its source was most likely a highly corrosive chloride flux. Figure 10(b) shows localized corrosion on the outside of the tube, and Fig. 10(c) shows the corrosion on the inside of the tube. Figure 10(d) shows a tube cross section with the entrapped green corrodent clearly visible. It was recommended that all fluxes be thoroughly cleaned from the tube before sealing.

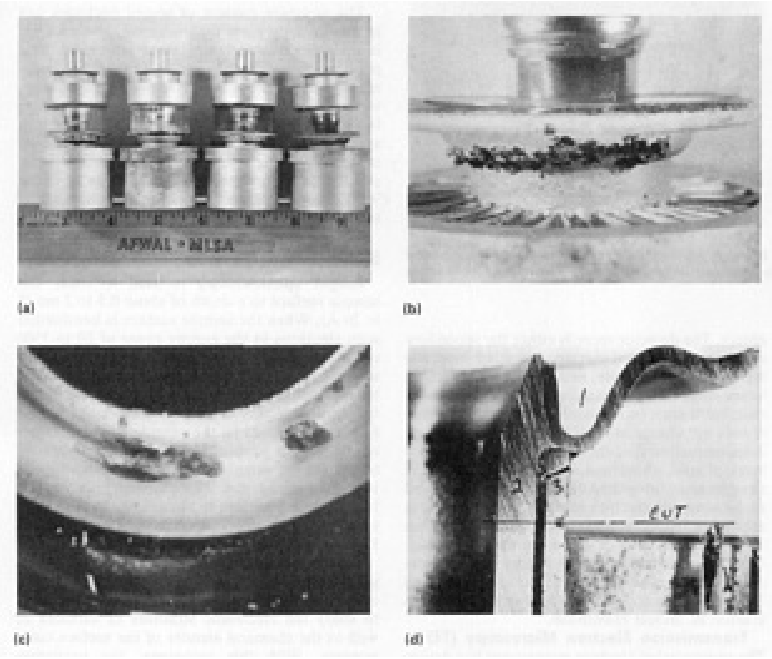

Fig. 10 Triode amplifier tubes (a) showing corrosion. (b) Exterior corrosion on the triode of a tube. (c) Interior corrosion on a triode (the glass tube envelope has been removed). (d) Cross section of triode showing entrapped corrodent (arrow)

Fuses. After storage for several years, some fuses were tested. The fuse failure rate was exceedingly high. The cause of this high failure rate required identification. Figure 11(a) shows the fuse electronics when removed from the package. The white vibration-dampening foam is visible between the circular printed circuit boards. Upon analysis, the foam was identified as polyvinyl chloride (PVC). The circular boards were examined, and it was found that they were heavily contaminated with chlorides. One of the boards was placed in a humidity cabinet for 24 h. The results of this test are shown in Fig. 11(b) and 11(c). Several failed plastic-encapsulated transistors from the board were opened (Fig. 11d and e). The arrow in Fig. 11(d) marks the region in which the aluminum metallization was completely melted. The transistor surface was heavily contaminated with chlorides. It was found that these chloride contaminants were originating from the vibration-dampening PVC foam. The chloride penetrated the transistor by wicking up the metal leads extending through the plastic package. The PVC foam was replaced with a polyacrylic elastomer foam, which does not emit chloride contamination.

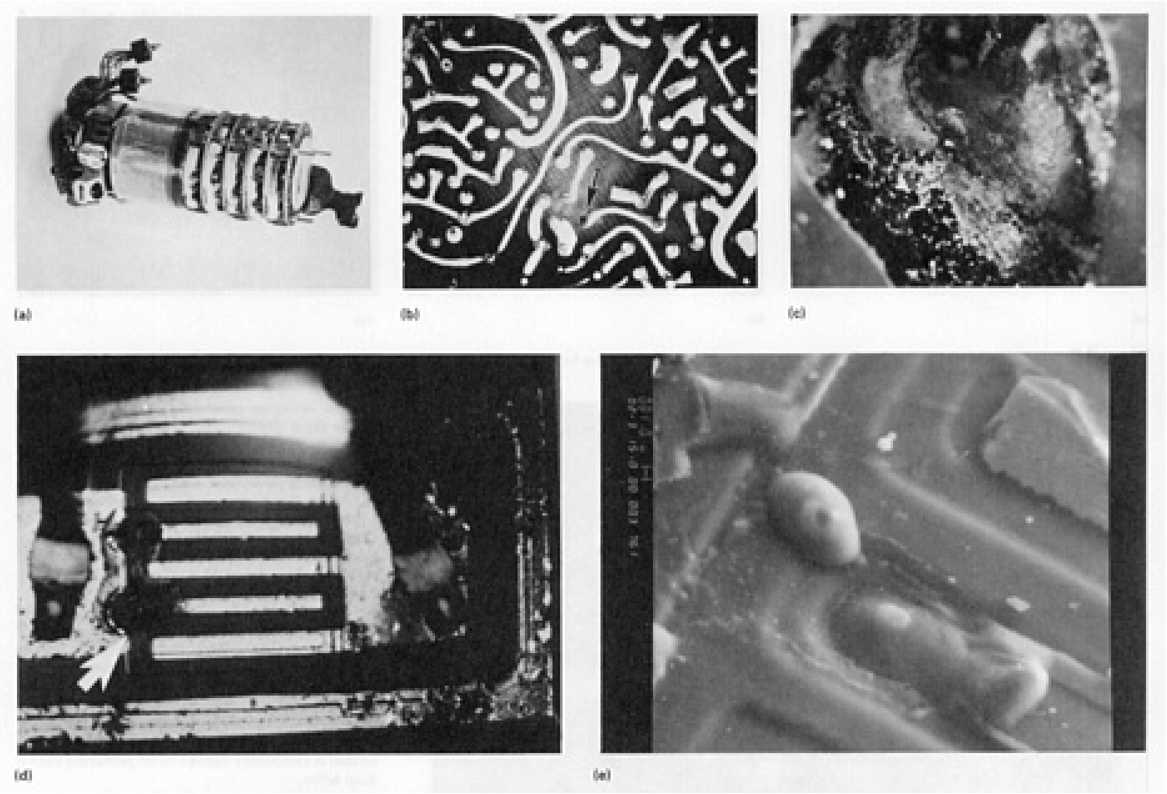

Fig. 11 Fuse that failed from corrosion after several years of storage. (a) Fuse electronics removed from package showing white vibration-dampening foam between printed circuit boards. (b) Corrosion (arrow) caused by chloride contamination on a printed circuit board. (c) Enlargement of area shown in (b). (d) Failed transistor (arrow marks site of open aluminum conductors) with high surface chloride contamination. (e) SEM micrograph of area marked by arrow in (d)

Steering Potentiometer. A linear feedback potentiometer is often used in the steering system of an aircraft nose wheel. A potentiometer of this type is shown in Fig. 12(a). Several failures of this device have been observed. The cause of these failures was investigated. It was found that the ends of the potentiometer were exposed to the environment. Sufficient moisture and contamination were collected on the potentiometer in this area to cause corrosion. Figures 12(b) and 12(c) show corrosion products collecting on the glass header insulation around the incoming electrical wires. These corrosion products were shorting out the electrical leads on the potentiometer. The problem was corrected by providing this area of the potentiometer with sufficient protection to prevent the entrance of the moisture and the contamination.

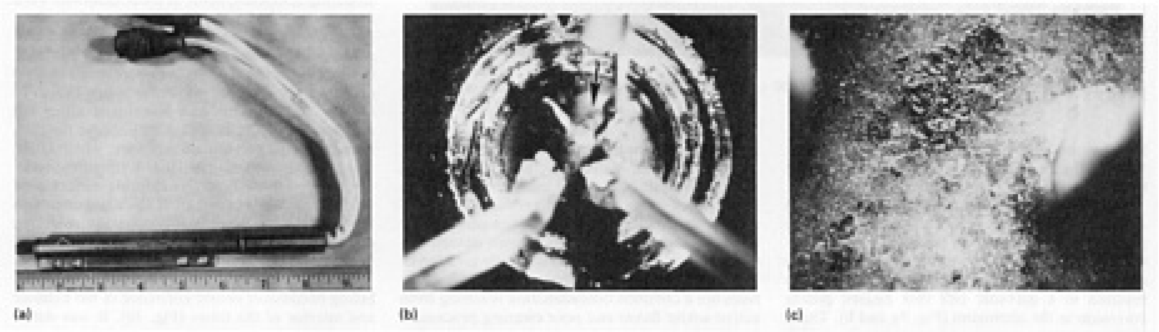

Fig. 12 Linear feedback potentiometer (a) used for aircraft nosewheel steering. (b) Corrosion product (arrow) on potentiometer exterior that shorted out electrical leads. (c) Enlargement of site marked by arrow in (b)

Stepper motors (Fig. 13a) are often submerged inside a fuel tank for cooling purposes. Of course, this means that the motor components are then exposed to the fuel environment. In all cases, there is a small amount of water in the fuel. With sufficient time, this water will hydrolyze polyimide wire insulation.

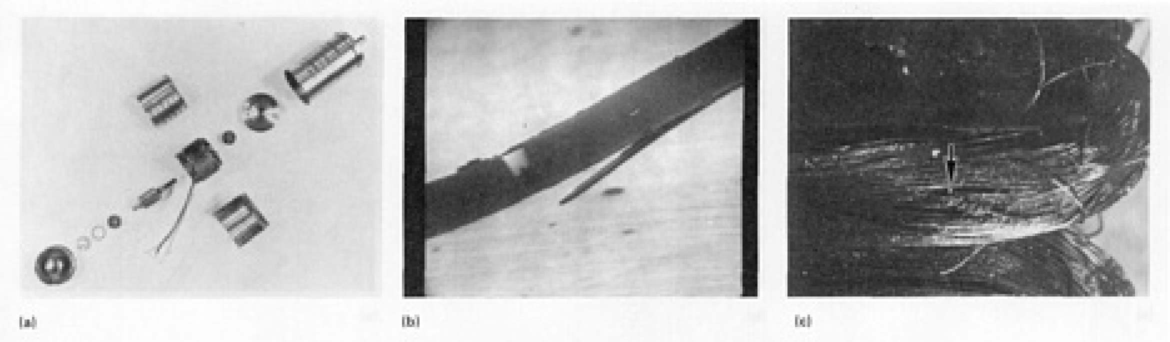

Fig. 13 Exploded view (a) of stepper motor. (b) Cracked polyimide insulation on field coils. (c) Arrow shows site of open field coils.

The stepper motor shown in Fig. 13 had polyimide insulation on the field coils. After sufficient exposure to the water in the fuel, some of the coil insulation cracked (Fig. 13b).

This defect exposes the copper of the field coils to the fuel. If some contamination in the fuel is available, copper ions will migrate into the fuel. This produces open circuits in the field coils, as shown in Fig. 13(c). This type of failure can be avoided by hermetically sealing the field coils from the fuel or by using polysulfide insulation.

An aircraft accelerometer was environmentally sealed instead of hermetically sealed. After extended use, the accelerometer failed. Several accelerometers were tested in the CERT chamber to establish the failure mode. The stresses used in the CERT chamber were selected to approximate the actual aircraft environment and included temperature cycling, humidity cycling, and altitude cycling. The accelerometer was electrically operational during a part of the cycle and failed after 150 test cycles. The package was opened (Fig. 14), and it was easily seen that corrosion residues were shorting out various parts of the circuits. This failure can be eliminated by hermetically sealing the accelerometer package.

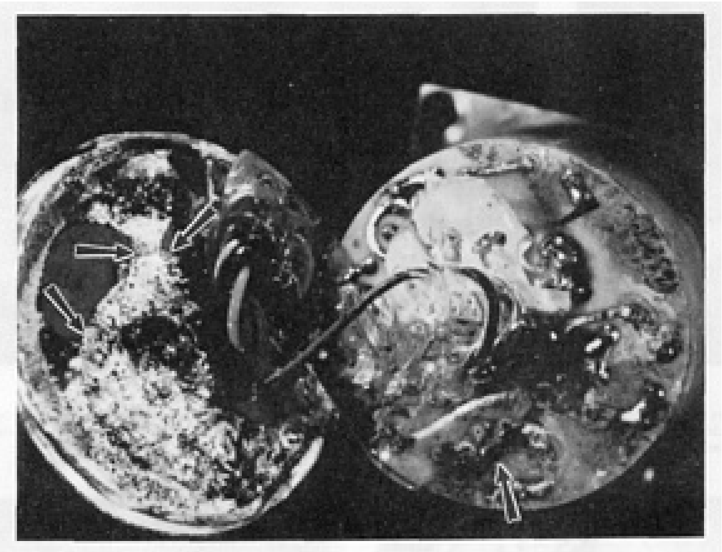

Fig. 14 Aircraft accelerometer that failed after 150 cycles in the CERT test. Arrows show regions of corrosion on the opened accelerometer.

Disk recorder heads (Fig. 15) were failing at a very high rate. This was occurring in an area where the recorder operator was smoking cigarettes. Some of the particulate matter in the smoke was being trapped between the disk and the head. This contamination, along with the moisture available from the air, was causing pitting corrosion in the head (Fig. 15b). It was recommended that the operator avoid smoking in the recording area and that the heads be cleaned with alcohol rather than a halogenated cleaning solvent.

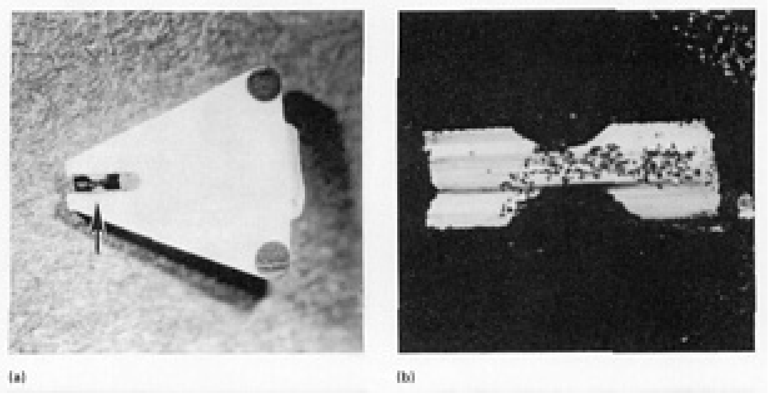

Fig. 15 Disk recorder head that failed by pitting corrosion. (a) Arrow marks metallic head. (b) Close-up view of head marked by arrow in (a)

Electrical connectors are subject to corrosion resulting from a variety of factors, including improper processing and poor design. Two such failures will be discussed.

Radar Modulator. The cause of failure of a radar modulator was identified as a corroded connector. Two connectors, one corroded and the other not, were joined by a wire insulated with a silicone rubber that had a chloride content under 0.16%. The surfaces of both connectors were silver plated. The connectors were sectioned (Fig. 16), and the base material was identified as leaded brass. The silver plating on the uncorroded connector (Fig. 16a) was 6.7 μm thick. The silver plate on the corroded connector (Fig. 16b) was 5 μm thick. Both plating thicknesses are too thin for adequate protection. The plating process should meet Federal Specification QQ-S-365C, which requires a nickel strike and a silver plating thickness of 13 μm. The corrosion was associated with a thin silver plating, and it is believed a silver plating of specified thickness will eliminate the corrosion problem.

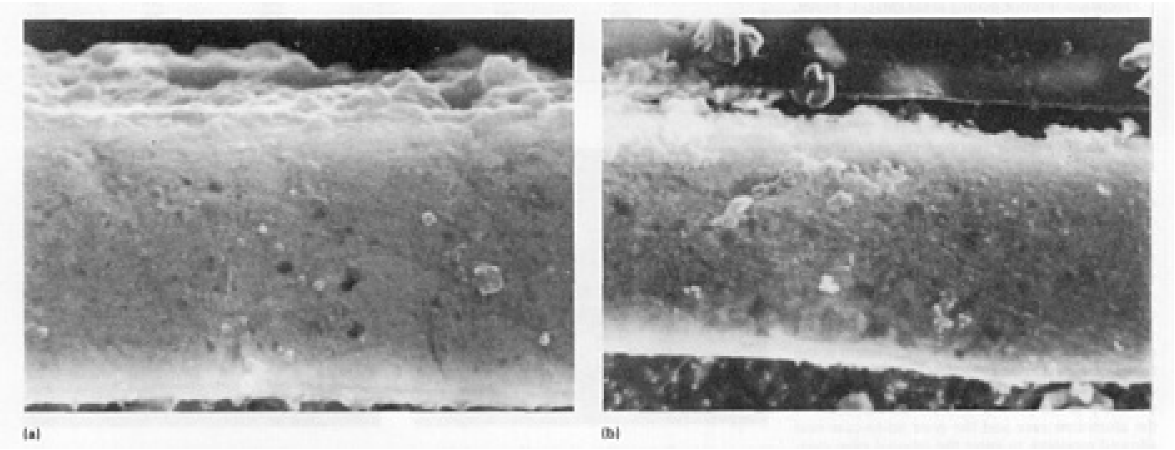

Fig. 16 Cross sections of good (a) and corroded (b) connectors from a radar modulator. The silver plating on (a) was 6.7 μm thick; the plating on (b) was only 5 μm thick. Both 8200×

Low-Voltage Connectors. Corrosion of electrical connectors (Fig. 17) causes a large number of electrical failures. These problems can be minimized by:

- Installing the connectors in a horizontal position
- Placing a loop in the wire so that water will not flow down the wire into the connector
- Using inhibitors on the connector pins and receptacle interior mating areas (MIL-C-81309, Type III)
- Using the proper inhibitors on the external connector surfaces (MIL-C-85054)

It is recommended that an aluminum connector with cadmium plate be used. The possibility of corrosion can be further minimized by using a chromate conversion coating over the cadmium plate.

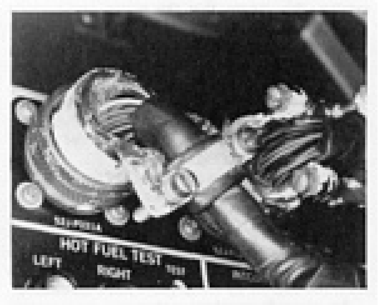

Fig. 17 Corroded low-voltage electrical connector on avionic equipment

A microwave detector (Fig. 18a) failed because of corrosion. The ferrite core surface and cavity of the detector are shown in Fig. 18(b) and 18(c). The detector case was constructed of nickel-plated aluminum. The cavity lid was removed and is shown in Fig. 18(d). Corrosion is visible along the edge. This corrosion is attributed to delamination of the nickel coating and the exposure of a dissimilar-metal couple to high levels of moisture. The nickel coating delamination is the result of a poor plating process. This is usually caused by inadequate cleaning of the aluminum surface prior to plating. The pitting corrosion of the aluminum case and the poor lid-to-case seal allowed moisture to enter the internal case cavity, which resulted in the corrosion shown in Fig. 18(b) and 18(c).

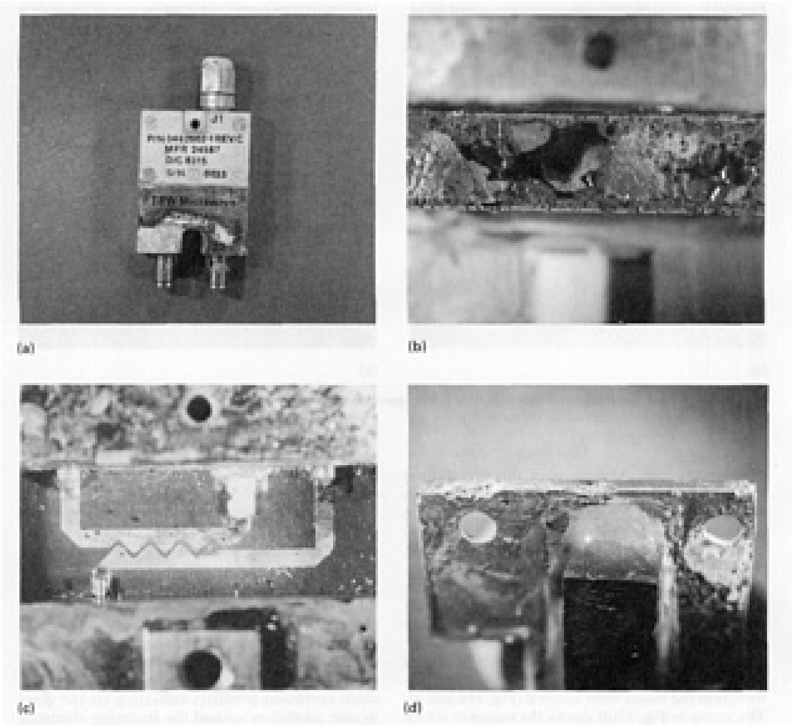

Fig. 18 Microwave detector (a) that failed by corrosion. (b) Corroded ferrite core of detector. (c) Corrosion in detector cavity. (d) Corrosion on the nickel-plated aluminum lid

An alternate plating for the aluminum should be considered. Ion vapor deposited aluminum should be used instead of nickel. A better lid-to-case seal should be obtained through the use of an appropriate gasket material.

Nickel/Boron-Plated Panels. For many applications, materials are required to meet conflicting requirements. An example of this is when metal panels are required to have corrosion resistance and good electromagnetic interference (EMI) protection. Such panels can be used to package electronic equipment.

Twelve nickel/boron-coated aluminum plates were given electrical and environmental tests. Samples 1, 2, and 3 were aluminum alloy 6062; samples 4 and 5 were aluminum alloy 2024. The nickel/boron coating was 90% Ni with 10% B diffused into the nickel. A plate was sectioned, and it was found that the coating was made in two layers (Fig. 19). Each layer was 16 μm (0.625 mils) thick. The faying surfaces were prepared for testing by overlapping the pieces and drilling holes through the panels. The two plates were bolted together with nylon screws, and a torque wrench was used to apply 0.1 J (1 in. · lb) of torque to each bolt.

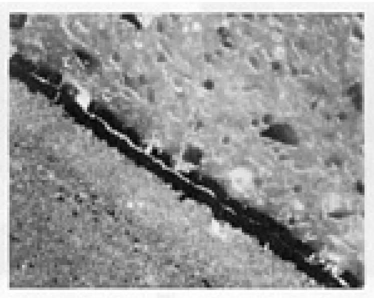

Fig. 19 Cross section of nickel/boron plating on aluminum panel for electromagnetic interference protection

The EMI protection requirement is that all faying surfaces maintain a resistance that does not exceed 2.5 mΩ after environmental exposure. A four-point probe test fixture (Fig. 20) was designed to measure the faying surface conductivity. The outer probes carried 1 A of current, and the inner probes were used to measure the voltage drop. For all measurements, the current was reversed, and the resistance values were averaged.

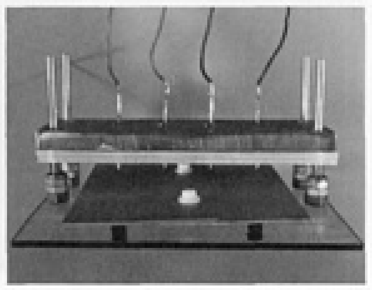

Fig. 20 Test fixture used to measure surface electrical resistance of nickel/boron-plated aluminum test panels

Five of the prepared specimens were submitted to humidity testing (95% relative humidity at 49 °C, or 120 °F, for 10 days), and one was kept as a reference. The specimens were periodically removed for visual inspection and, after retorquing, were measured for surface resistance. The surface resistance measurements for the specimens are shown in Table 1. The condition of sample 1, which was typical of all the samples, after the 10-day humidity exposure is shown in Fig. 21.

Table 1 Faying surface resistance of plates exposed to high humidity

Sample number	Average surface resistance at 1 A, μΩ					
	Initial	**After 24 h**	**After 48 h**	**After 96 h**	**After 192 h**	**Final 240 h**
1	140	245	256	201	226	183
2	130	282	263	220	208	214
3	134	207	230	219	230	243

5	144	374	333	346	356	326

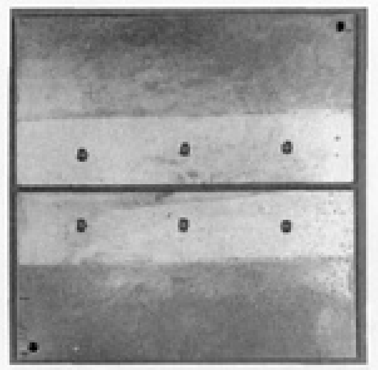

Fig. 21 Typical test panel (sample 1) after humidity testing

The five samples were disassembled and cleaned with distilled water in preparation for a salt fog test. The chamber was set up in accordance with ASTM B 117. A 5% salt solution of 35 °C (95 °F) and a condensation rate of 1 to 2 mils/h/80 cm inside the chamber were used to create the salt fog atmosphere. The specimen plates were bolted together again, as during the humidity test, and exposed to the salt fog for 336 h, or 14 days. The samples were removed periodically for

visual inspection and electrical testing. The samples were washed with distilled water, dried for 2 h, and retorqued before being electrically tested. After testing, the samples were then returned to the chamber.

The results of the electrical testing are shown in Table 2. All five samples exhibited signs of corrosion after 144 h. The number 4 and 5 samples exhibited severe corrosion (Fig. 22a). The surface resistances of these samples were higher than the other samples, but still below the maximum of 2.5 mΩ. After 336 h in the salt fog, samples 4 and 5 again exhibited severe corrosion (Fig. 22b). Only the surface resistance of sample 4 was above 2.5 mΩ after 192 h. After electrical testing, the samples were disassembled. The overlapping surfaces of all samples exhibited corrosion (Fig. 23a); Fig. 23(b) and (c) compare the samples with the least and most corrosion.

Table 2 Faying surface resistance of plates exposed to salt fog

Sample number	Average surface resistance at 1 A, $\mu\Omega$					
	Initial	**After 24 h**	**After 48 h**	**After 96 h**	**After 192 h**	**Final 240 h**
1	198	155	143	203	274	277
2	212	136	134	211	255	260
3	273	162	152	158	155	161
4	220	176	200	799	15,369	20,727
5	198	285	298	332	400	632

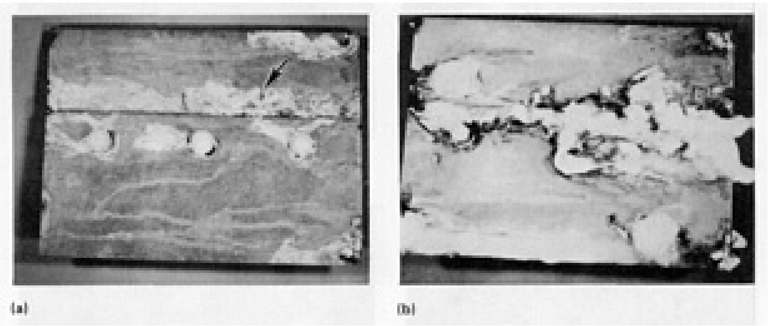

Fig. 22 Severely corroded test panel (sample 4) after 144 h of salt fog testing (a) and after 336 h of salt fog testing (b)

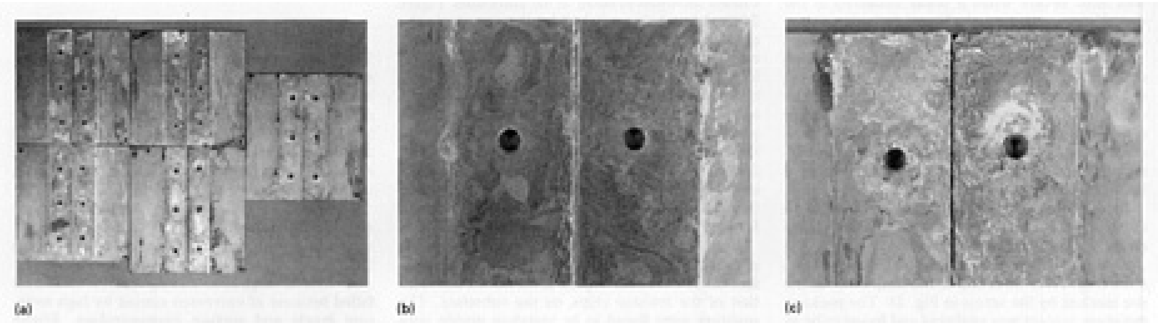

Fig. 23 Surfaces (a) of all samples after 336 h of salt fog testing. (b) Surface of the least corroded sample after 336 h. (c) Surface of the most corroded sample after 336 h

The nickel/boron-coated aluminum plates passed the humidity testing, but they did not perform as well in the salt fog testing. Corrosion was most severe when a break occurred in the nickel/boron coating and allowed the salt solution to penetrate into the coating/aluminum interface. The anodic relationship of aluminum to nickel resulted in pitting corrosion of the aluminum and in the formation of aluminum oxide. Aluminum oxide is an excellent insulator and will significantly

increase the surface resistance of the panel. The plating should be free of surface imperfections and protected from scratches that could break the coating and result in corrosion.

Integrated circuits are highly susceptible to corrosion-induced failure because of their geometries and high densities.

Thin-film chromium resistors in integrated circuits (Fig. 24) were found to fail frequently at the site marked by the arrow in Fig. 24. The package moisture content was analyzed and found to be as high as a few percent in a volume of about 0.5 cm^3 (0.03 $in.^3$). The thin-film resistors were found to be contaminated. Figure 24(b) shows a resistor with the protective glass coat on the integrated circuit. The arrows mark two particles of contamination. Figure 24(c) shows the same two particles of contamination shown in Fig. 24(b), but with the glass coat etched off. The contamination and moisture caused corrosion to occur in the chromium. Figure 24(d) shows holes, marked by the arrows, in the chromium. These holes may be mobile with high current densities and may cluster together. Regardless, the corrosion enlarges the size of the hole until the cross-sectional area of the chromium becomes too small to carry the required current. At this point, the chromium vaporizes and condenses on the glass coating, as indicated by the arrow in Fig. 24(a). This problem is eliminated when the sources of contamination are removed from the resistor and the package moisture content is reduced below a few tenths of a percent.

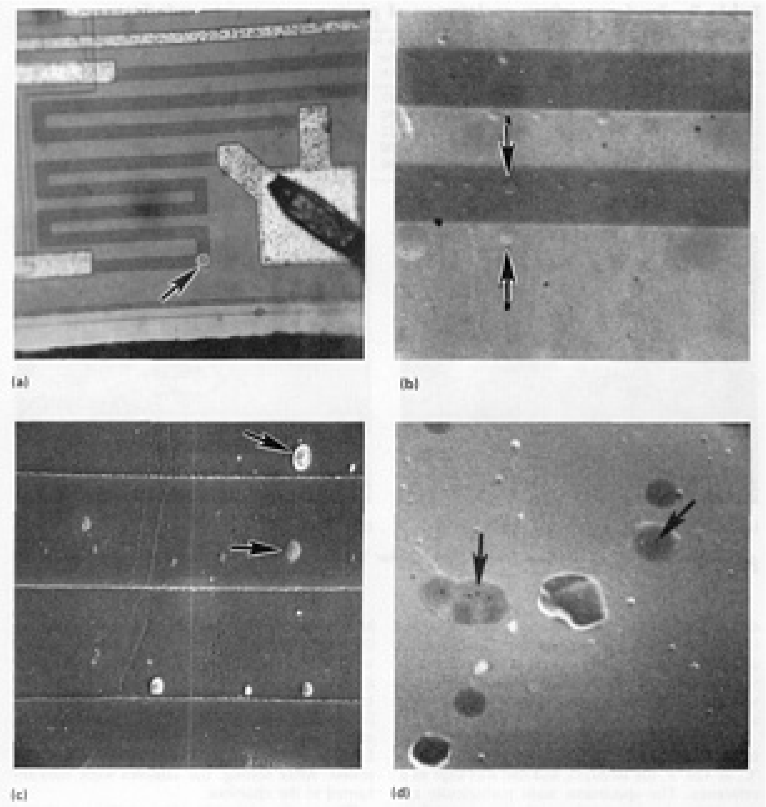

Fig. 24 Thin-film chromium resistor (a) in an integrated circuit showing location of failure (arrow). (b) Close-up of contaminated thin-film chromium resistor. Arrows mark contamination under glass film. (c) SEM micrograph of area shown in (b) with protective glass removed. Arrows mark the same contamination particles as those shown in (b). Holes in thin-film chromium resistor (arrows)

Thin-Film Resistor in a Photodetector. A photodetector was found to fail because the thin-film resistors failed. Figures 25(a) shows the location of the resistor chips on the substrate. The resistors were found to be tantalum nitride with aluminum metallization contact overlays; one of the resistors was completely open (Fig. 25b). There was no protective glass coating on the resistor chips. An Auger spectrum revealed that the resistors were contaminated with phosphorus. The package moisture content was found to be as high as 6%. The high moisture content and the contamination caused the corrosion of the resistor. The disappearance of the metal along the resistor edges is evident on Fig. 25(c).

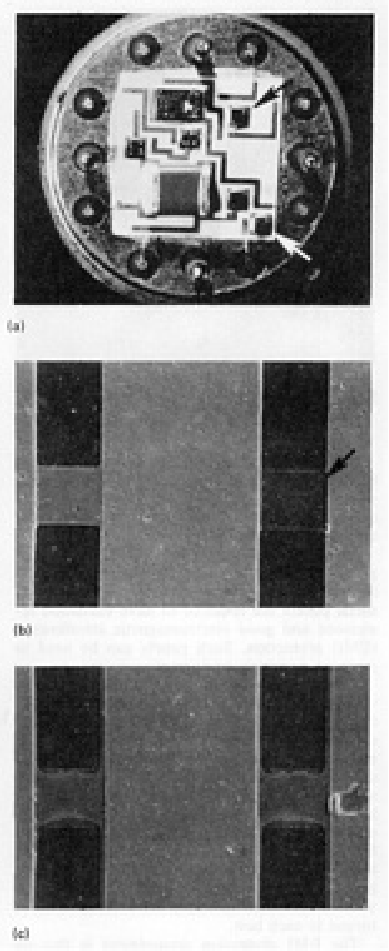

Fig. 25 Thin-film tantalum nitride resistor chips (a) in a failed photodetector. Arrows locate the resistor chips. (b) Open tantalum nitride resistor (arrow) between aluminum contacts. 170×. (c) Errosion along the edges of thin-film tantalum nitride resistors. 170×

Hybrid microcircuits are subject to corrosion-induced failures if packages are not properly sealed or are otherwise contaminated. Two such failures will be discussed.

A hybrid digital-to-analog (D/A) converter failed because of corrosion caused by high moisture levels and surface contamination. Figure 26(a) shows the voltage reference integrated circuit of the converter. The arrows mark damage sites on the aluminum metallization. Figure 26(b) shows the second operational amplifier. The arrows mark the damage sites. The wire bond damage can be seen in the upper right. Figure 26(c) shows an enlargement of the damage site on the operational amplifier. The surface contamination was identified by characteristic x-rays to be chlorine, sodium, and potassium. Corrosion will be minimized if the contamination is eliminated and if the moisture content is reduced.

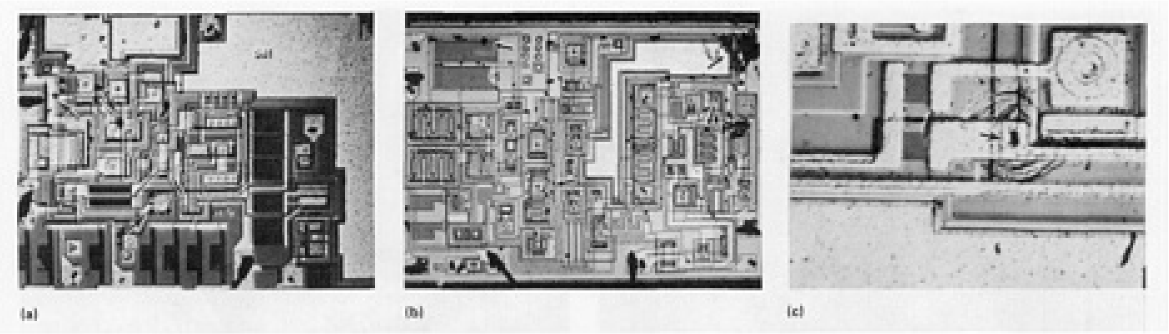

Fig. 26 Failed voltage reference integrated circuit (a) in hybrid D/A converter. Arrows mark corrosion sites. (b) Failed second operational amplifier integrated circuit from hybrid D/A converter. Arrows show corrosion sites. (c) Enlargement of one of the damage sites shown in (b)

Amplifier hybrid microcircuits (Fig. 27a) were analyzed to determine the cause of failure. The gases in the package were analyzed and found to contain high moisture levels as well as NH_3. This environment and some contamination caused the bridging between conductors shown in Fig. 27(b). Many of the chip capacitors were cracked because of poor handling techniques (Fig. 27c). When moisture penetrated this crack into the capacitor interior, significant changes occurred in the value of the capacitance. These failure modes can be minimized by ensuring that the package is a hermetic seal, that the gas contained in the package is dry, that the chip capacitors are not broken, and that the amount of epoxy used inside the package is small.

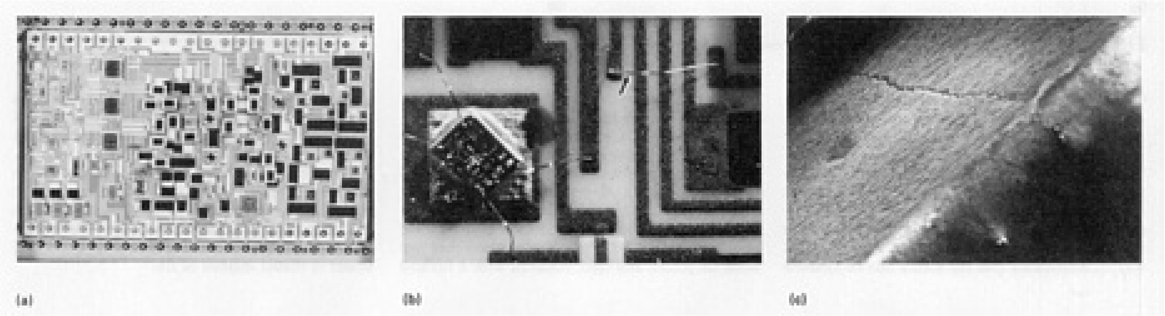

Fig. 27 Hybrid microcircuit (a) from an amplifier. (b) Bridging between conductors on the microcircuit shown in (a). (c) SEM micrograph of cracked ceramic chip conductor from microcircuit. 80×

Klystron electron tubes were failing because of corroded output connectors (Fig. 28). There were some white and green corrosion residues on the connector. With characteristic x-ray analysis, the white residue was identified as a form of tin chloride. The green corrosion was found to contain copper, zinc, and chlorine. The connector was found to be copper plated with silver, followed with a thin plate of gold. The solder used to join the connector pieces was tin, and it appeared that the solder flux was responsible for the chloride contamination. Both the gold plating and the silver plating were found to be thin and porous. It was recommended that the solder flux be cleaned from the connector and that the plating thicknesses be increased so that porosity is eliminated.

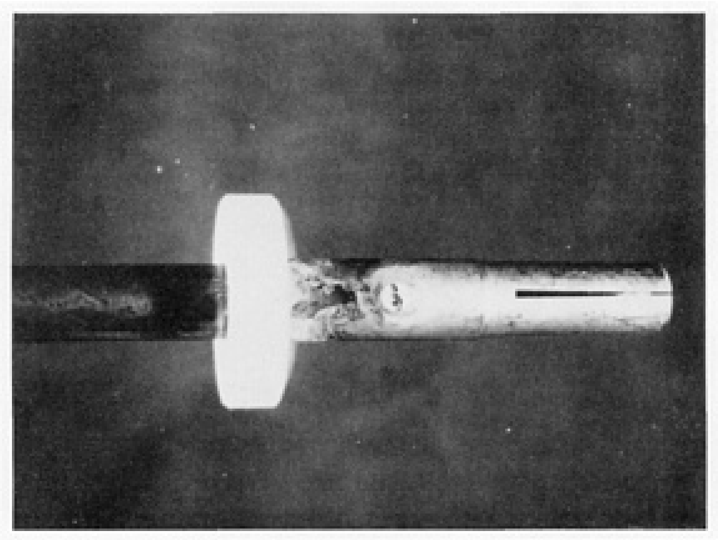

Fig. 28 Corroded output connector from a failed klystron electron tube

Tin Whiskers. Certain hybrid packages were found to have many cases of intermittent operation and failures that could not be duplicated upon retesting. In an investigation of these devices, it was found that whiskerlike growths were extending from the interior surface of the hybrid package lid. The lid was a Kovar metal that had been tin plated and then soldered with a tin/lead solder to the substrate. The whiskerlike growths (Fig. 29) were suspected of shorting out parts of the circuits during certain times, then moving to a different position.

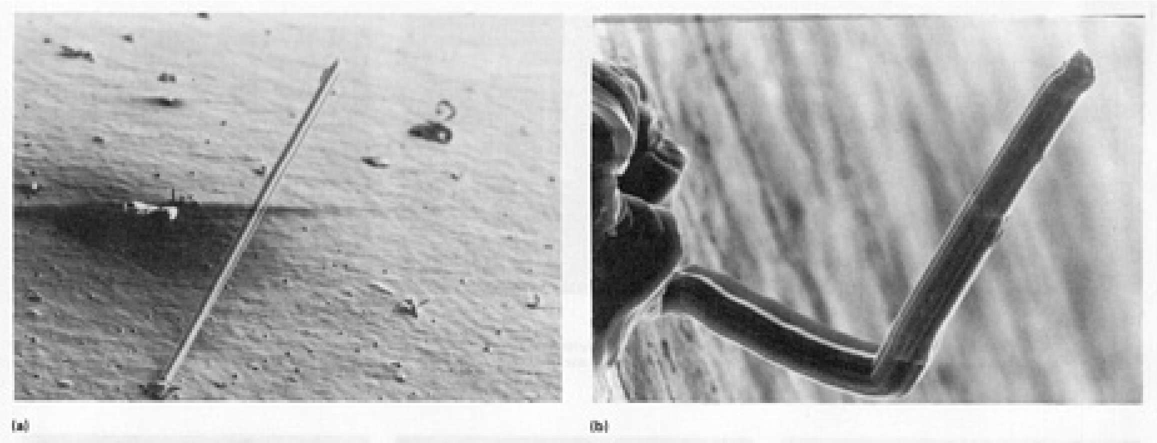

Fig. 29 SEM micrographs of tin whiskers on the interior surface of a hybrid device lid. (a) 245×. (b) 3280×

The actual cause of the whisker growth is unknown, but it is suspected to be an electro-chemical phenomenon to concentration cell corrosion. It is known that the whiskers do not occur if the tin plate is fused or if tin/lead solder is plated instead of tin.

Corrosion in Telephone Cable Plants

George Schick, Bell Communications Research, Inc.

Introduction

THE TELEPHONE CABLE PLANT consists of many different metals and alloys that may be directly exposed to the environment or may become partially exposed because mechanical, electrical, or biological effects, such as dig-ins, lightning, or termites, respectively, have damaged their coating or jacketing. This article will describe the components of the telephone plant where corrosion can take place and will discuss how the environment interacts with such components. This article will also describe various causes of corrosion and their prevention in the telephone plant. Finally, corrosion case histories and their solutions will be described in the aerial, underground, and buried plants.

Metallic Components of the Telephone Cable Plant

The telephone cable plant consists of many materials. In this section, the various metals that most often pose a corrosion problem and the typical locations in the plant where these problems occur will be identified.

Although only small amounts of new lead-sheathed cable are placed in the telephone plant, it still represents a substantial percentage of in-place cables, especially in the underground plant. The amount of polyethylene-jacketed cables is increasing. These cables contain aluminum or aluminum and steel shields. The multipair cables contain an enormous amount of copper. Some plastic-jacketed cables crossing rivers, lakes, or seas are mechanically protected with bare, jute and tar covered, or neoprene-jacketed galvanized steel armor wires.

Where the ends of two cables are joined or where part of a large cable branches off, the connections (splices) are enclosed in closures usually made of galvanized cast iron held together with stainless steel fasteners (aerial, underground, and buried plant), tin-coated steel (buried plant), aluminum (aerial plant), lead (aerial, underground, and buried plant), stainless steel (underground plant), or plastic (aerial, underground, and buried plant). Coaxial cables in the underground plant have tin-coated brass terminals. In the buried plant, metallic closures are protected with field-applicable coverings; in the underground plant, they are usually left bare. Carrier systems, which require signal amplification with repeaters, include apparatus cases of galvanized steel and galvanized cast iron held together with a stainless steel band clamp; repeater housings made of plastics are joined with stainless steel fasteners and may have tin-coated brass inserts (valves) for gas pressurization.

Support hardware in manholes, guy wires, rods, and anchors and most aerial strands are composed of galvanized steel. The wires used for lashing cables to aerial strands are made of galvanized steel or stainless steel. Some of the aerial strands have aluminum coatings; until about 30 years ago, telephone companies used Monel support hardware in very corrosive manholes.

Grounding systems use a variety of metals. Copper, copper-clad steel, galvanized steel, and stainless steel are used in rod or wire form to contact the earth, and copper (bare or insulated) wires, copper, and tin-coated copper ribbons or braids serve as conductors between the plant and the components that contact the earth. Connectors and clamps, depending on the area and type of exposure, are of copper, brass (in coated or bare), bronze (underground and buried plants), steel, galvanized steel, stainless steel, and aluminum (for exposure only to the atmosphere). Protector devices contain brass components that are exposed to the atmosphere because their plastic or aluminum housings require occasional reentry; thus, they are not sealed against moist and polluted air.

Access to the underground plant is provided with precast or cast-in-place concrete manholes. Because wet concrete is a conductive medium, the steel reinforcing bars of these manholes are indirectly exposed to the environment.

Interaction Between Telephone Cable Plants and the Environment

In this section, only the chemical effects of the environment and its pollutants or additives will be considered in general terms. Under non-extreme conditions (absence of stray dc currents, specific extremely corrosive chemicals, and strong

bacteriological colonies), directly exposed metals and alloys often fare better, because their selection criteria include corrosion resistance. Coated or jacketed metals and alloys rely on separation from the environment for corrosion protection. Man-made corrodents, design effects, and special environmental effects, such as stray currents, galvanic couples, and bacterial corrosion, respectively, will be discussed in the section "Causes of Corrosion" in this article.

Aerial Plant. The three most distinguishable environments to which the aerial plant can be exposed are industrial, marine, and rural. There are ever-increasing areas where these environments overlap. For example, some industrial complexes are located very close to the seashore, creating marine-industrial atmospheres. In suburban areas, pollution by automobile exhaust systems increases the corrosivity of the otherwise rural atmosphere, and the acid rain and chemicals used for fertilizers in rural areas can create corrosive conditions.

Industrial Atmospheres. The primary pollutants in the industrial atmospheres are carbon dioxide (CO_2) and sulfur dioxide (SO_2), but it can also contain nitrogen dioxide (NO_2), hydrogen sulfide (H_2S), chlorine (Cl_2), and ammonium compounds. These pollutants create acidic compounds that readily attack zinc and steel. Sulfur dioxide and NO_2 are also oxidizing agents, and together with O_2 in the air, they maintain the passive film on aluminum. Thus, aluminum or aluminum-coated steel may corrode less than galvanized steel in some industrial environments. Chemical plants may create extremely aggressive environments in their vicinity. For example, a plant that produces Cl_2 gas from salt brine electrolysis may occasionally release Cl_2 into the atmosphere. Because Cl_2 in contact with moisture forms hydrochloric acid (HCl), the telephone plant at such a location can experience corrosion failures of galvanized steel, discontinuity of aluminum shields at the nonhermetically sealed splice closures of polyethylene-jacketed cables, and advanced corrosion of brass binding posts, which may in turn lead to current leakage and noise.

Marine atmospheres can deposit airborne salt solution droplets, which generally attack galvanized steel. At seacoastal areas where fog frequently causes condensation of a thin moisture layer on the aerial plant, the corrosive conditions increase because the chloride salt deposit is reactivated by the moisture, and the moisture is saturated with air, which acts as a cathodic depolarizer, thus increasing the rate of corrosion. In such areas, even 400-series stainless steel lashing wire may corrode. Chloride salts can also corrode aluminum. This corrosion is usually localized, and it causes pitting. Marine atmospheres can affect copper and copper-base alloys, but their rates of corrosion are low compared to that of galvanized steel or aluminum.

Rural atmospheres, where the only corrosive medium is rain or moisture condensate containing CO_2, are the least aggressive to the aerial plant. Corrosion, if any, usually appears in the form of dull haze on galvanized steel, aluminum, lead, and copper or brass surfaces. Areas affected by acid rain may exhibit a similarity to industrial atmosphere.

The underground plant contains cables and hardware placed in circuits and manholes. Although new conduits are made of plastics, such as polyvinyl chloride (PVC) and polyethylene, the majority of those in the field are made of clay (old conduits), concrete, and fiber-cement (transite), all of which conduct electric current when permeated with moisture. The manholes are usually precast or cast-in-place concrete, both of which are reinforced with a network of steel bars. Older manholes are made of brick without steel reinforcing bars. Concrete, when permeated by moisture, also becomes a conductive medium. Because fresh concrete is alkaline, it passivates the reinforcing bar surfaces, thus rendering them more corrosion resistant than before passivation.

A large percentage of manholes are fully, partially, or seasonally flooded, and the waters contain soluble salts of the native soil. Some of these salts may be corrosive. Conduits may also contain mud and silt that can cause localized corrosion of lead cable sheaths. Manholes located close to the sea may be flooded with seawater, which is corrosive to all bare metallic components. Conduits and manholes may also contain man-made pollutants, such as deicing salts, industrial effluents, and fertilizers. Fertilizers containing ammonium compounds can cause stress-corrosion cracking (SCC) of stressed brass components. It is interesting to note that in the past, when cable ducts were made of wood, many lead cable sheaths failed by corrosion. Investigations indicated that acetic acid (CH_3COOH) leached from the wood caused these failures.

The buried plant is directly exposed to the earth, although some of the cables may be pulled into buried plastic conduits. Some of the older lead-sheathed cables are exposed to a wide variety of salts in various concentrations and to soils of widely varying PH. The soil in the United States ranges from 2.3 (acidic) to 9.5 (alkaline). Local conditions may cause even wider variations; for example, cinders may be strongly acidic. The buried plant can also be exposed to man-made corrodents, such as deicing salts, industrial effluents, and fertilizers. In addition to lead-sheathed cables, bare galvanized steel mounting posts of pedestal terminals and ground rods in the buried plant are exposed to the soils.

Causes of Corrosion

In this section, the corrosion-accelerating effects of electric currents, dissimilar metals, variations in the environment, combination of stresses and corrodents, and bacterial effects will be discussed. The various built-in and externally applied corrosion control measures will be discussed in the section "Corrosion Prevention" in this article.

Stray Currents and Interference Currents. Stray currents and cathodic protection interference currents create the most aggressive corrosive environment for the underground and buried telephone plants and for some components of the aerial plant, such as ground rods, guy rods, and anchors. Stray currents originate from grounded dc-powered systems, such as dc rail transportation (trains and subways), mining operations, welding plants, and high-voltage dc power transmission. The direct current from stay current sources usually travels through the environment and enters the telephone plant where its resistance to ground is low, for example, central offices, manholes, or bare lead cable sheaths. The current enters the environment from the telephone plant near its source, seeking a path of least resistance back to its origin. The location where the current leaves the telephone plant to enter the surrounding environment is where the plant corrodes. Inside multipair cables (not gas pressurized or filled) where water can enter the cable core and where small defects in the poly-ethylene wire insulation expose bare copper, the central office battery can provide driving voltage for corrosive current flow between wires that have a 48-V potential difference.

Interference currents originate at impressed-current cathodic protection installations of other (foreign) underground structures. The telephone plant can pick up such currents by crossing or closely paralleling the foreign structure, for example, gas pipelines. A potential gradient field exists around the impressed-current anode (anode field), with the potential being the highest (most positive) at the anode and with the current flowing away from the anode. The current flowing through the earth toward the protective structure creates a cathode field around it and renders the structure negative. Where the telephone plant passes through the anode field, the interference current enters the plant near the anode, flows on the cable in two opposite directions, and leaves (causes corrosion) the plant at two different locations some distance away, depending on the extent of the anode field and the resistance of the plant to the ground. When the telephone plant passes through a cathode field, it collects stray currents from extensive areas, and the current enters the environment (causes corrosion) at an area near the connecting point of the foreign plant to the negative output of the rectifier.

Galvanic Effects. Corrosive galvanic couples are unavoidable in the telephone cable plant. Although bare metallic components are necessary to provide electric safety through grounding, metals at various positions on the galvanic scale are used because of strength, conductivity, formability, and cost requirements. Galvanic corrosion may also take place between the telephone plant and other grounded, foreign metallic structures, such as copper or copper-clad ground rods.

In the aerial plant, galvanic corrosion is not a primary concern. This is because the corrosive environments exist in the form of thin moisture layers; thus, the electrolyte represents a relatively high-resistance path. Galvanic corrosion is expected in industrial and seacoastal environments where lead-sheathed cable is lashed to galvanized steel strand with galvanized steel or stainless steel wire. Corrosion caused by the bimetallic coupling is restricted to the vicinity of the contact area.

In the underground plant, the electrolyte is contaminated water, mud, and silt in manholes and conduits. The plant components that corrode the most, as a result of bimetallic coupling, are galvanized steel support hardware and galvanized steel or galvanized cast iron closures. The corrosion-accelerating cathodes are steel man-hole reinforcing bars (passivated by the alkalinity of the concrete), lead cable sheath, copper-base alloy (brass, bronze) closures and hardware, stainless steel closures and fasteners, and tinned or bare copper bonding conductors. Copper pipes or grounding conductors in foreign plants bonded to the telephone plant may also act as corrosion-accelerating cathodes.

In the buried plant, lead cable sheath or galvanized steel pedestal mounting posts can galvanically corrode through direct or indirect contact to copper ground rods, grounding conductors, or power cable concentric neutrals. Although, strictly speaking, galvanized steel guy rods and anchors are part of the aerial plant, they are directly buried in the soil. Copper and copper-clad ground rods of the power company cable plant may be indirectly connected to the rods and anchors through bond wires and cable shields. Such bi-metallic coupling can cause galvanic corrosion of the galvanized steel.

Concentration Cell Effects. Bare lead sheath cables in conduits that contain water usually corrode by differential aeration cells where the cables are in contact with the conduit wall. The presence of mud or silt in the conduit further enhances this effect. Directly buried cables and other buried structures, such as fuel storage tanks, compact the soil below them more than at their tops or sides. Because compacted soil contains less dissolved oxygen than loose soil, differential

aeration cells develop under these conditions. Concentration cell corrosion can also take place where a bare lead cable sheath passes through soils of various composition or where ground rods or guy rods pass through soil layers of different compositions.

Stress-Corrosion Cracking. Although many telephone plant components have residual manufacturing stresses or applied stresses, they are seldom exposed in environments that induce SCC. The most notable exceptions to this rule are the stressed copper-base alloys. Low concentration of ammonia or ammonium compounds present in industrial pollutants or in fertilizers have caused SCC of copper-base alloys. Most of these failures involved yellow brass (65Cu-35Zn) or cartridge brass (70Cu-30Zn).

Hydrogen-stress cracking usually takes place where hydrogen enters the stressed metal. In the telephone cable plant, this phenomenon was found on some stainless steel fasteners in contact with galvanized steel or galvanized cast iron. The galvanic coupling generated the hydrogen on the stainless steel cathodes.

Corrosion Fatigue. The aerial cable plant is exposed to winds and, as a result, to cyclic movement. This movement exerts cyclic stresses. The copper tail wire of aerial clamps exposed to cyclic stresses in a marine atmosphere can experience corrosion fatigue failure.

Bacterial Corrosion. The most frequently encountered bacterial corrosion in the telephone cable plant is caused by sulfate-reducing bacteria. Such bacteria can cause corrosion of lead cable sheath in anaerobic soils (dense clay-type soils) in the pH range of 5.5 to 8.5. The same bacteria can also thrive in stagnant manhole water and corrode the galvanized steel support hardware. The bacteria reduces inorganic sulfates to sulfides when organic matter is present according to the following reactions:

$$\text{At the anode } 4Fe \rightarrow 4Fe^{2+} + 8e^-$$

$$\text{At the cathode } 8H_2O \rightarrow 8H \text{ (adsorbed on the metal)} + 8OH^- - 8e^-$$

$$8H \text{ (adsorbed)} + Na_2SO_4 \xrightarrow{\text{bacteria}} 4H_2O + Na_2S$$

$$Na_2S + 2H_2CO_3 \rightarrow 2NaHCO_3 + H_2S$$

The overall reaction is $4Fe + 2H_2O + Na_2SO_4 + 2H_2CO_3 \rightarrow 3Fe(OH)_2 + FeS + 2NaHCO_3$.

Corrosion Prevention

In general, telephone cable plant corrosion-preventive techniques fall into two major categories: those incorporated into the design and those applied in the field when conditions require them.

Corrosion Prevention Incorporated in the Design. Most new cables placed in service since the 1950s are polyethylene jacketed. The polyethylene outer jacket reduces the stray and interference current pickup and discharge areas and protects the cables from chemicals, such as organic acids and nitrates, as well as galvanic and concentration cell effects that attack the lead cable sheath. In the aerial plant, self-supporting cable encloses both the cable and support strand in polyethylene, and continuous polyethylene web holds the two together, describing a figure 8 cross section. This construction protects both cable and strand from the environment and precludes the need for lashing wire, thus eliminating a galvanic couple between galvanized steel and stainless steel. Many splice closures and apparatus cases are also made of noncorroding plastics with stainless steel fasteners and generally corrosion-resistant tin-coated copper-base alloy inserts, for example, pressure valves. As a second line of defense, the aluminum and steel cable shields, under the polyethylene outer jackets, are covered with flooding compounds that can seal small defects on the polyethylene outer jacket and prevent moisture entry. Further protection of polyethylene-insulated wire pairs in the cable core is accomplished with a gel-type filling compound that occupies the space between the wires and prevents moisture entry. Similarly, filling compounds are also used in some splice closures to prevent the corrosion of splices.

Metallic coatings are also used for corrosion protection of the telephone cable plant. Practically all support hardware is made of galvanized steel. The thickness of galvanizing depends on the severity of the exposure. For example, support strands have 205 to 285 g/m^2 (0.65 to 0.90 oz/ft^2) of zinc (class A galvanizing) at mild, rural areas and 470 to 850 g/m^2 (1.5 to 2.7 oz/ft^2) of zinc (class C galvanizing) at industrial and seacoastal areas. Because aluminum coating is several times more resistant in industrial atmospheres than zinc of the same thickness, aerial support strands are also used with aluminum coating in industrial environments (Ref 1).

Brass housings for terminals or transducers, brass valves, most of the copper bonding ribbons, and some of the copper-base alloy connectors used in manholes are tin coated. The coating is applied primarily to reduce the galvanic potential differences between the copper or copper-base alloys and the more active metals (galvanized steel, lead) in the manhole.

When the strength, forming, conductivity, or cost requirements override galvanic-corrosion considerations, mitigation measures must be applied to reduce the corrosive effect of bimetallic couples. One such method is to design the component made of the more noble metal (cathode) small as compared to the more active metal. Stainless steel bolts and nuts holding together galvanized cast iron splice cases or tin-coated brass valves in galvanized cast iron splice cases exemplify this method.

The steel reinforcing bars in precast or cast-in-place concrete manholes are passivated by the alkalinity of the concrete. Their potential can be as noble as -0.2 V versus a standard copper/copper (cupric) sulfate reference electrode. The potential of galvanized steel support hardware in the same manhole may be as active as -1.1 V versus the same reference. The surface area of the reinforcing bars can be considerably larger than that of the support hardware. These conditions can lead to galvanic corrosion of the galvanized steel in flooded manholes. At areas where the manhole reinforcing bars need not be part of the ground, an option is given to break the bimetallic couple. The reinforcing bar system is contacted through a welded steel stud in each manhole section, and short sections of tin-coated bonding ribbons are attached to them inside the manhole. The support hardware is mounted on the manhole wall through nonconductive bushings to avoid accidental direct contact with the reinforcing bars. This system can provide or eliminate contact between the reinforcing bars and the rest of the plant.

Materials selection and heat treatment can reduce susceptibility to SCC. Using annealed red brass (85Cu-15Zn) instead of stressed cartridge brass (70Cu-30Zn) and using commercial bronze (90Cu-10Zn) instead of yellow brass (65Cu-35Zn) where applied stress cannot be eliminated are good examples of these methods.

Corrosion Prevention for Existing Plants. Because the telephone cable plant corrodes the most under the influence of stray and interference currents, the most important preventive measures are to reduce such currents entering the plant and, if that is not possible, to provide a metallic path for these currents to return to their origin. Central offices usually represent low resistance to ground and thus serve as current pickup areas. Insulating joints that cut into the cable shields just before crossing through the wall of a cable entrance facility can stop such current pickup. Insulating joints can also be cut in cables where they enter other large buildings (low-resistance grounds) or, because the shield of an aerial cable can carry stray currents, on the riser poles connecting aerial to underground or aerial to buried plants. Strain insulators are often placed in the guy wires to prevent stray, interference, or galvanic currents from corroding guy anchors and rods.

In stray or interference current areas, a potential survey over the plant can establish the location(s) where such currents corrode the telephone plant. Current leaving the plant through the environment will render its potential more positive (less negative) than in the absence of such currents. Low-resistance drainage or interference bonds connecting the telephone plant to the system where the stray or interference current originates serve as a conducting path to avoid corrosion. Where the stray current originates at a dc transport system, the magnitude and direction of the current changes with time and may flow toward the telephone plant, causing corrosion at another location. In order to prevent this undesirable current flow, a reverse current switch is placed in the drainage bond, thus allowing the current to flow away from the telephone plant but blocking the current flow in the opposite direction.

Cathodic protection is used as a corrosion-reducing measure in stray and nonstray current areas. At stray or interference current locations, galvanic or impressed-current systems are used when bonds and insulating joints do not solve the problem. Care must be taken to avoid overprotecting the lead-sheathed cable. Lead that is polarized to a more negative potential than -1.5 V may be cathodically overprotected. The cathodic reaction generates a strongly alkaline environment at the lead surface. Lead, an amphoteric element, dissolves in strong alkalies; thus, cathodic overprotection leads to lead corrosion.

Most coated steel fuel tanks are cathodically protected. Small tanks that do not have the ground paved over them are protected with galvanic anodes. Large tanks, and where the surface is paved over the tank, are protected with impressed-current systems. In flooded manholes, the cathodic protection applied consists primarily of magnesium anodes.

The central office batteries are grounded at the positive terminal to prevent the corrosion of lead cable sheath and conductors at wire insulation defects in polyethylene-jacketed cable if and when water enters the cable core. Negative grounding would corrode lead cable sheath the same way as stray currents would. Inside the cable, one member of the wire pair is grounded together with the bare aluminum cable shield. The other conductor of the pair is connected to the -48 V terminal of the central office battery. If water enters the cable core, the corrosion currents will flow from a very large surface area of the shield (as compared to the size of an insulation defect on the wire), and the very low corrosion current density will cause negligible corrosion of the shield. Other field-applied corrosion control measures are wrapping galvanized cast iron splice closures or tin-coated steel sleeves with hot- or cold-applied tapes for buried plant use and protecting lead sheath cable segments with irradiated cross-linked heat-shrinkable polyethylene sleeves.

Case Histories

Example 1: Corrosion Fatigue of the Tail Wire of an Aerial Clamp.

The small cable (drop wire) providing service for individual subscribers from the aerial plant is held in place by a clamp made of a tin-coated brass body (attached to the cable) and a copper tail wire loop (attached to a galvanized steel hook or to a porcelain insulator). The tail wire is 2.6-mm (0.102-in.) diam annealed copper, and the clamp assembly must withstand a 2470-N (555-lb) load without breaking or slipping.

A number of these clamps, located a few hundred feet from the ocean, have failed (Fig. 1). The sharply broken wire indicated to weakening by abrasion. The combination of the corrosive action of saltwater spray and cyclic stresses arising from the "dancing" of aerial cables can cause failure by corrosion fatigue. The copper tail wire failures indicated characteristics that are generally associated with corrosion fatigue. The broken wires showed multiple cracks near the failure (Fig. 2 and 3). The cracks are transgranular and originate at the bases of pits (Fig. 4). These pits can act as stress points; therefore, the stress and number of stress cycles that cause corrosion fatigue failure of a metal are lower than the fatigue limit of the same metal without the corrosive environment.

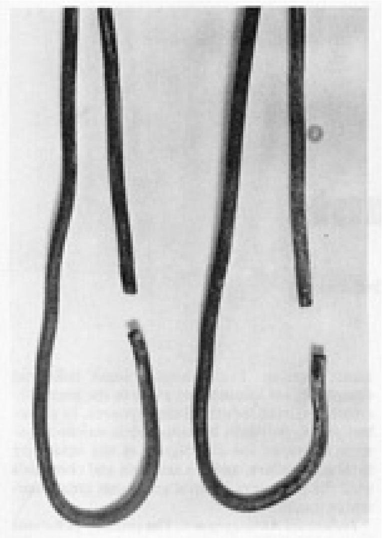

Fig. 1 Broken copper tail wires of an aerial clamp

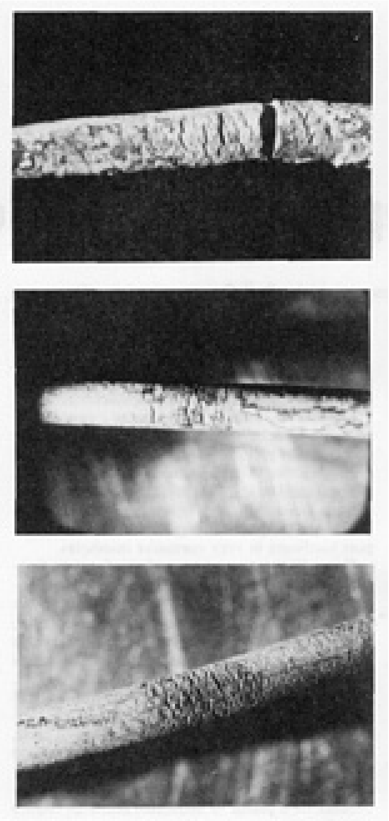

Fig. 2 Tail wires near failures. 3×

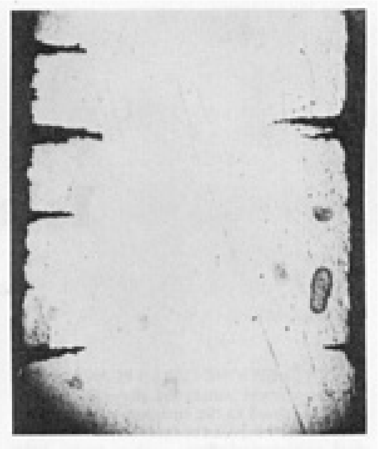

Fig. 3 Photomicrograph indicating many closely spaced cracks near a failure. 14×

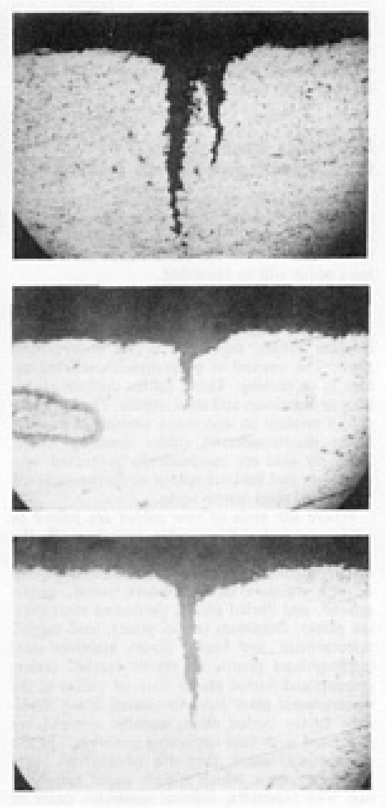

Fig. 4 Photomicrographs of transgranular cracks on copper tail wires. The cracks are initiated at the bottoms of the pits. 60×

Based on the circumstances of exposure and the characteristics of the cracks, it was diagnosed that the copper tail wire failures were due to corrosion fatigue. The solution to this problem was to change the tail wire material for direct seashore exposure from annealed copper to annealed Monel. The annealed Monel has a corrosion fatigue limit in saltwater that is 2.8 times higher than that of annealed copper (Ref 2).

Example 2: SCC of Aerial Plant Fuses.

Several fuses, made of nickel silver (57 to 61% Cu, 11 to 13% Ni, bal Zn), exposed in central offices where the air contained industrial atmospheric contaminants that were particularly high in ammonium and nitrate ions failed by SCC (Fig. 5). Test solutions of 1 *N* ammonium nitrate (NH_4NO_3) and a 1:1 mixture 1 *N* sodium nitrate ($NaNO_3$) and 1 *N* calcium nitrate ($Ca(NO_3)_2$) were prepared (NH_4^+, Na^+, and Ca^{2+} were the major cations in the pollutants). In addition, stressed fuses made of nickel silver and of cupro-nickel (80Cu-20Ni) were exposed to 1 drop of corrosive solution at the stressed area. All specimens were exposed for 42 days in a container in which the relative humidity was maintained at 76%.

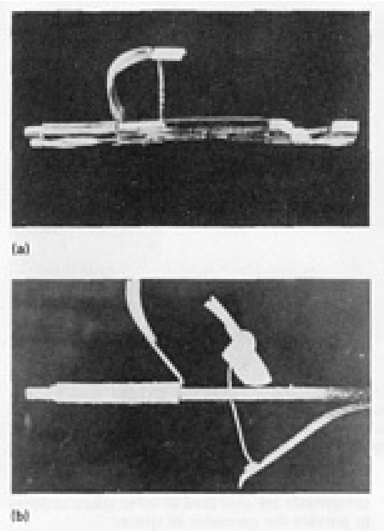

Fig. 5 Nickel-silver aerial plant fuses. (a) New exposed fuse. (b) Fuse that failed because of SCC

All nickel silver specimens failed after 2 days of exposure to NH_4NO_3 solution. However, 17% of them failed and 67% showed crack initiation but no failure after 42 days of exposure to $NaNO_3$ + $Ca(NO_3)_2$ solution. None of the cupro-nickel specimens failed, but among those exposed to NH_4NO_3, 17% displayed crack initiation and 83% showed partial dealloying after 42 days. Based on the test results, the fuse material was changed from nickel silver to cupro-nickel, and this material change solved the SCC problem.

Example 3: Hydrogen-Stress Cracking of Type 410 Stainless Steel Splice Case Bolts.

Type 410 stainless steel bolts were used to hold together galvanized gray cast iron splice case halves. Before installation, the bolts were treated with molybdenum disulfide (MoS_2) antiseize compound. The torque applied to these bolts can exceed 70 N · m (600 in. · lb). In flooded manholes, the galvanic-corrosion reaction between zinc (galvanizing) and stainless steel can generate hydrogen at the stainless steel cathode. The rate at which absorbed hydrogen on the cathode combines to form H_2 gas is affected by the catalytic properties of the metal surface. Good catalysts, such as iron, increase the rate of H_2 formation; poor catalysts do not. Catalyst poisons, such as sulfides, retard the formation of H_2, increase the concentration of atomic hydrogen on the cathode surface, and therefore facilitate the entrance of hydrogen atoms into the metal lattice, causing loss of ductility. In stressed high-strength alloys, such as type 410 stainless steel, they induce hydrogen-stress cracking (Ref 3). For the type 410 splice cause bolts, the MoS_2 antiseize compound provided the catalyst poison.

Several failures of splice case bolts were discovered in flooded manholes after they were in service for 3 to 4 months (Fig. 6 and 7). Laboratory experiments were conducted to determine if the failure mode was hydrogen-stress cracking, if sulfides accelerate the failure, if heat treatment can improve the resistance against this failure mode, and if the type 305 austenitic stainless steel would serve as a replacement material.

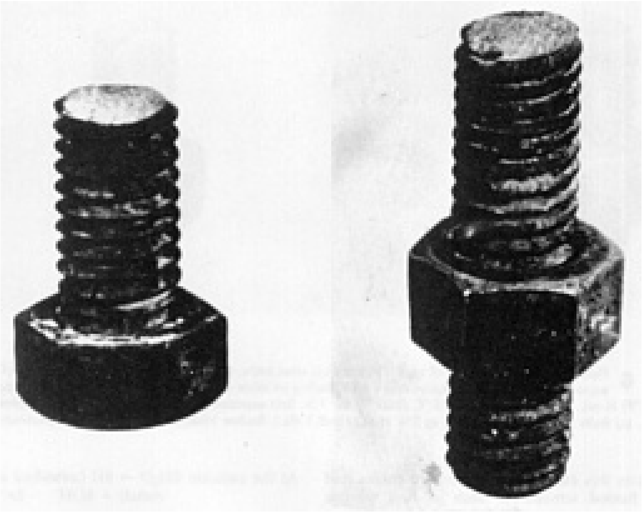

Fig. 6 Field failures of type 410 stainless steel bolts

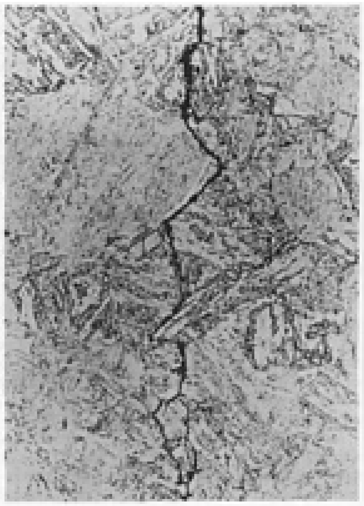

Fig. 7 Section of type 410 stainless steel bolt. The bolt failed after 3 months of service in a flooded manhole. 180×

The experiments were conducted in sulfuric acid (H_2SO_4) solution that contained 1 mL/L Rodine inhibitor. The test specimens were tightened in a high-strength steel fixture with 60 N · m (540 in. · lb) of torque. Three threads of each bolt were exposed to the solution, and the remainder of the assembly was covered with paraffin wax. The bolts (cathodes) were connected to the negative terminal of a battery through a current-limiting resistor against a platinum anode and cathodically charged with hydrogen. The time to failure was measured. All type 410 stainless steel bolts were quenched from 1010 to 65 °C (1850 to 150 °F) in oil, then tempered.

For the first series of experiments, all bolts were tempered at 370 °C (700 °F) for 1 h, and the test solution was 0.33 *N* H_2SO_4. The average failure time of these bolts was 22 ± 2 h. The experiment was repeated with 1 g/L sodium monosulfide (Na_2S) added to the solution. The bolts failed in 6.3 ± 2.5 h, indicating that the sulfide acts as a catalyst poison. For the next series of experiments, the solution was 5% H_2SO_4, and the bolts were tempered for 1 h at 370, 425, and 535 °C (700, 800, and 1000 °F) (Fig. 8 and 9). They failed after 16 ± 3 h, 20 ± 4 h, and 23 ± h, respectively. These results indicate that tempering has only a limited effect on the failure time and does not solve the problem.

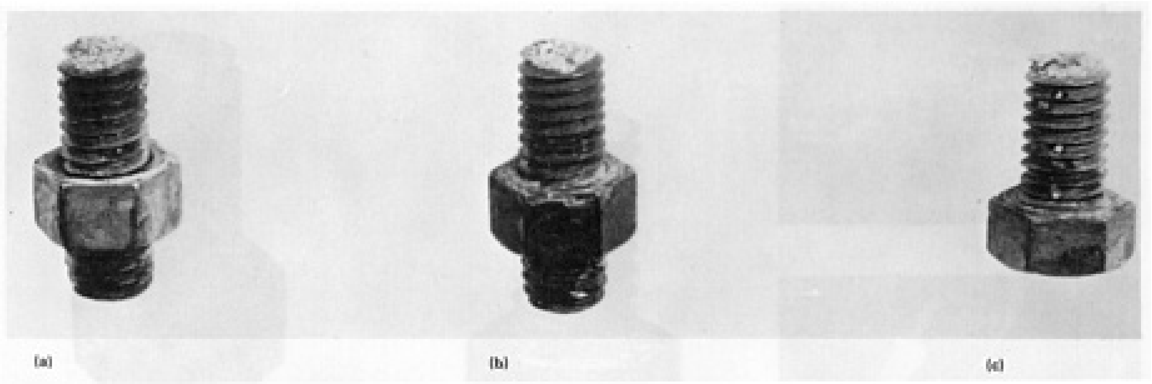

Fig. 8 Hydrogen-stress cracking of type 410 stainless steel bolts. (a) Quenched from 1010 to 65 °C (1850 to 150 °F) in oil, then tempered at 535 °C (1000 °F) for 1 h. Bolt exposed in 5% H_2SO_4 solution and 1 m/L/L Rodine inhibitor as cathode with platinum anode. Applied current: 180 mA/2 bolts. (b) Quenched from 1010 to 65 °C (1850 to 150 °F) in oil, then tempered at 425 °C (800 °F) for 1 h. Bolt exposed in 5% H_2SO_4 and 1 mL/L Rodine inhibitor as cathode with platinum anode. Applied current: 180 mA/2 bolts. (c) Bolts as-received exposed in 5% H_2SO_4 and 1 mL/L Rodine inhibitor as cathode with platinum anode. Applied current: 180 mA/2 bolts

Fig. 9 Section of type 410 stainless steel bolt. Quenched from 1010 °C (1850 °F), then tempered at 425 °C (800 °F) for 1 h. Bolt (cathode) broke under a torque of 70 N · m (600 in. · lb) after being hydrogen charged in 5% H_2SO_4 solution. 185×

Finally, type 305 stainless steel bolts were tested, and they did not fail after 219 h under test conditions similar to those used to establish the effect of tempering. Based on these results, the solution to the hydrogen-stress cracking problem consists of changing the bolt from type 410 to 305 stainless steel, eliminating use of MoS_2, and limiting the torque to 60 N · m (540 in. · lb).

Example 4: Hydrogen-Stress Cracking of Type 301 Stainless Steel Clamp.

When they have been severely cold worked, even austenitic stainless steels can hydrogen stress crack (Ref 4). Several type 301 stainless steel clamps, which were used to hold cylindrical galvanized steel covers to galvanized cast iron bases, failed in flooded manholes after 1 to 6 months of service. Like the type 410 stainless steel splice case bolts, they were treated with antiseize compound containing MoS_2. These clamps were made of half-hard type 301 stainless steel. Further stresses were introduced by forming small-diameter loops at the two ends of the clamp and by applying 30 N · m (260 in.

· lb) of torque for clamping. Based on the conditions (the clamp is the cathode of a galvanic cell with zinc) and the brittle nature of the cracks, the failures were diagnosed as hydrogen-stress cracking (Fig. 10 and 11).

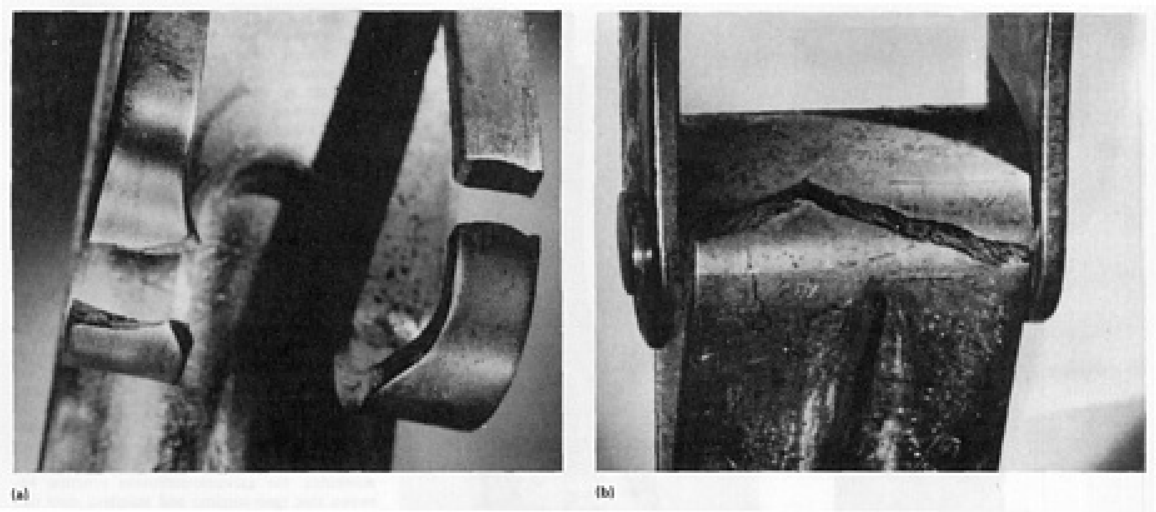

Fig. 10 Type 301 half-hard stainless steel band clamp illustrating a characteristic brittle hydrogen-stress crack. (a) Loop. (b) Hinge

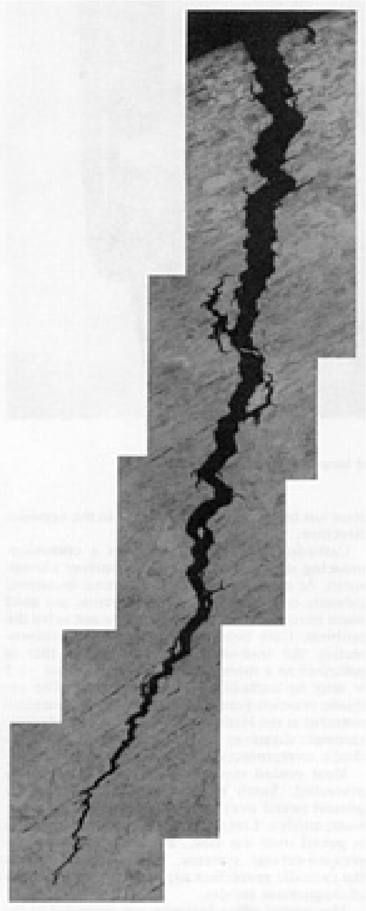

Fig. 11 Photomicrograph of a type 301 half-hard stainless steel band clamp loop field failure by hydrogen-stress cracking. 250×

Laboratory experiments were conducted to substantiate the above diagnosis and to evaluate the effect of annealing and the hydrogen-stress cracking behavior of type 316 stainless steel. Half-hard type 301, annealed type 301, and annealed type 316 stainless steel clamp ends were placed in 0.1 *N* sodium chloride (NaCl) solution with or without MoS_2 treatment. Half of each specimen type was coupled to galvanized steel panels for 106 days, and the other half was connected as cathode to a 3.2-V potential source against platinum anodes for 5 days (Fig. 12).

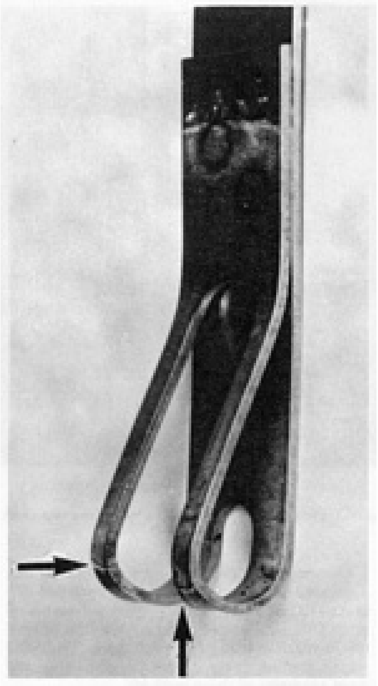

Fig. 12 Type 301 half-hard clamp loops that were hydrogen charged in diluted NaCl solution with platinum anode in the presence of MoS_2 lubricant for 5 days

One of the half-hard type 301 specimens that was MoS_2 treated and charged with hydrogen from an outside power source cracked after 5 days. All the other half-hard 301 specimens showed cracks after hydrogen charging regardless of the presence of MoS_2 or the method of exposure (coupled to a galvanized steel panel or connected to an outside potential source). When tensile tested, they all showed brittle fracture. The hydrogen charging reduced both the breaking load and the ductility, and MoS_2 treatment further reduced both. Although the annealed type 301 specimens exhibited ductile failure, they also indicated reduction of breaking load and ductility after hydrogen charging. Annealed hydrogen-charged type 316 specimens showed ductile failure, and had no adverse effect on hydrogen charging. The problem was solved by changing the clamp material from type 301 to type 316 stainless steel and by eliminating the MoS_2 antiseize compound.

Example 5: Corrosion Failures in Buried Plants.

Corrosion failures of concentric power cable neutrals necessitated the development of corrosion control measures for the neutral wires. One measure is the application of a carbon black filled outer polyethylene jacket extruded over the concentric neutral wires. This jacket separates the corrosive environment from the neutral wires while ensuring continuous grounding of the plant. Telephone and power cables are often buried jointly in the same trench. For electric safety, the power and telephone plants are bonded together. Because the carbon black (approximately 35% by weight) filled polyethylene can act as a large cathode, it accelerates the corrosion rate of relatively small bare metallic components of the telephone cable plant, for example, galvanized steel mounting posts. This galvanic corrosion, although normally innocuous, can be particularly aggressive in porous and oxidizing soils in which oxygen or other oxidizing agents act as cathodic depolarizers (Ref 5).

Laboratory studies in 0.1 *N* NaCl solution predicted a penetration (corrosion) rate of 0.75 to 1.6 mm/yr (30 to 65 mils/yr) in galvanized steel when coupled to carbon black filled polyethylene-jacketed power cable at an anode/cathode area ratio of 0.015, and 50 to 150 μm/yr (2 to 6 mils/yr) when the same ratio was 1.0 (Ref 6). Similar experiments with 14-gage copper wire anode at a 0.0003 anode/cathode area ratio produced the failure of copper in 8 months. Field experiments

conducted for 1159 days in 11, 200-Ω · cm resistivity soil with galvanized steel pedestal mounting posts showed that the posts connected to carbon black filled polyethylene-jacketed power cable corroded at a rate 7.3 times higher than that of similar posts connected to bare concentric neutral-type power cable (Table 1). Mounting an additional galvanized steel post on the pedestal terminal and using solid, uninsulated No. 6 American Wire Gage copper conductor for bonding can solve this galvanic-corrosion problem.

Table 1 Corrosion of galvanized steel mounting posts

Environment: 11, 200-Ω · cm soil; length of test: 1159 days

Number of mounting posts connected to the power cable	Average corrosion rate			
	Posts coupled to carbon black filled polyethylene-jacketed cable		**Posts connected to cable with bare concentric neutral wires**	
	μm/yr	**mils/yr**	**μm/yr**	**mils/yr**
1	254	10.00	41.1	1.62
2	193	7.58	23.6	0.93
3	169	6.65	21.3	0.84
4	159	6.25	23.1	0.91

Corrosion in the Chemical Processing Industry

Chairman: Thomas F. Degnan, Consultant

Introduction

THIS ARTICLE covers two groups of subjects: one concerns significant problems in the control of corrosion and protection of chemical-processing equipment, and the other concerns the handling and corrosive effects of the most commercially important acids and bases produced and used by the chemical-processing industries.

Environmental protection is of primary importance to the processing industries. Unexpected corrosion failures, which could cause the release of chemicals, cannot be tolerated. Methods of preventing and detecting corrosion hidden under thermal insulation are described in the Section "Corrosion Under Thermal Insulation" in this article. The causes of unexpected corrosion failures from process and environmental variables are covered in the Section "Effects of Process and Environmental Variables" in this article. Fouling of equipment and piping can lead to premature failures, release of

chemicals, and reduced efficiency. Three methods of cleaning are described in the Section "Chemical Cleaning of Process Equipment" in this article.

The Sections on corrosion by commercially important acids and bases briefly discuss the various grades, methods of manufacture, the most common materials of construction, and their effect on a broad range of metals and nonmetals. The latest developments in corrosion-resistant alloys, plastics, and electrochemical techniques, such as anodic polarization, applicable to each chemical are also covered in this article.

Many of the materials and techniques used to combat corrosion in the chemical-processing industries were developed by processing companies in response to corrosion problems in their plants. One large chemical company, for example, recognized more than 50 years ago the basic importance of both unit operations and materials in the design and construction of the large-scale plants emerging from their research and established a technical division with two groups at its experimental station. The materials group developed silicon bronze (Copper Development Association, CDA, C65500), Alloy Casting Institute (ACI) CN-7M stainless steel casting alloy (Alloy 20), 20Cb-3 stainless steel (Ref 1), dispersion-strengthened nickel-base corrosion- and wear-resistant alloys, and other significant advancements in new metals. Several of the larger chemical companies were also instrumental in the commercialization of titanium (Ref 1). Corrosion engineers employed by a large German chemical company were responsible for the development of Hastelloy C-276.

Corrosion monitoring using instantaneous corrosion measurement is based on an electrochemical theory formulated by the employees of a major chemical industry firm (Ref 2). Their work on polarization also led to the design of the titanium-palladium alloy, with its broader range of passivity in reducing environments. The many chemically resistant plastics and elastomers used in chemical-processing industry plants today were also developed by the industry.

The chemical-processing industry has undergone profound changes in the past decade. Energy costs, environmental considerations, and employee and public health concerns have brought about changes in plant construction. Plants are now more energy efficient and less polluting. Also, fewer large plants are being built. High-value, low-volume specialty chemicals and biotechnical products are favored over the commodity products. The resulting products are often of high purity. Electronic grades of acids are not uncommon. High-quality products often require more corrosion-resistant materials for equipment and containers for shipping and storage. Titanium alloys are routinely considered for chemical applications, and zirconium, niobium, and tantalum are also being used more often (Ref 3). More expensive materials are more affordable in small equipment, for which design and fabrication costs represent a higher percentage of the installed cost than the cost of the materials used in fabrication. Purity levels can also be improved by electrochemical means, such as the anodic or cathodic protection of steel storage tanks and stainless steel coolers and liners.

Acknowledgement

The author wishes to thank R.E. Tatnall, J.L. Cooney, W.I. Pollock, B.J. Moniz, and E.L. Perry for their assistance in the preparation of this article.

Two chemical-processing plants making the same product and using the same or a similar process will sometimes have different experiences with corrosion. At one plant, a steel pipeline may last for many years in a given service, yet an identical pipeline many fail within weeks or months in the same service at another plant. A major piece of equipment may suddenly fail after 15 or 20 years of service as a result of less than 1 ppm of metal ion contamination in a new source of raw material.

In designing a chemical-processing plant, considerable attention is paid to fluid flows, sizings of lines, pumps and processing equipment, and temperatures and pressures. Materials are selected on the basis of past experience, corrosion tests, the literature, and the recommendations of material suppliers. The nominal compositions of process streams and raw materials are known with some accuracy. Occasionally, however, variables come into play that cause corrosion failures. Table 1 lists variables that can affect the performance of metals in corrosive environments.

Table 1 Effects of process variables on corrosion of metals in aggressive environments

Process variable	Carbon steels	Austenitic stainless steels	Nickel, nickel-copper alloys	Nickel-copper, nickel-chromium-molybdenum alloys	Titanium	Zirconium	Copper, copper alloys
Velocity							
Increasing	>[a]	0 to >	0 to >	0 to >	0[b]	0	>
Decreasing	<L[c][d]	<L	0 to <	0 to <	0	0	<
Aeration	>	0 to <	>	V[e]	0 to <	0	>
Galvanic couple	>	0	0	0	HE[f]	HE	0
Impurities							
Nonchloride oxidants	V	<	>	V	0	0	>
$FeCl_3$, $CuCl_2$	>	>L, SCC[g]	>	0 to >	0	>E[h]	>
Neutral chlorides	>	>L, SCC	0	0 to >	0, unless H[i]	0	>
Ammonia	0	0	>	0	0	0	>SCC
Sodium, potassium	0, SCC if H	0, SCC if H	0	0	0, unless H	0	0, unless H
Fluorides	0	0	0	0	>	>	0
Nitrites	V	V	>	V	0[j]	0	>SCC
Nitrates	<, SCC	0 to <	0	0	0	0	0
HCl in chlorine	>	>	>	>	>[k]	>	>
Mercury	0	0	0, SCC if H	0	0, unless H	0	> SCC
Sulfur compounds	V	0, SCC if S[l]	>	0, SCC if S	0	0	>

(a) >, generally increases attack.

(b) 0, generally has no effect on metal in question.

(c) <, generally decreases attack.

(d) L, local attack or crevice corrosion is possible.

(e) V, may increase or decrease attack, depending on specific alloy and environment.

(f) HE, hydrogen embrittlement is possible.

(g) SCC, stress-corrosion cracking is possible.

(h) E, embrittlement.

(i) H, hot (from 80 to 150 °C, or 175 to 300 °F, depending on variable and alloy).

(j) Except in fuming HNO_3.

(k) Except for dilute solutions.

(l) S, sensitized by heat treatment

Plant Environment

One factor that is occasionally overlooked is the surrounding environment. For example, the instrument tubing at a new facility, built at an existing chemical plant in West Virginia, consisted of a combination of copper (C12200) tubing and yellow brass (C27000) fittings. However, within a few weeks, the fittings had failed by stress-corrosion cracking (SCC). The new building was located near, and downwind of, another facility that occasionally vented small amounts of nitric oxide (NO) to the atmosphere (Ref 4).

Tests later showed that brass samples would fail by SCC if exposed to the source of NO emissions. An expensive shutdown was necessary to replace all of the instrument tubing and fittings with stainless steel.

Similar failures of brass heat exchangers have occurred as a result of their proximity to sources of ammonia (NH_3). In one case, cooling tower water became contaminated with a few parts per million of NH_3 when an ammonia-manufacturing plant was built nearby. In another case, the admiralty brass (C44400) heat-exchanger tubing in a large air compressor stress cracked in cold-worked areas after it was installed about 30 m (100 ft) from a building in which laboratory reagents, including ammonium hydroxide (NH_4OH) and nitric acid (HNO_3), were bottled.

Cooling Water

The quality of water used to cool shell and tube heat exchangers can vary from season to season and year to year, particularly if the water is taken from a river that discharges into a bay or sea. In one case, for example, a plant had 64 identical AISI type 304 stainless steel condensers cooled on the shell side, with river water that varied in chloride content from less than 50 ppm to as high as 2000 ppm. The stainless steel tubes failed by external pitting at baffles. It was discovered that an almost perfect correlation could be obtained by plotting the average monthly chloride content against the number of leaking condensers retubed that month.

In a similar case, a series of stainless steel heat exchangers cooled with recirculating treated water had been in service for more than 10 years (Ref 5). During an emergency, untreated river water was used to cool the units for about 48 h. Several weeks later, five of the coolers failed by massive chloride SCC. There was a large buildup of dried mud in the units, which caused reduced heat transfer and higher wall temperatures.

Steam

The corrosive properties of the steam that will be used in a plant are seldom considered, particularly if the steam will be supplied by a public utility or power plant that has good boiler water treatment that will prevent condensate corrosion. However, the impurities in steam can cause corrosion problems.

At one site, for example, high-pressure steam was purchased from a central power station; pressure was reduced to 2.76 MPa (400 psi) as it entered the plant. Some years later, plant operators decided to cool the superheated steam by spraying with deionized water at a point just beyond the depressurizing valve. There were no problems until 15 years later, when it became necessary to replace and reroute part of the steam line inside the plant. Within a few months, cracks and resulting leaks appeared adjacent to and across the welded joints in the new piping. The plant operators blamed the welding contractor for poor welding.

However, metallographic examination showed that the cracking was the result of caustic embrittlement. The deionized water contained 10 ppm of sodium, which formed concentrated sodium hydroxide (NaOH) as the water evaporated. The older piping did not crack, because it had been stress relieved by the superheated steam over a period of years before cooling of the steam was initiated.

A similar case was reported in which a stainless steel bellows in a 2.76-MPa (400-psi) steam line failed by caustic cracking (Ref 4). The failure was attributed to carryover of boiler compounds.

Aeration

The design of the plant and, in particular, equipment selection can influence the amount of air introduced into a process stream, which in turn may profoundly affect corrosion. This can account for different corrosion experiences in plants having identical chemistries and products.

Solid-liquid separation (Fig. 1) can be accomplished in several ways. Some methods, such as centrifuging, can cause more aeration than others--pressure filtration, for example--with occasional disastrous results.

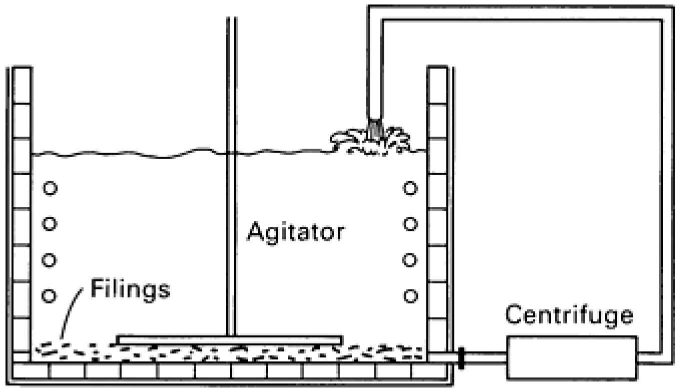

Fig. 1 Equipment used for iron reduction and removal of spent filings

In iron reductions, iron filings and dilute hydrochloric acid (HCl) are agitated with an organic nitro compound, which is reduced to an amine by the hydrogen evolved. In the design of one such unit, for example, a Monel 400 centrifuge, coils, and agitator were selected based on laboratory corrosion tests and general experience with units using filter presses having no return stream. Aeration caused by the centrifuge, together with a return pipe that terminated in the vapor space of the vessel, caused conversion of ferrous chloride ($FeCl_2$) to ferric chloride ($FeCl_3$), with resulting rapid corrosion of all Monel 400 parts. The temporary solution involved blanketing the equipment with nitrogen, extending the return pipe below the liquid level, and adding a corrosion inhibitor.

In a caustic chlorine plant, steel piping that transferred saturated alkaline brine at ambient temperature failed by crevice corrosion and pitting shortly after start-up, although steel piping had been successfully used at other plants. Failure was attributed to aeration caused by centrifuges removing precipitated salt from caustic liquors and returning the salt to the dissolver.

Start-Up and Shutdown Conditions

Start-ups and shutdowns are variables that can easily be overlooked in the design stage or conducted improperly by operations. Such a case was reported in a high-sulfur coal gasification plant operating at 430 to 595 °C (800 to 1100 °F) (Ref 6). A designer selected type 310 stainless steel rather than type 304 because he felt that the higher chromium content of the type 310 would result in improved high-temperature resistance. The unit failed, however, by massive intergranular polythionic acid SCC that occurred during the first shutdown.

This type of corrosion occurs in sensitized stainless steels in an acidic sulfide environment in the presence of air. It can be mitigated by following the guidelines in National Association of Corrosion Engineers (NACE) standard RP-01-70 (Ref 7). Perhaps a better approach is to use a carbide-stabilized grade of stainless steel, such as type 347 or type 321.

In another example, silicate cement was selected for use with unalloyed tantalum repair plugs in a new glass-lined vessel and its accessories for a bromination process, because bromine would attack the organic cement that is normally used with the plugs. The vessel was obtained plug-free, but the agitator and baffle both required tantalum plugs. As part of the start-up procedure, plant operators boiled out the equipment with water. This dissolved the silicate cement. When the vessel was placed in operation, the bromine attacked the steel under the plugs. The agitator dissolved, leaving only the stub revolving above the liquid level.

In a third case, type 304 stainless steel was correctly selected for a 99% sulfuric acid (H_2SO_4) pipeline. During the first shutdown, the plant operators decided to blow the acid out of the line. They used compressed air, which was unwise, because compressed air is commonly saturated with water. Within a few days, leaks were discovered adjacent to some welds where dilute acid had accumulated. Dry nitrogen is now used to blow out the line, which has been in service for 20 years and as many shutdowns.

Seasonal Temperature Changes

Ambient temperature is an important variable that can vary widely. Metal parts exposed to the sun may reach 60 °C (140 °F) in the summer. In one case, for example, a steel pipeline carrying 98% H_2SO_4 was supplied with properly designed steam tracing that maintained a maximum temperature of 50 °C (125 °F) during the winter (Ref 6). During the summer, the line failed by corrosion. The steam had not been disconnected, and the temperature of the line exceeded 70 °C (150 °F).

Heat exchangers (Fig. 2) are usually designed conservatively for summer water temperatures. During the winter, the colder cooling water can cause a lower exit process temperature than desired. To correct this problem, plant operators will frequently decrease the water flow. All too often, the water flow is throttled at the water inlet. This can result in a fluctuating liquid level, with buildup of solids, pitting, and/or SCC of tubes. The correct arrangement, with the water control valve on the discharge line, is shown in Fig. 2.

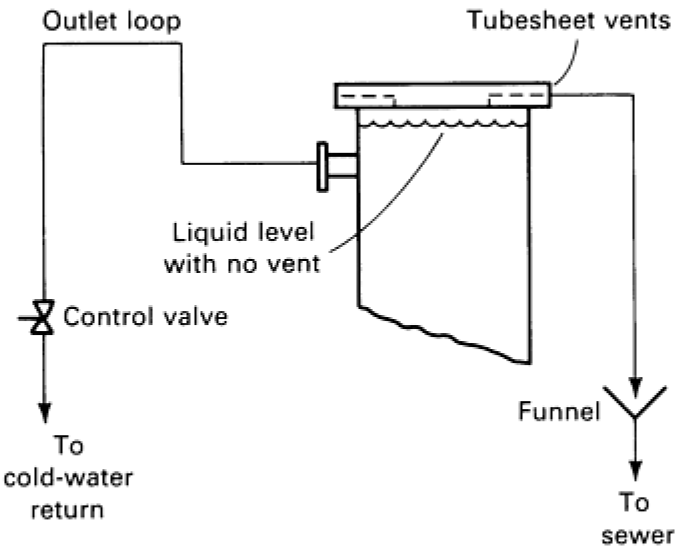

Fig. 2 Correct piping arrangement for venting fixed tubesheet heat exchangers. Source: Ref 8

Variable Process Flow Rates

Plants are frequently operated at flow rates other than design capacity. They may be turned down to considerably less than capacity or pushed above it by eliminating bottlenecks. Either condition can cause corrosion problems.

In an H_2SO_4 plant, for example, the last 150 mm (6 in.) of the steel waste heat boiler tubes were safe-ended with alloy 20Cb-3 stainless steel to protect against dew-point corrosion. (Safe ending is the welding of a length of corrosion-resistant tubing to the end of a less resistant material.) Unfortunately, the steel tubes corroded upstream of the alloy. The process was not operated within reasonable design limits. Corrosion resistance in this case would have required 1.8 m (6 ft) rather than 150 mm (6 in.) of safe-ending because the tubes were operating at 66 °C (119 °F) below the design temperature and well below the dew point.

In another case, a five-pass Monel 400 heat exchanger was used to vaporize anhydrous hydrofluoric acid (HF). Severe corrosion occurred throughout the fifth and part of the fourth pass, with no corrosion in the first three passes. Insufficient flow caused nonvolatile acid impurities, present in the HF at part per million levels, to be concentrated in the last one-plus passes.

In a third example, plant operators decided to install a higher-capacity pump to reduce the time required to transfer a charge of 98% H_2SO_4 through a steel line from 1 h to 15 min. This also increased the velocity from less than 0.6 m/s (2 ft/s) to more than 1.5 m/s (5 ft/s). The line failed within a week.

In another instance, a Monel 400 shell and tube heat exchanger had given satisfactory service in an organic acid oil for more than 5 years. The exchanger was a two-pass unit with a divider plate in the bottom head. The bottom head also

contained the inlet and outlet nozzles. The divider plate was gasketed to a groove in the tubesheet. The velocity through the unit was increased by increasing the pump pressure. Because it was not designed for the higher pressure, the divider plate deflected, allowing the gasket to blow out. The product bypassed the divider at high velocity, which caused the unit to fail by erosion-corrosion.

Impurities

A principal cause of unexpected corrosion failures is the presence of small amounts of impurities in the chemical environment. Producers of H_2SO_4 sometimes provide facilities to recover spent acid as a service to their customers, who would otherwise have difficulty in disposing of the acid in an environmentally acceptable manner. The acid, contaminated with organic matter, is burned, and the hot gases travel through a waste heat boiler.

The operators of one such plant, for example, discovered that the steel tubes of their waste heat boiler had short service lives. Examination of the tubes showed that they were being attacked by a molten slag from the spent acid. Analysis showed that the slag had a high phosphate and lead content, a low melting point, and was very corrosive to steel when molten.

In another plant, zinc chloride ($ZnCl_2$) is made by dissolving zinc recovered from galvanizing operations and from other sources in HCl, treating the various chemicals, and concentrating the salt solution by evaporation. The nickel coils in a concentrating tank pitted and had short service lives. After a 30-day test, a zirconium coil appeared to be unaffected; therefore, a zirconium coil was installed in a tank. It failed after only 6 months of service. Failure was traced to a galvanizing company that had used fluorides in its flux. Zirconium is not resistant to fluorides.

At a New Jersey plant, a titanium-clad auto-clave was used for the air-HNO_3 procedure in the manufacture of an organic acid. After several years of successful operation, the liquid-phase surfaces were found to be pitted and cratered, although they were unattacked when inspected a few weeks earlier. The presence of H_2SO_4 was suspected. Investigation revealed that a trailer of mixed H_2SO_4 and HNO_3 had been mistakenly unloaded into a HNO_3 tank.

In another example, a Monel 400 petrochemical plant extraction unit handling 50 to 65% H_2SO_4 and alcohol at 30 to 40 °C (85 to 100 °F) had given satisfactory service for 17 years, with a 5-year life expectancy for heat-exchanger tubes (Ref 9). Unexpectedly, tubes began to fail within 5 weeks. Replacement piping failed in as little as 3 weeks, predominately at welds. Laboratory analyses revealed that the plant solutions contained copper in quantities greater than could be explained by the simple dissolution of Monel 400. Tests showed that copper was being leached from the surfaces in a manner similar to zinc in a dezincification process.

Investigation uncovered that there had been a change in the feedstock supply. The new supply was contaminated with a few parts per million of copper ions. This contamination initiated the corrosion process, which fed upon itself by leaching more copper ions from the surface of the Monel 400.

In a similar case, a Monel 400 isomerization reactor was built based on laboratory corrosion tests and plant tests, with corrosion coupons in different locations in a glass-lined isomerizer (Ref 6). The process involved heating terpenes in the presence of H_2SO_4, followed by decantation, with the acid layer returned to the reactor. Precautions were taken to provide a nonaerated system by using a nitrogen blanket.

Shortly after the Monel 400 reactor was installed, the H_2SO_4 was found to be discolored, and excessive corrosion was discovered. Successive isomerizations using the recycled H_2SO_4 had caused a buildup of cupric ion (Cu^{2+}). Sulfuric acid with 0.5 ppm or more Cu^{2+} ion will cause autocatalytic destruction of Monel 400, as was found in the earlier case. The copper can come from an outside source, excessive corrosion, or buildup of corrosion products from recycling. Once started, this reaction is almost impossible to stop, because the Monel 400 surfaces become a ready source of more copper.

At another plant, 20Cb-3 stainless steel piping had been used for many years to handle denitrated 80% H_2SO_4 at 50 °C (120 °F). Unexpectedly, a number of failures occurred. Potentiostatic studies, using diluted reagent grade acid, showed that 20Cb-3 stainless steel should be passive under these conditions. The plant operators, some distance from the laboratory, continued to complain about the shortened service life of the piping, and plant acid was eventually shipped to the laboratory. The potentiostatic plot showed borderline active-passive behavior. Further studies showed that an extremely small amount of HNO_3 present in the denitrated acid caused the unstability and that the absence of all HNO_3 or the presence of more than a critical amount promoted passivity. The efficient, but not perfect, operation of the denitrating system caused the corrosion.

Water

One of the most important process variables, from the corrosion viewpoint, is the amount of water in a process stream. The water may be present as water vapor in a gas stream or may be soluble. Water is most likely to contribute to corrosion when it is present as a separate liquid phase, particularly in the presence of hydrogen chloride ($HCl \cdot H_2O$), which has a great affinity for water (Fig. 3).

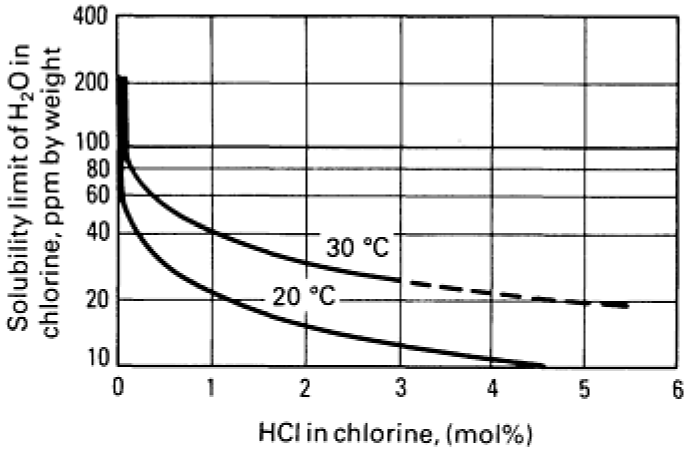

Fig. 3 Effect of HCl on solubility of water in chlorine. Source: Ref 10

When the water is present as vapor, it is likely to condense at cold spots, such as pipe supports welded directly to process piping or nozzles in the top or vapor phase of reactors, even though the lines and nozzles are insulated. Hydrogen chloride raises the dew point. Chlorinations are a particular problem for several reasons. Commercial chlorine contains variable amounts of water, up to 50 ppm or more, because the solubility limit of water in HCl is about 200 ppm at room temperature. The $HCl \cdot H_2O$ formed during chlorinations reduces the solubility of water in chlorine to well below 50 ppm at room temperature (Fig. 3). The condensate of water-chlorine-$HCl \cdot H_2O$ is corrosive to all metals except tantalum.

For example, stainless steel reactors are used in the manufacture of fluorinated hydrocarbon refrigerants from chlorinated hydrocarbons by reacting them with HF in the presence of chlorine and a catalyst. After many years of service, the cover of a reactor exhibited chloride SCC just below two nozzles. Higher-than-normal water content in one or more of the reactants had caused condensation in the blind nozzles. The condensate evaporated when it ran onto the cover, causing concentration of chloride salts and subsequent chloride SCC. Steam tracing of the nozzles (Fig. 4) prevented condensation and corrected the problem.

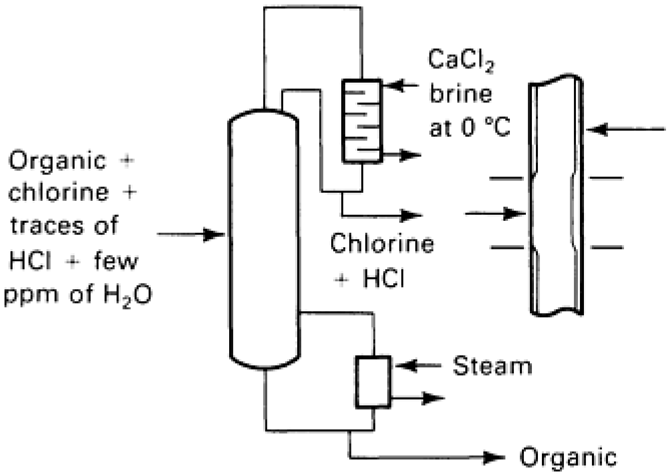

Fig. 4 Arrangement of chlorine recovery column and corrosion pattern on condenser tubes. Source: Ref 11

In the same plant, a column was installed to recover excess chlorine from a supposedly dry process stream containing fluorocarbon, $HCl \cdot H_2O$, traces of HF, and chlorine. The brine-cooled condenser had 20Cb-3 stainless steel tubes. A few weeks after start-up, the tubes failed from process-side corrosion. Attack occurred preferentially on the coldest side of the tubes facing the brine flow. The unit was temporarily retubed with heavy-wall steel tubes. After a few weeks, these tubes leaked. The brine was drained from the shell, and almost immediately, the steel tubes caught on fire. The hydrogen generated by corrosion of the outside of the tubes reacted exothermically with the chlorine present, raising the temperature of the tubes to the ignition temperature of steel in chlorine (about 250 °C, or 480 °F). The process of removing chlorine by distillation was abandoned. No metallic heat-exchanger tube is available that will resist aqueous HCl saturated with chlorine in the presence of acid fluorides.

The trace amounts of water in the stream fed to the column were not detectable by the analytical methods used at the plant; the water was present in small but variable amounts. The presence of large amounts of $HCl \cdot H_2O$ raised the dew point enough to cause the water to condense on the coldest parts of the tube walls.

Process equipment and piping must be cleaned to prevent contamination of a process or product, to improve the operation of a process, to reduce the opportunity for premature failure, and to prepare equipment for inspection. However, equipment should be cleaned only for good reason. In addition to the cost of unnecessary cleaning, problems may be introduced. For example, most chemical cleaning processes cause some metal loss. In other cases, washing before cleaning may cause accelerated corrosion, such as during the preparation of a concentrated H_2SO_4 storage tank for inspection. Other potential problems are:

- Difficulties associated with pumping hot corrosives through temporary connections
- Difficulties associated with a crowded work space, for example, during a turnaround
- The need to dispose of wastes
- The possibility of generating toxic or flammable by-products during cleaning

There are four types of equipment cleaning: preoperational, chemical, mechanical, and online. These must be evaluated for each job in order to select the most cost-effective. To make a sound evaluation, the deposit to be removed must be thoroughly characterized.

Fouling of Equipment

Deposits that cause fouling accumulate in equipment and piping and impede heat transfer or fluid flow or cause product contamination. Deposits may be organic, inorganic, or a mixture of the two. Scales are crystalline deposits that precipitate in a system (Table 2). There are four principal sources of deposits: water-side, fire-side, process-side, and preoperational.

Table 2 Summary of common types of scale-forming minerals

Scale	Chemical formula
General	
Sodium iron silicate	$NaFe(SiO_3)_2$
Barium sulfate	$BaSO_4$
Sodium aluminum silicate	$NaAl\ Si_2O_6 \cdot H_2O$
Aragonite (rhombic crystals)	$CaCO_3$
Calcium carbonate--(hexagonal crystal)	$CaCO_3$
Calcium sulfate	$CaSO_4$
Magnesium carbonate and hydroxide	$3MgCO_3 \cdot Mg(OH)_2 \cdot 3H_2O$
Calcium phosphate	$Ca_{10}(OH)_2(PO_4)_6$
Iron oxide	Alpha FeO (OH)
Iron oxide--magnetite	Fe_3O_4
Iron oxide--red	Fe_2O_3
Iron chrome spinels	$CrFe_2O_4$
Iron sulfide	FeS
Magnesium hydroxide	$Mg(OH)_2$
Magnesium oxide	MgO
Manganese dioxide	MnO_2
Aluminum silicate	$Al_2O_3 \cdot 4SiO_2 \cdot 4H_2O$
Sodium aluminum silicate	$Na_8Al_6Si_6O_{24} \cdot SO_4$
Calcium sodium silicate	$4CaO \cdot Na_2O \cdot 6SiO_2 \cdot H_2O$
Magnesium silicate	$Mg_3Si_2O_7 \cdot 2H_2O$
Silica	SiO_2
Sodium aluminum silicate	$Na_8Al_6Si_6O_{24} \cdot Cl_2$
Magnesium iron aluminum silicate	$(Mg,Fe)_3(Si,Al)_4O_{10}(OH)_2 \cdot 4H_2O$
Calcium silicate	$5CaO \cdot 5SiO_2 \cdot H_2O$
Copper or copper alloy equipment	
Copper iron sulfide	CuFeS
Copper sulfide	CuS and Cu_2S
Basic copper chloride	$CuCl_2 \cdot 3Cu(OH)_2$
Copper oxide	Cu_2O
Chalcopyrite	$CuFeS_2$
Beta zinc sulfide	ZnS
Green basic carbonate	$CuCO_3Cu(OH)_2$

Water-side deposits are of many types. Hardness (calcium and magnesium) based deposits and iron oxide are the most common water-side deposits and often affect boilers and cooling systems. Process and oil leaks can foul boilers and cooling systems. Biofouling, mud, and debris are often found in cooling systems. Treatment chemicals, if not properly controlled, can add to deposits and scale. Silica can form hard, adherent deposits in boilers, steam turbines, and cooling systems. Corrosion products can add to deposits.

Fire-side deposits can be extremely corrosive. Slags from burning oil and wastes can corrode boiler equipment if they become moist. Fly ash deposits can accumulate in coal-fired boilers. Gas-fired boilers are generally clean. Some compounds that are burned in incinerators or waste heat boilers can seriously corrode or erode boiler tubes.

Process-Side Deposits. There are many types of process-side deposits. Organic residues, tars, and coke are common in the petroleum and petrochemical industries. Iron oxide and sulfides are often present in these organic deposits. Sulfate deposits are common in H_2SO_4 plants. Iron-, copper-, and nickel-containing deposits often occur in HF plants.

Organic deposits may develop through the polymerization of leaking gases or from the decomposition of process constituents. In some cases, organics help to bond inorganic deposits, such as iron oxides or sulfides.

Some process-side deposits are pyrophoric when exposed to air or oxygen. The most common is iron sulfide, which is likely to be found in natural-gas- and petroleum-refining processes or when aqueous solutions of hydrogen sulfide (H_2S) are dried in the absence of air.

Preoperational deposits are formed during the fabrication and erection of process equipment and piping. In addition to mill scale residues, metal surfaces become coated with dirt, oil, grease, weld spatter, pipe-threading compound, protective shop coatings, and corrosion products.

Highly alloyed materials, such as stainless steels, nickel-base alloys, reactive metals, or high-temperature alloys, may become contaminated with iron from tooling; zinc, cadmium, and aluminum from scaffolding; and zinc, sulfur, and chlorine in certain marking materials. These elements can cause corrosion or embrittlement.

Critical Equipment Areas

Requirements for cleaning will vary with the type of equipment. The operating characteristics and design must be assessed before selecting a cleaning method.

Columns. The two critical areas for deposit formation in a column are at the trays, where vapor passes through a valve, sieve, flapper, or riser, and in the flash zone, where vapor condenses. Operating history sometimes indicates which areas require cleaning; for example, the vapor line is suspect if the column vapor rate becomes limiting. Inspection is necessary to determine the extent and location of fouling.

Glass-lined vessels require special attention when their water jackets are chemically cleaned. The recommendations of the manufacturer must be followed. The most commonly recommended cleaning solution is dilute alkaline sodium hypochlorite (NaClO) (Ref 12). If strong acids are used, atomic (nascent) hydrogen formed by corrosion diffuses into the shell and recombines as hydrogen molecules at the glass/metal interface, which causes spalling of the glass.

Oxygen, chlorine, and fluorine piping systems must be free of organic contaminants. Organic materials, particularly, hydrocarbon greases and oils, react violently with these chemicals. Preoperational cleaning is mandatory in such cases (Ref 13). After cleaning, the lines should be blown dry, using oil-free nitrogen or air.

Identification of Deposits

To select an effective cleaning procedure, the deposit must be characterized, or identified. The sample should represent the deposit in the most critical fouling area. For exchangers and boilers, this is the highest heat transfer section. Expediency should not dictate the location of the sample. A cleaning procedure should not be based on a sample of loose deposit from a noncritical area, because the sample at this location may not be representative. Table 3 lists some common components of boiler deposits.

Table 3 Components of boiler deposits

Mineral	Formula	Nature of deposit	Usual location and form
Acmite	$Na_2O·Fe_2O_3·4SiO_2$	Hard, adherent	Tube scale under hydroxyapatite or serpentine
Alpha quartz	SiO_2	Hard, adherent	Turbine blades, mud drum, tube scale
Amphibole	$MgO·SiO_2$	Adherent binder	Tube scale and sludge
Analcite	$Na_2O·Al_2O_3·4SiO_2·2H_2O$	Hard, adherent	Tube scale under hydroxyapatite or serpentine
Anhydrite	$CaSO_4$	Hard, adherent	Tube scale, generating tubes
Aragonite	$CaCO_3$	Hard, adherent	Tube scale, feed lines, sludge
Brucite	$Mg(OH)_2$	Flocculent	Sludge in mud drum and water wall headers
Copper	Cu	Electroplated layer	Boiler tubes and turbine blades
Cuprite	Cu_2O	Adherent layer	Turbine blades, boiler deposits
Gypsum	$CaSO_4·2H_2O$	Hard, adherent	Tube scale, generating tubes
Hematite	Fe_2O_3	Binder	Throughout boiler
Hydroxyapatite	$Ca_{10}(PO_4)_6(OH)_2$	Flocculent	Mud drum, water walls, sludge
Magnesium phosphate	$Mg_3(PO_4)_2$	Adherent binder	Tubes, mud drum, water walls
Magnetite	Fe_3O_4	Protective film	All internal surfaces
Noselite	$4Na_2O·3Al_2O_3·6SiO_2·SO_4$	Hard, adherent	Tube scale
Pectolite	$Na_2O·4CaO·6SiO_2·H_2O$	Hard, adherent	Tube scale
Serpentine	$3MgO·2SiO_2·H_2O$	Flocculent	Sludge
Sodalite	$3Na_2O·3Al_2O_3·6SiO_2·2NaCl$	Hard, adherent	Tube scale
Xonotlite	$5CaO·5SiO_2·H_2O$	Hard, adherent	Tube scale

When removed by scraping, the samples should be as intact as possible. They should be removed to the base metal, taking care not to introduce any metallic chips from the blade or substrate. Thickness, density, porosity, type (homogeneous or layered), and color should be noted.

When only a limited amount of deposit is available, replication tape is a useful method of removing it. Polyvinyl chloride (PVC) or other chloride-containing tapes should not be used on stainless steels, which are susceptible to chloride pitting and stress cracking.

Many analytical techniques are used to characterize deposit samples. Typical methods include x-ray diffraction, optical emission spectroscopy, and x-ray spectrometry. Most chemical cleaning contractors, water treatment supplies, and analytical laboratories have the facilities to characterize deposits.

Preoperational Cleaning

Unlike process- or water-side deposits, the types of deposits in original equipment are easily categorized (Ref 14). Preoperational cleaning should include consideration of the degree of cleanliness required and the material of construction. Areas where preoperational cleaning is used include:

- Process equipment start-up, boilers, and steam-generating and compression systems
- Lubricating oil systems before oil flushing
- Critical services, such as oxygen, chlorine, or fluorine piping
- Water treatment and inhibition programs

Boilers are cleaned to remove oils, grease, and mill scale. When boilers are coated with heavy protective greases, two-stage cleaning (for organic and inorganic deposit removal) should be used. A degreasing step using alkaline boilout solutions or emulsions is first used. Common second-step solvents include chelants, organic acids, or HF.

Columns contain similar contaminants. They are cleaned by fill and soak, cascade, or foam methods, using solvents similar to those used for boilers. The design of the column may eliminate certain methods, such as cascade cleaning for a packed column.

Shell and Tube Heat Exchangers. The most serious fouling is found on the interior (tube side) or exterior (shell side) of the tubes. Other locations are on the shell side at baffles or drain nozzles. Figure 5 shows a fouled heat-exchanger tube bundle.

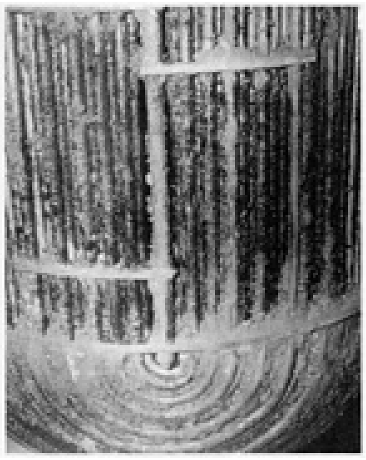

Fig. 5 Fouled heat-exchanger tube bundle

The head should be removed for inspection if tube-side fouling of the tubes is suspected. The shell is more difficult to inspect, unless the tube bundle is removable, but limited information may be gained through nozzles.

Heat-exchanger tubes may be cleaned mechanically or chemically. Mechanical cleaning may damage tubes. Individual tubes should not be steam blown, because this may damage rolled tube joints. Tubes should not be hammered with any metallic tool, scraping or rodding should be done with care because any scoring or gouging can lead to premature failure. High-pressure and ultrahigh-pressure water cleaning are preferred.

Chemical cleaning methods use circulation, fill and soak, or foam. However, severely blocked tubes may resist the entry of the cleaning agent or may retain it beyond the neutralization step of the cleaning process, leading to corrosion during shutdown or in service.

Heat-exchanger shells are normally chemically cleaned using the circulation or the fill and soak method. If the tube bundle is removable, mechanical cleaning with high-pressure or ultrahigh-pressure water is a good technique.

Boilers. Typical water-side deposits found in boilers are listed in Table 3. Deposits vary depending on raw water composition, feedwater treatment, and operating pressure.

The heaviest deposition occurs in tubes with the highest heat input, an area that may be physically impossible to inspect. A tube section can be taken from the area where deposition is known to be heaviest in order to characterize the deposit. Although various yardsticks (in grams of scale per square foot) have been proposed for determining the need to clean, each case should be individually evaluated. Factors to be considered are the degree of fouling, the type of service, the reliability required, the operating history, and future operation.

Chemical cleaning of the water side is generally more effective than mechanical cleaning, particularly in designs with heavily swaged tubes and tight bends. Preoperational cleaning of boilers must be conducted to allow the steel surface to develop a protective film of magnetite (Fe_3O_4) when the boiler is put into service and to remove mill scale.

Furnaces. The external fouling of furnace tubes depends on the nature of the fuel. Oil-burning furnaces usually have significantly more deposit formation and corrosion problems than coal-burning types, while natural-gas-burning furnaces have very few problems.

Slag accumulates when metallic salts and oxides are vaporized and condense in various parts of the furnace. Because its melting point is relatively low, the slag forms a sticky corrosive deposit of various salts, primarily sodium and vanadium. These slags should be mechanically removed by chipping or dry sandblasting. Wet cleaning methods may cause acid formation. For internally coked tubes, steam-air decoking or mechanical cleaning is preferred.

Pumps and Compressors. Cooling water jackets are often chemically cleaned to remove iron oxide, water-formed scale, and possible oil infiltration. All loose material is first removed by opening the clean-out plates and flushing. A two-stage chemical cleaning process is then used, first to dissolve any organic deposits and then to remove inorganic scales. The acidic cleaner selected for inorganic scales should be compatible with the materials of construction.

Piping may contain various contaminants, including dirt, loose paint, sand and grit, varnish, grease and oils, weld spatter, mill scale, and rust. Piping should first be inspected and all construction debris removed. Dirt, loose paint, sand, and grit are removed by flushing with clean water or blowing with dry compressed air or steam. Varnish, grease, and oils are removed by steam blasting with detergent or hot water containing an alkaline degreasing agent. Mechanical cleaning may be required, depending on the amount of weld spatter, mill scale, and rust. The piping may then be chemically cleaned if necessary, using organic acids and chelants, followed by neutralizing and passivating.

Moisture removal may be required for such specific applications as compressor or refrigeration piping. When all traces of moisture must be removed, the system can be filled with alcohol, evacuated to evaporate the alcohol, then flushed with an inert gas.

Piping carrying oxygen, chlorine, and fluorine requires stringent cleaning to remove organic contamination. No organic-containing residues cab be permitted (Ref 13).

Chemical cleaning

Chemical cleaning is the use of chemicals to dissolve or loosen deposits from process equipment and piping. It offers several advantages over mechanical cleaning, including more uniform removal, no need to dismantle equipment, lower overall cost (generally), and longer intervals between cleanings. In some cases, chemical cleaning is the only practical method.

The primary disadvantages of chemical cleaning are the possibility of excessive equipment corrosion and solvent disposal. Chemical cleaning solvents must be assessed in a corrosion test program before their field acceptance.

Chemical cleaning is performed by a contractor who specializes in this work. Some cleaning procedures are protected by patents.

Chemical Cleaning Methods

There are six major chemical cleaning methods: circulation, fill and soak, cascade, foam, vapor phase organic, and steam-injected cleaning. A seventh variation is discussed in the section "On-Line Cleaning" in this article.

Circulation, the most common method, is applied to columns, heat exchangers, cooling water jackets, and so on, where the total volume required to fill the equipment is not excessive. The equipment is arranged such that it can be filled with the cleaning solution and circulated by a pump to maintain flow through the system. Movement of solution through the equipment greatly assists the cleaning action. As cleaning progresses, temperature and concentration are measured in order to monitor the progress. The cleaner may be replenished (sweetened) occasionally to maintain efficiency. Corrosion coupons or on-line monitoring determines the effect of the cleaning chemicals on the equipment materials.

With circulation cleaning, the rate of flow through the equipment is critical. Large-diameter connections are preferred, and a high-capacity pump may be necessary to produce the required circulation. After cleaning, the equipment is drained, neutralized, flushed, and passivated.

Fill and soak cleaning involves filling the equipment with the cleaner and draining it after a set period of time. This may be repeated several times. The equipment is then water flushed to remove loose insolubles and residual chemicals.

Fill and soak cleaning offers limited circulation. The poor access of fresh cleaning solution to the metal, together with the inability to maintain solution temperature, may cause the cleaning action to cease.

The method is limited to relatively small equipment containing light amounts of highly soluble fouling and to equipment in which circulation cannot be properly controlled. Because good agitation is achieved only during the flushing stage, flushing should be as thorough as possible. Circulation and fill and soak cleaning are sometimes used alternately.

Cascade cleaning, a modification of the circulation method, is usually applied to columns with trays. The column is partially filled, and the liquid is continuously drawn from the reservoir and pumped to the highest point. The liquid then cascades down through the column, cleaning surfaces as it passes over them. The liquid draw-off point must be suitably located to avoid recirculation of loosed foulants. High-capacity pumps and large-diameter piping are required to achieve the necessary transfer of liquid to produce a flow pattern that will contact all fouled surfaces within the column.

The cascade method is primarily used in large columns and is suitable for most types, except for packed columns. Cleaning is not effective in inaccessible areas, such as the underside of trays, due to poor contact with the cleaning solution. Contact may be improved by injecting air or nitrogen at the base of the column. If steam is used to heat the chemicals, the location of the steam injection point should not lead to localized overheating. High temperature can also increase corrosion in the vapor space.

Foam cleaning uses a static foam generator that employs air or nitrogen to produce a foamed solvent (Ref 15). Foam stabilizers are required to prolong foam life and increase the effectiveness of the cleaning chemicals. Foam cleaning is used on equipment that cannot support full or partial filling with liquid. Foam cleaning results in significantly less liquid volume for disposal compared with other methods.

Vapor phase organic cleaning is used in equipment that is difficult to clean with liquids. For example, vaporized organic solvents are used to remove organic deposits from columns. The organic solvent is vaporized, injected into the top of the column, condensed, collected in a circulation tank, and revaporized.

The principal concerns are the handling and disposal of the solvent and its flammability (when applicable). The recirculating tank should be purged and blanketed with nitrogen, fitted with an adequate venting and condensing system, and grounded to prevent accumulation of an electrical charge.

Steam-injected cleaning involves the injection of a concentrated mixture of cleaning chemicals into a stream of fast-moving steam. The steam is injected at one end of the system and condensed at the other. The steam atomizes the chemicals, increasing their effectiveness, and ensures good contact with the metal surface.

Steam-injected cleaning is very effective for critical piping systems. As with foam cleaning, the method produces a relatively low amount of liquid for disposal.

Chemical Cleaning Solutions

A wide variety of standard chemical cleaning solutions are available (Table 4). Many proprietary solutions are based on these chemicals. Some are patented or involve patented equipment. Chemical cleaning contractors are the best source of information on standard or patented techniques.

Table 4 Scales and solvents

Scale component	Solvent[(a)]	Testing conditions
Iron oxide	5 to 15% HCl	65-80 °C (150-175 °F)
Fe_3O_4 (magnetite or mill scale)	2% hydroxyacetic/1 formic	65-80 °C (150-175 °F) circulating
Fe_2O_3 (red iron oxide or red rust)	Monoammoniated citric acid	85-105 °C (185-220 °F) circulating
	Ammonium EDTA	75-150 °C (170-300 °F) circulating
	EDTA organic acid mixtures	40-65 °C (100-150 °F) circulating
Copper, oxides	Copper complexor in HCl	65 °C (150 °F)
	Ammoniacal bromate	50-85 °C (120-185 °F)
	Monoammoniated citric acid	60-85 °C (140-185 °F), pH 9 to 11
	Ammonium persulfate	Below 40 °C (100 °F)
	Ammonium EDTA	65-85 °C (150-185 °F), pH 9 to 11
Calcium carbonate	5 to 15% HCl	Preferably not above 65 °C (150 °F)
	7 to 10% sulfamic acid	Do not exceed 60 °C (140 °F)
	Sodium EDTA	Circulate at 60-150 °C (150-300 °F)
Calcium sulfate	Sodium EDTA	Circulate at 60-150 °C (150-300 °F)
	1% NaOH-5% HCl	Circulate at 50-65 °C (120-150 °F)
	EDTA organic acid mixtures	40-65 °C (100-150 °F) circulating
Hydroxyapatite of phosphate compounds ($Ca_{10}(OH)_2 \cdot (PO_4)_6$)	5 to 10% HCl	Preferably above 65 °C (150 °F)
	Sodium EDTA	Undesirable to add fluoric
		Circulate at 65-150 °C (150-300 °F)
	Sulfamic acid 7 to 10%	Do not exceed 60 °C (140 °F)
Silicate compounds, for example, acmite ($NaFe(SiO_3)_2$) and analcite ($NaAlSi_2O_6 \cdot H_2O$)	Prolonged treatment with 0.5 to 1% soda ash at 345 kPa (50 psi), follow with HCl containing fluoride	Alkaline preboil at 345-690 kPa (50-100 psi) for 12 to 16 h
Pedtolite ($4Ca \cdot Na_2O \cdot 6SiO_2 \cdot H_2O$)	HCl containing ammonium bifluoride	65-80 °C (150-175 °F)
Serpentine ($Mg_3Si_2O_7 \cdot 2H_2O$)		
Sulfides ferrous: troiline (FeS) and pyrrhotite (FeS)	HCl, inhibited	Heat slowly to avoid sudden release of H_2S toxic gas
Disulfides, FeS_2, marcasite and FeS_2, pyrite	Chromic acid, followed by HCl	Boiling 7 to 10% chromic acid, followed by inhibited HCl
Organic residues	Potassium permanganate, followed by HCl containing oxalic acid	Circulate at 100 °C (210 °F), add 1 to 2% $KMnO_4$ solution. Oxalic acid added to HCl controls release of chlorine toxic gas
Organo lignins		
Algae		
Some polymeric residues		

(a) The chemicals listed are to be considered possible solvents only. There are many alternative solvents for each deposit listed.

Most chemical cleaning contractors calculate the concentration of chemicals in weight percent, but some use volume percent. The user must be aware of this. For example, a 10 wt% solution of HCl is equivalent to 25 vol% of the normal 30% concentrated HCl.

Chemical cleaning solutions include mineral acids, organic acids, bases, complexing agents, oxidizing agents, reducing agents, and organic solvents. Inhibitors and surfactants are added to reduce corrosion and to improve cleaning efficiency. Following the cleaning cycle, a passivating agent can be introduced to prevent further corrosion or to remove trace ion contamination.

Mineral acids are strong scale dissolvers. They include HCl, hydrochloric/ammonium bifluoride (HCl/NH_4HF_2), sulfamic acid (NH_2SO_3H), HNO_3, phosphoric acid (H_3PO_4), and H_2SO_4.

Organic acids are much weaker. They are often used in combination with other chemicals to complex scales. An advantage of organic acids is that they can be disposed of by incineration. They include formic (HCOOH), hydroxyaceticformic, acetic (CH_3COOH), and citric acid.

Bases are principally used to remove grease or organic deposits. They include alkaline boilout solutions and emulsions.

Complexing agents are chemicals that combine with metallic ions to form complex ions, which are ions having two or more radicals capable of independent existence. Ferricyanide $[Fe(CN_6)]^{4-}$ is an example of a complex ion. Complexing agents are of two types: chelants and sequestrants. Chelants complex the metallic ion into a ring structure that is difficult to ionize, and sequestrants complex the metallic ion into a structure that is water soluble.

Oxidizing agents are used to oxidize compounds present in deposits to make them suitable for dissolution. They include chromic acid (H_2CrO_4), potassium permanganate ($KMnO_4$), and sodium nitrite ($NaNO_2$).

Reducing agents are used to reduce compounds in deposits to a form that makes them suitable for dissolution and to prevent the formation of hazardous by-products. They include sodium hydrosulfite ($NaHSO_2$) and oxalic acid.

Inhibitors are specific compounds that are added to cleaning chemicals to diminish their corrosive effect on metals. Most inhibitors are proprietary, and recommendations for their use are available from the supplier.

Surfactants are added to chemical cleaning solutions to improve their wetting characteristics. They are also used to improve the performance of inhibitors emulsify oils, improve the characteristics of foaming solvents, and act as detergents in acid and alkali solutions. As with inhibitors, most surfactants are proprietary products.

Hydrochloric acid is the least expensive and most widely used solvent for water-side deposits on steels. The concentration and temperature vary from 5 to 15% and 50 to 80 °C (120 to 175 °F). The acid must be replenished if the concentration falls below 4%.

Hydrochloric acid must always be used with a filming inhibitor to minimize corrosion. Inhibited HCl is usually suitable for cleaning carbon or alloy steel, cast iron, brasses, bronzes, copper-nickel alloys, and Monel 400.

Hydrochloric acid, even inhibited, is no recommended for cleaning stainless steels, Incoloy 800, Inconel 600, aluminum, or galvanized steel. Its applicability for cleaning titanium or zirconium depends on the oxidizing contaminants present in the acid.

Hydrochloric Acid/Ammonium Bifluoride. The addition of about 1% NH_4HF_2 releases HF, which not only improves the potency of the HCl but, more important, also aids in dissolving silicate scales. A filming inhibitor should be added. Materials compatibility is similar to that of HCl except that titanium, zirconium, or tantalum should never be exposed to an acid containing NH_4HF_2.

Hydrofluoric acid can be used as a preoperational cleaner to remove mill scale, at 1 to 2% and 80 °C (175 °F). It is not widely used in North America, because of unfamiliarity and perceived handling difficulties.

Sulfuric acid is used on a limited scale, from 5 to 10% at temperatures up to 80 °C (180 °F). Although inexpensive, it has several disadvantages, including the extreme care required during handling and the precipitation of calcium sulfate ($CaSO_4$) with deposits containing calcium salts.

When inhibited, H_2SO_4 may be used on carbon steel, austenitic stainless steels, copper-nickel alloys, admiralty brass, aluminum bronze, and Monel 400. Sulfuric acid should not be used on aluminum or galvanized steel.

Nitric acid is primarily used for cleaning stainless steel, titanium, or zirconium. It is an extremely strong oxidizer and is rarely used, because of handling difficulties. Conventional inhibitors, detergents, and other additives are not stable in HNO_3. It should not be used on carbon steel, copper alloys, or Monel 400. Piping for handling HNO_3 should be lined with stainless steel or polytetrafluoroethylene (PTFE).

Phosphoric acid is sometimes used at 2% and 50 °C (120 °F) for 4 to 6 h to pickle and passivate steel piping. It is not as effective as HCl in removing iron oxide scale, but is preferred for cleaning stainless steels.

Phosphoric acid was originally used for removing mill scale from new boilers because it also helped passivate the surface. It is also used to brighten aluminum.

Sulfamic acid is used from 7 to 10% up to 60 °C (140 °F) to remove calcium and other carbonate scales and also iron oxides. It is not as effective as HCl on iron oxides. If NH_2SO_3H is heated above 75 to 80 °C (170 to 180 °F), it begins to hydrolyze to H_2SO_4, greatly reducing its effectiveness. If mixed with sodium chloride (NaCl), HCl is slowly released, and the mixture is more effective in removing iron oxide deposits.

Although relatively expensive, NH_2SO_3H is reasonably safe to handle and may be transported solid and diluted on-site. This greatly facilitates handling and makes it preferred for in-house cleaning.

Inhibited NH_2SO_3H can be used to clean carbon steel, copper, admiralty brass, cast iron, and Monel 400. Without the chloride addition, it is effective on most stainless steels. The addition of ferric ion (Fe^{3+}) is used to protect 400-series stainless steels.

Formic acid is generally used as a mixture with citric acid or HCl because alone it is unable to remove iron oxide deposits. Formic acid can be used on stainless steels, is relatively inexpensive, and can be disposed of by incineration.

Hydroxyacetic-formic acid is used as a 2:1% hydroxyacetic-formic mixture at 80 to 105 °C (180 to 220 °F) to remove iron oxide and calcium deposits. When added, NH_4HF_2 will also remove silica-containing deposits. The acid must be inhibited for use on carbon steel.

Hydroxyacetic-formic acid is especially advantageous in nondrainable sections of reactors or boilers, because it may be decomposed to harmless by-products by heating to 150 to 175 °C (300 to 350 °F). The primary use of this cleaner is to remove Fe_3O_4 in critical boilers and in superheater sections of other boilers. It can be used on stainless steels and is applicable in mixed-metal systems.

Acetic acid is used to clean calcium carbonate scales, but it is ineffective in removing iron oxide deposits. Weaker than formic acid, it may be preferred where extremely long contact times are necessary.

Citric acid at 3% and 65 °C (150 °F) is used to clean iron oxide deposits from aluminum or titanium. Monoammoniated citric acid is effective in removing iron oxide deposits at pH 3.5. By adjusting the pH to 9 and adding an oxidant, such as $NaNO_2$, copper can be removed with the same solution. This technique is patented. Citric acid is also used to scavenge residual iron oxide from boilers after HCl cleaning in order to facilitate passivation treatment.

Alkaline boilout solutions are used to emulsify and disperse various oils, greases, and organic contaminants from new steel or stainless steel equipment, such as drum boilers and retubed heat exchangers. Examples are combinations of NaOH, trisodium phosphate (Na_3PO_4, or TSP), sodium carbonate (Na_2CO_3, or soda ash), and sodium silicate (Na_2SiO_3). These are added in concentrations of 0.5 to 1% and boiled or circulated for many hours, often under pressure. A low-sudsing dishwater-type detergent is usually added. Proprietary compositions are available from suppliers.

Some operators avoid using NaOH because of the possibility of SCC (caustic embrittlement) of steel. A controlled amount of sodium nitrate ($NaNO_3$) may be added to the NaOH to inhibit cracking.

Alkaline emulsions are used to remove coatings of oily material from inorganic deposits that prevent their dissolution by cleaning chemicals. For light-bodied oil, a Na_3PO_4-surfactant combination may be circulated for a few hours at 95 °C (200 °F) to remove it. The equipment is then flushed with water.

Chelants will complex such deposits as iron oxide or copper. They include ethylenediaminetetraacetic acid (EDTA), citric acid, gluconic acid, and nitroacetic acid.

Chelating agents must be pH adjusted by using acids or alkalis, depending on the type of chelating agent and the scale constituents to be complexed. For example, under alkaline conditions, the sodium salt of EDTA will complex calcium-containing deposits, but it will not remove iron oxide.

The most common chelating agent is the ammonium salt of EDTA, which is used to remove Fe_3O_4 scale from boilers at 75 to 150 °C (170 to 300 °F). Following this, the solution is oxidized using air to remove copper. This solution must be inhibited to prevent corrosion of the steel.

Some chelating processes are patented, such as the Alkaline Copper Removal Process (Ref 16), which uses triammonium EDTA at a pH of 9.2 for removing copper and iron oxides from a boiler while it is intermittently fired. Another patented chelating agent is the Citrosolv Process (Ref 17), which uses inhibited ammoniated citric acid to dissolve iron oxides and copper in utility steam generators. Chelating agents can often be incinerated, minimizing disposal problems.

Copper complexers, such as thiourea and hexhydropyrimidine-2-thione, are added to HCl when both iron and copper oxide deposits are present. The complexers help dissolve the copper and prevent it from plating out on steel in the system.

Chromic acid is used at 7 to 10%, primarily to remove iron pyrite and certain carbonaceous deposits that are insoluble in HCl. The iron pyrite is oxidized to the sulfate without the evolution of H_2S. With carbonaceous deposits, H_2CrO_4 degrades the tar that holds the deposits together.

Chromic acid is a strong oxidizing agent and should not be used on copper, brass, bronze, aluminum, zinc, or cast iron. It is acceptable on carbon steel and stainless steel. Steel piping should be used for handling it because nonmetallic hose materials, other than PTFE, are rapidly degraded.

Caustic permanganate is widely employed as a pretreatment in refinery-cleaning operations to remove carbonaceous deposits coupled with pyrophoric sulfides. A solution of 1% NaOH and 0.7% $KMnO_4$ is used at 65 to 80 °C (150 to 175 °F). This converts iron sulfide to iron oxide and sulfur, both of which can be removed with acid cleaning. Little or no H_2S is generated. If HCl is used for the acid-cleaning step, oxalic acid should be added to reduce any chlorine gas that might be evolved upon reaction with the insoluble manganese formed during the first stage of cleaning.

Organic solvents used to dissolve organic deposits include kerosene, xylene, toluene, xylene bottoms, heavy aromatic naphtha, 1,1,1-trichloroethane, N-methyl-2-pyrrolidone, alcohols, glycols, and ortho-dichlorobenzene (Ref 18).

Some solvents are strictly regulated by Environmental Protection Agency (EPA), Occupational Safety and Health Administration (OSHA), and state and local regulations. The use of any solvents should be carefully reviewed. With few exceptions, rubber hoses or rubber-lined equipment should not be used to handle organic solvents.

Organic emulsions are solvent-based cleaners for heavy organic deposits, such as tar, asphalts, and polymers. These solutions typically consist of an aromatic solvent, a chlorinated hydrocarbon, and emulsifying agents. The mixture should be capable of being heated to 65 to 70 °C (150 to 160 °F). A thorough rinsing step is necessary to remove the sludge left behind when the cleaning agent is drained. The possibility of hydrolysis of the chlorinated hydrocarbons prevents use of these mixtures on stainless steels.

Passivating solutions are used to prevent carbon steel from rusting after acid cleaning, before it is returned to service. The term passivation is also applied to procedures that are used to remove surface iron contamination from stainless steel and titanium equipment.

Most passivating solutions for carbon steel are alkaline and contain an oxidizing agent, even if it is only air. They are applied after rinsing and neutralization.

For the passivation of stainless steel and titanium, mild iron contamination may be removed by using a mixture of 1% each of citric acid and HNO_3. For more persistent contamination, strong HNO_3 solutions must be used (Ref 19).

Corrosion inhibitors are added to chemical cleaning agents to permit effective cleaning without excessive corrosion of the equipment. Most inhibitor formulations are organic compounds and function in three ways (Table 5):

- *Cathodic inhibitors* impede the cathodic half of the corrosion reaction, for example, $2H^+ + 2e^- \rightarrow H_2$
- *Anodic inhibitors* limit the anodic half of the corrosion reaction, for example, $Fe \rightarrow Fe^{2+} + 2e^-$
- *Adsorption inhibitors* form a physical barrier on the metal surface and prevent corrosion

Table 5 Classification of selected corrosion inhibitors

Cathodic	Anodic	General adsorption
Alkylamines	Benzotrizole (H)	Acetylenic alcohols
Benzotriazole (L)	Mannich bases	Benzotriazole
Diphenylamine	Pyridines	Dibenzylsulfoxide
Thioureas (L)	Quinolines	Diphenylamine
	Thiols	Furfuraldehyde
	Thioureas (H)	

Inhibitors must be capable of dispersing or dissolving in the chemical cleaning solution, both fresh and contaminated. They must also be compatible with the equipment materials of construction, for example, low-chloride inhibitors should be used on stainless steels.

The concentration of the inhibitor used is related to the type of solvent, its temperature, the equipment materials of construction, the surface-to-volume ratio in the equipment, and the degree of turbulence. Typical film-forming inhibitor concentrations for mineral acids on steel are of the order of less than 0.2%.

Most common inhibitors are proprietary formulations, and technical data may be obtained from suppliers. Inhibitors often contain dyes, which confirm whether or not the inhibitor has been added.

Chemical Cleaning Procedures

In addition to selecting the optimum solvent, other factors essential to successful chemical cleaning are the development of a safe and effective procedure and the prevention of excessive equipment corrosion. Selection of the chemical cleaning contractor is important because the quality of individual crews can vary. Also, the contractor must have the ability and experience to use specific procedures, some of which may require unique steps or patented procedures. The proposed procedure should be written and included in a scope of work that is mutually agreeable to the owner and the contractor. When the job is complete, the key elements must be documented.

Planning Stage. The proposed cleaning procedure should be reviewed with the contractor or personnel who will conduct the cleaning. The procedure should outline the specific duties of the contractor and the owner and should include the following:

- Listing of all chemicals used, including primary solvent and corrosion inhibitor, surfactants, emulsifiers, neutralizers, passivators, and antifoams
- Solution contact times, temperatures, and pressures
- Method of corrosion control and monitoring
- Special contractor equipment required, such as filter elements, high-volume pumps, and heat exchangers
- Contractor safety procedures and owner safety requirements, for example, methods of treating hazardous by-products, such as H_2S and hydrogen cyanide (HCN), which may be generated during cleaning
- Disposal requirements for waste material, including adherence to federal, state, and local regulations
- Lay-up requirements after cleaning, if equipment is not to be used immediately

When mutually agreed upon, the procedure is developed into a scope of work.

Cleaning Stage. The equipment is readied for cleaning. After isolation, all restrictions, such as orifice plates, should be removed. Tubes of a shell and tube heat exchanger should be cleaned of obstructions before chemical cleaning. Failure to free the tubes could result in solvent remaining in tubes and possible damage at start-up. In general, the chemical cleaning operation consists of the following steps:

- Leak testing of contractor fittings
- Hooking up of cleaning system
- Establishment of circulation rate and temperature
- Blending in of chemicals
- Circulation and monitoring, which include recording of solvent strength and deposit removal. If the solvent strength remains constant for two or more consecutive readings, cleaning is usually considered complete
- Draining system of solvent
- Flushing with water
- Neutralizing, if an acidic solvent was used
- Passivation, if required
- Inspection and evaluation of cleaning

Documentation of Cleaning. A simple format will include relevant information on the equipment temperature, materials of construction, chemicals, method of circulation, time of circulation, and evaluation of equipment. The format may be modified for different pieces of equipment.

Corrosion Monitoring in Chemical Cleaning. Chemical cleaning introduces the real possibility of equipment damage from corrosion. Various precautions may be taken to eliminate damage or to reduce the corrosion rate to acceptable levels, such as reducing the cleaning temperature or contact time. Corrosion monitoring during chemical cleaning may consist of on-line electrochemical monitoring, corrosion coupons, or a bypass spool piece containing a sample of the deposit.

On-line electrochemical monitoring provides an instant record of the corrosion rate during cleaning. However, localized corrosion effects are not indicated.

Corrosion coupons should be representative of the materials of construction of the equipment being cleaned. They should be insulated from one another to avoid galvanic effect. If necessary, special coupons, such as U-bends, should be included to check for SCC. The corrosion rates of coupons are generally higher than the actual corrosion rate of the equipment during the cleaning cycle. However, excessively high coupon rates suggest that cleaning has been performed outside of the desired range of temperature, chemical concentration, or circulation rate. Experience dictates acceptable corrosion rates obtained from corrosion coupons. Localized corrosion observed on coupons is unacceptable. A bypass spool piece containing a sample of the deposit is the ideal coupon because it will indicate the effectiveness of the cleaning as well as the condition of the metal after cleaning.

Corrosion should be monitored during every chemical operation. Post-inspection is extremely important to check for damage and to gage the effectiveness of cleaning. Certain scales may increase the corrosiveness of the chemical cleaning solution as they dissolve.

Corrosion Rate. Chemical cleaning contractors measure the general corrosion rate in pounds per square foot per day ($lb/ft^2/d$). This unit is converted to mils per year (mils/yr) by using a factor that varies with the density of the metal under consideration. To obtain mils per year, multiple pounds per square foot per day by 70.3×10^3/density (grams per cubic centimeter). For steel, 0.01 $lb/ft^2/d$ = 91 mils/yr.

A significantly higher corrosion rate is tolerable during chemical cleaning than would be allowed in service. For example, 400 mils/yr obtained from coupons may be acceptable for carbon steel. With relatively thick components, such as pump casings, even higher rates may be tolerable. Less than 200 mils/yr should be the goal. Localized corrosion--for example, pitting or SCC--is not tolerable.

Localized Corrosion. The principal forms of localized corrosion that occur during chemical cleaning are pitting, SCC, and under-deposit corrosion (crevice corrosion).

Pitting occurs when filming inhibitors break down or there is insufficient inhibitor addition. Pitting will also occur with HCl and incompatible metals, such as aluminum or stainless steels. Oxidizing conditions, such as free Fe^{3+} ion, and the presence of the chloride ion (Cl^-) will also encourage pitting in metals resistant to general corrosion, especially the active-passive metals mentioned. Pitting is especially harmful on thinwall equipment, for example, heat-exchanger tubes.

Stress-corrosion cracking is likely to occur in specific chemical alloy combinations when the threshold temperature and concentration requirements for cracking are exceeded. This usually occurs in vapor spaces, splash zones, or crevices where the cleaning agent can concentrate. If the chemical cannot be washed out, SCC may occur later, for example, during service. The two most common situations to guard against are the hydroxyl ion (OH^-), for example, from caustic, with carbon steel and the Cl^- ion, for example, from HCl, with austenitic stainless steels. In some cases, an inhibitor can be added to minimize cracking. Hydrogen-assisted cracking may also occur in hardenable low-alloy and stainless steels in specific heat-treated conditions during acid cleaning.

Under-deposit corrosion occurs when cleaning is incomplete and the deposits left behind harbor or concentrate corrosives. The corrosion is difficult to see because it is hidden by the deposits.

Temperature, Pressure, and Flow Rate. Of these factors that affect corrosion rate, temperature is the most significant. The higher the temperature of the solvent, the more effective the cleaning generally is. However, corrosion rate increases significantly with temperature and limits the temperature that can be used (Fig. 6). Increasing temperature also increases the amount of inhibitor required.

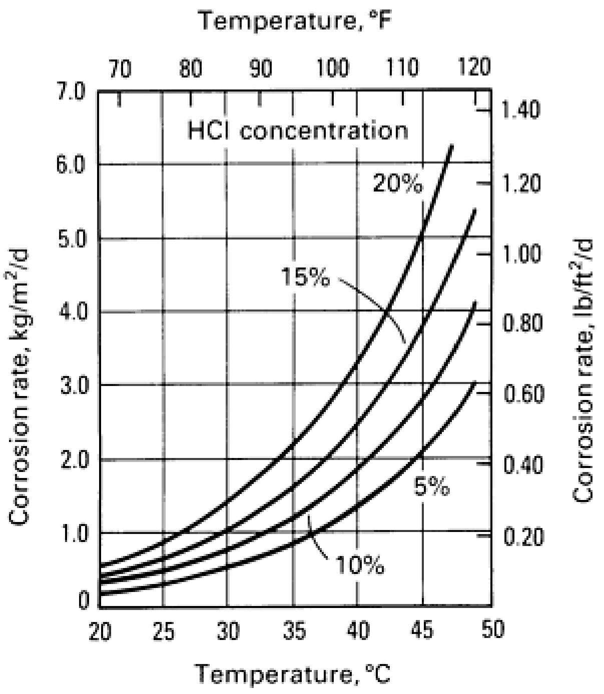

Fig. 6 Effect of temperature on corrosion of low-carbon steel in uninhibited HCl

Each cleaning operation should include a review of the pressure (hydrostatic and gas) that may be experienced. Acceptable limits should not be exceeded. For example, in one operation, impervious graphite heat-exchanger tube failures were significantly reduced when the recirculating solvent pressure was decreased from 690 to 207 kPa (100 to 30 psig).

It is extremely difficult to relate flow rate or solution velocity directly to the corrosion rate. This is because the key to increased corrosion rate is turbulence. Experience is the best indicator of velocity or flow limitations during chemical cleaning.

Ferric ion corrosion is a form of general or localized corrosion that occurs on carbon steel, nickel, Monel 400, copper, brass, and zirconium during chemical cleaning. The effect is worst with HCl (because of the presence of the Cl^- ion), but can also occur in other mineral acids, citric acid, EDTA chelant formulations, and HCOOH.

Ferric iron corrosion occurs when there are heavy deposits of iron oxide coupled with aeration during cleaning. Dissolution during cleaning, together with aeration, generates the Fe^{3+} ion, which corrodes steel as follows:

$$2Fe^{3+} + Fe \rightarrow 3Fe^{2+} \qquad \textbf{(Eq 1)}$$

Other metals can also be corroded because of the oxidizing nature of the Fe^{3+} ion, especially if the Cl^- ion is present.

Ferric ion corrosion may be prevented with specific inhibitors, for example, stannous chloride ($SnCl_2$). It prevents the formation of Fe^{3+} ion, as follows:

$$\begin{aligned} Sn^{2+} &\rightarrow Sn^{4+} + 2e^- \\ Sn^{2+} + 2Fe^{3+} &\rightarrow Sn^{4+} + 2Fe^{2+} \end{aligned} \qquad \textbf{(Eq 2)}$$

Proprietary Fe^{3+} ion corrosion inhibitors are also available.

Even if an Fe^{3+} ion inhibitor is added, the total iron content (ferrous and ferric) must be monitored regularly (at least every 30 min) during cleaning. Measurement of the Fe^{3+} ion content may be misleading. When the iron content reaches 2 to 3%, the solution should be removed.

Sulfide Corrosion. Sulfides are present in many refinery deposits, and H_2S may be released when sulfides are contacted by acid cleaning solutions. Sulfides and H_2S are extremely corrosive and reduce the effectiveness of corrosion inhibitors. Hydrogen sulfide will also crack hardenable low-alloy steels and blister low-strength carbon steels.

Corrosion problems with sulfides and H_2S may be reduced by lowering the acid concentration and temperature. Inhibitors are effective in preventing cracking or blistering.

Sulfide stringers present in free-machining steels have increased susceptibility toward corrosion during acid cleaning. Selenium-containing free-machining steels or low-sulfur regular grades are less susceptible to attack.

Effectiveness of Corrosion Inhibitor. A useful qualitative test to check whether a filming inhibitor has been added to the system before circulation is the steel wool test. In this test, a small wad of steel wool is completely immersed in a breaker containing the inhibited acid at the strength and temperature to be used during cleaning. If the inhibitor addition is effective, there should be no hydrogen evolution from the beaker for at least 5 min and the wad of steel wool should remain at the bottom of the beaker.

As noted above, by-products formed during cleaning can reduce the effectiveness of the corrosion inhibitor. Also, increasing temperature and concentration of cleaning chemicals usually necessitates a greater dose of inhibitor.

Mechanical Cleaning

Mechanical cleaning is extensively used to clean many types of equipment. There are three broad categories: hydraulic, abrasive, and thermal.

The hydraulic category includes water cleaning, high-pressure water blasting, ultrahigh-pressure water blasting, and ultrasonic cleaning. The abrasive category includes rodding, drilling, sandblasting, pigging and scraping, turbining, and explosive removal. The thermal category includes steam cleaning.

Hydraulic cleaning is carried out at pressures from 2070 kPa to 221 MPa (300 to 32,000 psig).

Water cleaning is often used to flush mud and debris from pipelines at pressures to 2070 kPa (300 psig). Slug flow flushing with air injection will obtain better scouring and will conserve water. Water, coupled with a pipeline pig, is often effective in removing scale and corrosion products from lines.

High-pressure water cleaning, the most common form of mechanical cleaning, is carried out at pressures of 6.9 at 69 MPa (1000 to 10,000 psig). It is used to remove such deposits as light rusting, minerals, and polymers. There are three types of high-pressure water cleaning: tube lanching, line moling, and shotgun jetting.

In tube lancing, a rigid or flexible lance is used to clean the inside of tube bundles, and the operation is repeated for each tube. In line moling, a short self-propelled jet nozzle (mole) and a high-pressure hose are used to clean the inside of piping. In shotgun jetting, a relatively short handheld gun (shotgun) is used to clean surfaces that cannot be cleaned practically by the other means. Shotgun jetting is not effective in cleaning tubes.

High-pressure water cleaning reduces the risk of corrosion damage to equipment, and disposal of the water is less of a problem than with chemical cleaning. Also, the risk of generating hazardous or toxic by-products is eliminated.

The jetted stream is provided by an operator holding a water lance. The lowest pressure with appropriate volume of water is selected, consistent with achieving the required degree of cleaning. This is dictated by experience and risk to personnel.

High-pressure water cleaning must be done by trained personnel using appropriate safety devices and regularly inspected equipment. The area around the job should be suitably barricaded and sign posted.

Line friction leads to a significant loss of pump pressure. To counteract friction loss when pumping through a long hose, organic polymers have been developed that, when added to water in concentrations as low as 0.05 to 0.1%, reduce friction loss as much as 90%.

Ultrahigh-pressure water blasting is conducted at 221 MPa (32,000 psig), using a flow rate of 1 to 4 gal/min. The low flow rate means there is a very low back thrust, allowing the equipment to be operated in congested work spaces with a higher degree of safety. The ultrahigh pressure and low volume of delivery are achieved by using intensifiers rather than the standard plunger pumps. Nozzle configurations are tailored to the application. The nozzle is usually held 19 to 100 mm ($\frac{3}{4}$ to 4 in.) away from the workpiece. The tooling is specially designed for specific applications, primarily scale, rust, and polymer removal; tube bundle cleaning; and such specialized items as cleaning turbines, diaphragms, and rotors. Cleaning is not effective around more than one 90° turn. The low volume of water minimizes disposal problems.

The technique is particularly advantageous where high-pressure water blasting is ineffective and sandblasting is not desirable, for example, adjacent to pumps, valves, and compressors. Ultrahigh-pressure water blasting has been cost-effective in preparing surfaces for inspection, such as the wet fluorescent magnetic-particle inspection of deaerator welds. In these cases, an inhibitor is added to the water to prevent flash rusting.

Ultrahigh-pressure water blasting is a proprietary process and is limited to a few vendors who tailor their tools to specific jobs. It is more expensive than high-pressure water blasting, but has the advantages of quality and speed.

Abrasive cleaning is implemented where hydraulic cleaning may not be practical.

Rodding is used for lightly plugged heat-exchanger tubes where scale has not built up. Care should be taken to prevent scoring of the tubes.

Drilling may be used on tightly plugged heat-exchanger tubes. The drill is hollow, and a fluid connection is used to flush out freed material, eliminating the need to pull the drill out to clear the point and remove loose material.

Sandblasting involves cleaning the internal surface of process lines and equipment by using an abrasive blasting tool. These are available for different pipe sizes. A standard sandblast nozzle is used that impinges the sand against the conical carbide tip of the nozzle, spraying the sand out radially against the walls of the tube. A circular end plate removes most of the sand as the tool is pulled back out of the pipe.

Piping and Scraping. Pipeline pigs and scrapers are sometimes used, alone or with special chemicals, to clean pipelines. This is a combination of mechanical and chemical cleaning.

The pig is a flexible bullet-shaped foam cylinder that is propelled through the pipeline with water. A typical system consists of several pigs, launching and trapping facilities, and a water source. Pigging has been used to clean lines from 25 to 914 mm (1 to 36 in.) in diameter.

Turbining is a tube- or pipe-cleaning method that uses air, steam, or water to drive a motor that turns cutters, brushes, or knockers in order to remove deposits. Many different heads are available for different deposits and equipment, including models for curved tubes.

Overzealous turbining may damage pipes because the cutter types will cut into the base metal. Also, turbining is relatively slow and costly compared to other mechanical and chemical methods.

Explosive removal of pipe deposits requires experience and has been used on hard and brittle deposits in piping. Primacord is manufactured in various degrees of explosive power; selection of the proper strength depends on pipe size and type of deposit.

Thermal cleaning is the third major mechanical cleaning method.

Steam cleaning can be used to remove mill scale and debris from lines and equipment. When mixed with oxygen, steam cleaning can remove coke and polymers from equipment.

On-Line Cleaning

The cleaning methods discussed so far require that the equipment be removed from service and opened to some degree for the cleaning. In some cases, on-line cleaning is effective and more convenient. On-line cleaning can be chemical or mechanical, infrequent or regularly scheduled. Effective on-line cleaning can save time and labor and can prevent a shutdown. Examples of on-line cleaning include:

- Side-stream filtration
- Air bumping of heat exchangers
- Washing soft deposits from steam turbines
- Reversing flow in heat exchangers
- Passing brushes or sponge balls through exchanger tubes
- Depressing pH or adding sequestrants and dispersants in a cooling water system
- Increasing chelant or dispersant feed to a boiler

Not all cleaning jobs are conducive to on-line cleaning. Hard or insoluble deposits may not be removed effectively. In boilers, if the deposit is heavy, on-line cleaning may cause the deposit to slough and plug tubes--possibly leading to tube failures. Also, some on-line cleaning costs can be high, for example, the initial cost of installing brushes or sponge balls to clean heat exchangers. Each case must be evaluated individually to determine if on-line cleaning will be cost-effective.

The proliferation in recent years of corrosion failures of both steel and stainless steel under insulation has caused this problem to be of great concern to the operators of petroleum-, gas-, and chemical-processing plants. Piping and vessels are insulated to conserve energy by keeping cold processes cold and hot processes hot. Once a vessel is covered with insulation and operating satisfactorily, concern for the condition of the metal under insulation usually diminishes. Thus, corrosion of steel and SCC of stainless steel begins and develops insidiously, often with serious and costly consequences many years later. To deal with corrosion under insulation effectively and economically, a systems approach must be developed that considers the metal surface, temperatures, water, insulation, and design.

Corrosion of steel under insulation did not receive a great deal of attention by the corrosion engineering community until the late 1970s and early 1980s. Although considerable attention was being given to the SCC of stainless steel under insulation (see below), steel vessels and piping were rarely mentioned. This situation existed because of the slow corrosion rate of the steel equipment, together with the fact that many large hydrocarbon-processing plants were built 10 to 20 years earlier.

The most significant turn of events, which fortunately revealed the corrosion problem to many, was the energy shortage and the resultant emphasis on energy conservation. The effort to conserve energy soon led to replacement of much of the 10- to 20-year-old insulation with more efficient systems. As the old insulations were removed, localized, often severe corrosion damage was found.

In 1978, the Materials Technology Institute (MTI) of the Chemical Process Industry initiated a project at Battelle Columbus Laboratories to define the problem of corrosion of steel equipment under thermal insulation and identify nondestructive techniques potentially capable of detecting such corrosion (Ref 20). This work on nondestructive testing for corrosion under insulation has been continued by MTI through a second and third phase, leading to a new electromagnetic technique. Another example of the recent interest in this corrosion problem was the Joint Conference on Corrosion Under Insulation held in San Antonio, TX, in October of 1983 (Ref 21).

Stress-corrosion cracking of stainless steel under thermal insulation has been observed and recognized for many years (Ref 22, 23). The collection of and concentration of chlorides on austenitic stainless steels can lead to rapid failure of expensive equipment. The study of this phenomenon has attracted much attention, and many approaches have been attempted in order to alleviate the problem. The roles of the insulation materials, atmospheres, moisture entry, and operating temperature have been investigated (Ref 21). Many of these concepts can also be applied to the general corrosion of steel under insulation. This section is divided into two parts: one discusses steel, and the other discusses stainless steel, because the nature of the problem, aside from the presence of insulation, is different.

Corrosion of Steel Under Insulation

The Problem. Steel does not corrode simply because it is covered with insulation. Steel corrodes when it contacts water and a free supply of oxygen. The primary role of insulation in this type of corrosion is to produce an annular space in which water can collect on the metal surface and remain, with full access to oxygen (air).

The most active sites are those where the steel passes through the insulation and on horizontal metal shapes--for example, insulation support rings where water can collect. Figures 7, 8, 9 show some of the types of damage that occur near insulation entry points.

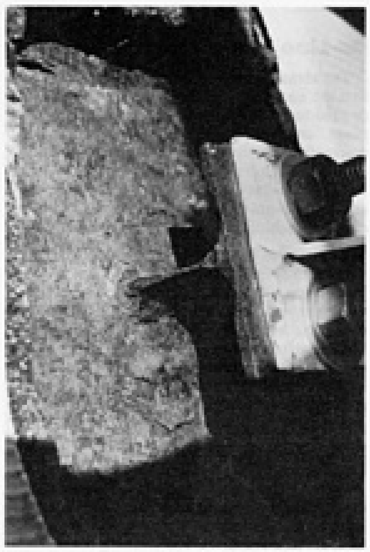

Fig. 7 Heavy corrosion of a steel support bracket where it passed through cellular glass insulation on a cold-temperature column. Moisture condensed on the column shell where the support was warmed by the extended attachment.

Fig. 8 Corrosion around the ladder clip of a gas-processing column. The column was painted with an inadequate protective coating (0.05 mm, or 2 mils, of epoxy) that could not prevent corrosion near the moisture entry points.

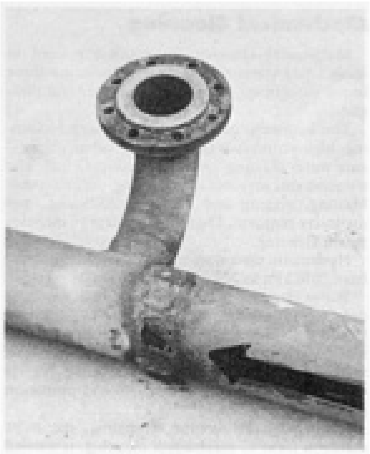

Fig. 9 Steel pipe corroded on the bottom side where a poorly sealed insulation joint allowed water to enter the insulation/pipe annulus. The moisture ran around the pipe and collected on the bottom.

The other major corrosion problem develops in situations where there are cycling temperatures that vary from below the dew point to above ambient. In this case, the classic wet/dry cycle occurs when the cold metal develops water condensation that is then baked off during the hot/dry cycle. The transition from cold/wet to hot/dry includes an interim period of damp/warm conditions with attendant high corrosion rates. Figures 10 and 11 show examples. In both cases, if the lines had operated constantly either cold or hot, no significant corrosion would have developed.

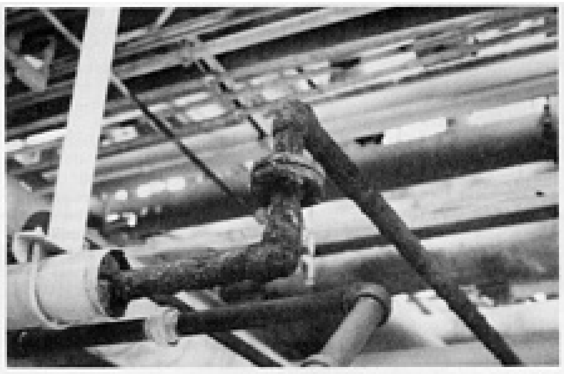

Fig. 10 Heavy general corrosion of a steel line insulated with cellular glass and aluminum outer jacketing. The line is at ambient temperature except when it is used to vent hydrocarbons. Temperature then decreases, causing moisture condensation, followed by warming to ambient temperature and slow corrosion. The line was replaced after 11 years of service.

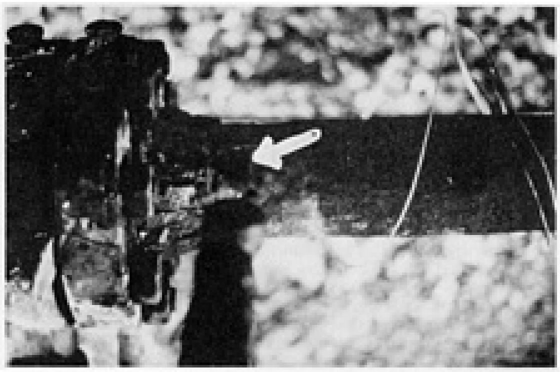

Fig. 11 Severe corrosion of a steel line in cyclic hot and cold service. The line was originally in fuel gas service, painted with inorganic zinc, and left uninsulated. It was changed to hydrocarbon/steam cyclic service and insulated for safety reasons. Wetting of the line under the end of the insulation and failure of the inorganic zinc paint caused corrosion in less than 3 years.

The Mechanism. The corrosion rate of steel in water is largely controlled by two factors: temperature and availability of oxygen. In the absence of oxygen, steel corrosion is negligible.

In an open system, the oxygen content decreases with increasing temperature to the point where corrosion decreases even though the temperature continues to increase (Fig. 12). A numberof recent case histories of corrosion under insulation have been reviewed, and the estimated corrosion rates have also been plotted in Fig. 12. These field data confirm that corrosion of steel under insulation increases steadily with increasing temperature, matching the curve for a closed system.

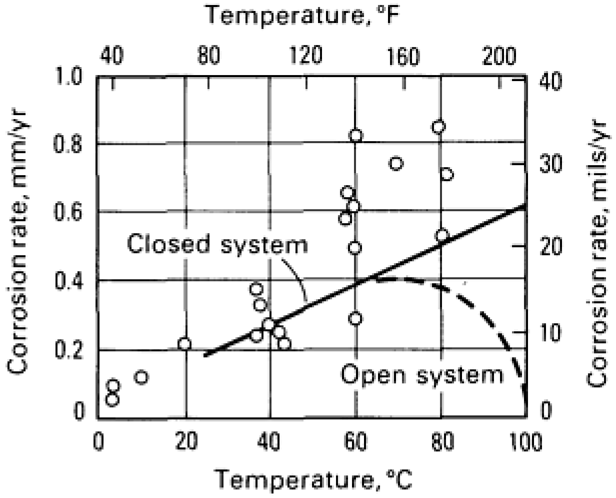

Fig. 12 Effect of temperature on corrosion of steel in water. Data points are from actual plant measurements of corrosion under insulation.

The problem of steel corrosion under insulation can be classified as equivalent to corrosion in a closed hot-water system. The thermal insulation does not corrode the steel, but, more correctly, forms an annular space where moisture collects. The insulation also forms a barrier to the escape of water or water vapors, which hastens the normal corrosion rate of wet steel.

In an attempt to determine which insulation contributes most and which contributes least to corrosion of steel, tests were conducted that compared 12 common insulation materials (Ref 24). After a 1-year exposure to the elements, dousing with water, and daily heating with steam, it was concluded that, although the insulation materials that absorbed water developed higher corrosion rates than those that did not, the difference between the two was not great. Therefore, efforts to select a type of insulation to prevent corrosion would not be practical. Field observation and reports from the literature confirm that corrosion of steel occurs under any and all types of insulation.

Prevention. One attempt to prevent corrosion damage involves adding a corrosion inhibitor to the insulation. Inhibitors such as Na_2SiO_3 are added for this purpose. The practical effects of such an approach are questionable. In one set of laboratory tests, inhibited insulation material was submerged in water, then set out to dry. After several cycles of wetting and drying, the insulation was found to have no benefit over uninhibited insulation of the same brand.

A corrosion inhibitor for insulation must be water soluble so that it can be dissolved and carried to the steel surface. If the insulation is waterproofed on the outside, water will enter through cracks and openings in the insulation system. This water is in the annulus and contacts only the inner surface of the insulation. The water-soluble inhibitor will soon be extracted and displaced by the water running down the vessel walls. Therefore, relying upon a consumable inhibitor for long-term protection may not be dependable.

If water entry to the insulation/steel annulus is the problem, perhaps the solution lies in more effective waterproofing. Advancements in various metal jacketings, sealants, and mastics have improved the protection of insulation materials from water, weather, and man. However, these waterproofing systems probably do not prevent water entry, because, in order to seal and prevent the annulus from breathing with temperature changes, the seal would have to be equivalent to a pressure vessel.

Waterproofing systems are designed to keep the insulation dry. They are not capable of preventing water vapor and air from contacting the annular space. In fact, a waterproofing system keeps the water vapor in the annulus and effectively produces the hot-water closed system, with attendant high corrosion rates.

Therefore, selection of insulation, inhibiting the insulation, and waterproofing of the insulation are not effective deterrents to corrosion. Instead, a high-quality protective coating, correctly applied to the steel before insulation, can offer long-term

protection. Although a specific coating system cannot be recommended, the requirements that must be met by the coating can be specified.

In the insulation industry, a primer is sometimes used, particularly under spray-on foam insulation materials. It should be understood that the purpose of the primer is to present a clean surface for bonding of the insulation. The primer-type paints are not intended to and will not prevent corrosion by hot water. The key to specifying a paint system is to remember that it will be exposed to hot water vapors, a very severe environment for paints.

The use of inorganic zinc paint as a primer, coupled with the hot water, will not cause accelerated corrosion of the steel. Zinc and the silicate binder are both dissolved by hot water. Even if conditions favored the zinc becoming cathodic to steel, the protective coating binder would dissolve and the coating would break down. The piping shown in Fig. 11 had inorganic zinc paint, which dissolved when the pipe was insulated and put into hot/cold cyclic service.

The advisability of using inorganic zinc under other protective coatings is not as clear. Some tests seem to indicate good performance. Others show that inhibited primers with topcoats achieve maximum performance in hot-water systems. Therefore, the main criterion for a protective coating under insulation is that it resist hot water and water vapors. This severe service will also require high-quality surface preparation.

Inspection. The final subject regarding corrosion of steel under insulation is monitoring or inspection. Due to the widespread occurrence of corrosion under insulation, the need for rapid, quantitative nondestructive testing inspection of the steel has developed. The most common procedure is to cut plugs or windows in the insulation, exposing the steel for ultrasonic thickness testing.

Spot thickness testing is relatively accurate, but covers only a very small portion of the vessel or piping. Corrosion under insulation tends to be localized; therefore, spot checking can miss potential trouble areas. Several private inspection companies are working on devices to measure corrosion of steel through insulation be eddy-current techniques. Although these seem to have merit, they are greatly restricted by the usually complicated geometry of a chemical plant piping system.

In 1979, MTI commissioned a study to evaluate this corrosion problem and review the state-of-the-art for inspection through insulation (Ref 20). This project was followed by a second phase to evaluate use of x-rays and fluorescent image enhancers plus continuous television monitoring (Ref 25). The results showed that piping could be inspected at 1.5 m/s (5 ft/s) and revealed significant corrosion. The practical problems of using the massive inspection equipment in the field makes its usefulness in the plant uncertain.

A third MTI study was authorized to develop a special-frequency electromagnetic analyzer. The work is in progress and is reportedly meeting with success. Field trials are planned to evaluate the practical feasibility of this method in the plant.

However, the established procedure of cutting windows and measuring directly is still the most widely used. With an enhanced understanding of the mechanism, the inspectors can make better choices about where to spot check in order to locate corrosion. Specific areas that should be on the inspection checklist include:

- All surfaces exposed to frequent hot/cold temperature cycling
- Cold-temperature equipment where nozzles, clips, and brackets extend through the insulation
- The hot-to-cod interface area of cold-temperature distillation columns with a hot base temperature
- Horizontal piping, particularly at joints or piping branches and on the bottom of the pipe
- Wherever the insulation weather barrier has been mechanically damaged or removed
- Wherever the insulation has changed shape or started to swell, indicating a possible rust build-up

Once the steel equipment has been covered with a good protective coating, the inspection at windows can be made less frequently and is necessary only to monitor the condition of the paint. Thickness readings are not necessary unless the paint film has failed.

SCC of Stainless Steel Under Insulation

The Problem. During and after World War II, many new petrochemical plants were built in the United States. Many of these plants contained equipment built with the new austenitic stainless steels. These alloys, such as types 304, 316, and 347, were widely used to combat process corrosion and to maintain product purity. As in all chemical processes, a large percentage of this equipment was insulated for thermal efficiency.

During this period, corrosion and materials engineers discovered some of the limitations of these stainless "wonder metals." In addition to crevice corrosion and weld decay, the engineers encountered SCC. In 1956, a paper was published describing a lab test for evaluating insulation materials as SCC initiators (Ref 26).

As the insulation systems and their weather barrier coatings aged, more incidents of SCC under insulation began to occur in the chemical-processing industry (Fig. 13). In the following years, much work was done to investigate the problem and the counter measures (Ref 23, 26).

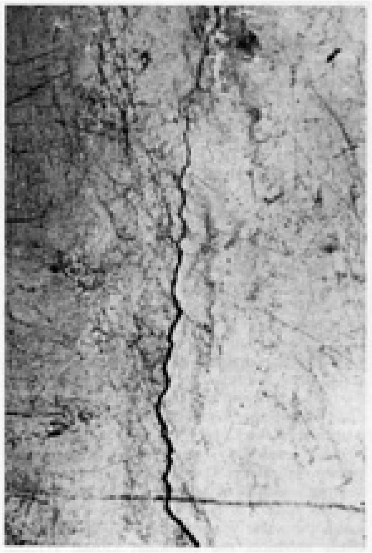

Fig. 13 Typical chloride SCC of stainless steel under insulation. The major crack is accompanied by a branched network of very fine cracks. Approximately actual size

The Mechanism. Soon after the widespread use of the 18-8 austenitic stainless steels, beginning in the late 1930s, it became clear that the Cl^- ion in water could be very damaging (Ref 27). In addition to causing localized corrosion, such as pitting and crevice corrosion, rapid failure was seen in the form of a fine network of transgranular cracking (Fig. 14). This pattern of cracking is very destructive and is found on the surface (Fig. 13) as well as in cross section (Fig. 14).

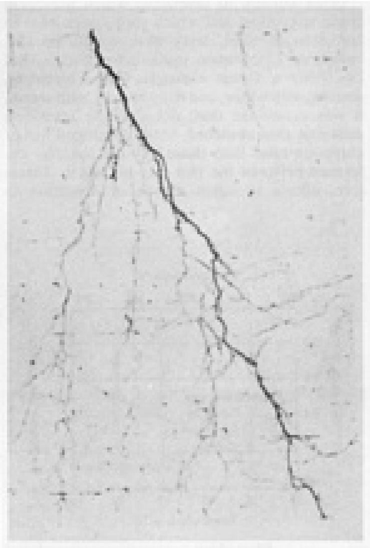

Fig. 14 Fine transgranular cracks typical of those found in 18-8 stainless steels. 80 ×

The theoretical processes of chloride SCC of the 18-8 stainless steels are under investigation. However, it has been established that four conditions are necessary for SCC to develop:

- An 18-8 austenitic stainless steel
- The presence of residual or applied surface tensile stresses
- The presence of chlorides; bromide (Br^-), and fluoride (F^-), ions may also be involved
- The presence of an electrolyte (water)

When these conditions are present, the occurrence of SCC is highly probable.

The stainless steel alloys susceptible to SCC are generally classified as the 18-8's. This includes the molybdenum-containing grades (types 316 and 317), the carbon-stabilized grades (types 318, 321, and 347), and the low-carbon grades (types 304L and 316L). Many variations of the basic 18-8 have been developed in order to combat SCC. These variations are higher in nickel, chromium, and molybdenum, and there are also grades with lower nickel and higher chromium (duplex stainless steels). All of these alloys are highly resistant to SCC and therefore not part of the problem of SCC under insulation.

For SCC to develop, sufficient tensile stress must be present in the material. If the tensile stress is eliminated or greatly reduced, cracking will not occur. The threshold stress required to develop cracking depends somewhat on the severity of the cracking medium. Most mill products, such as sheet, plate, pipe, and tubing, contain enough residual tensile stresses from processing to develop cracks without external stresses. When the austenitic stainless steels are cold formed and welded, additional stresses are imposed. As the total stress increases, SCC becomes more severe.

The Cl^- ion is damaging to the passive protective layer on the 18-8 stainless steels. Once the passive layer is penetrated, localized corrosion cells become active. Under the proper set of circumstances, SCC can lead to failure in only a few days or weeks. Sodium chloride, because of its high solubility and widespread presence, is the most common culprit (Ref 28). This neutral salt is the most common, but not the most aggressive. Chloride salts of the weak bases and light metals, such as LiCl, $MgCl_2$ and $AlCl_3$, can rapidly cracks the 18-8 stainless steels under the right conditions of temperature and moisture content. The practical aspects of SCC of stainless steels are discussed in Ref 27.

The concentration of chlorides necessary to initiate SCC is difficult to ascertain. Researchers have developed cracking in solutions with remarkably low levels of chlorides (<10 ppm). The situation of chlorides under insulation is unique and ultimately depends on the concentration of chlorides deposited on the external surface of the metal. The concentrating

mechanism is discussed in some detail in the following Section of this article. Therefore, the amount of chlorides present becomes a debatable issue. If any chlorides are detected, there will probably be some localized sites of high concentration.

The most important condition affecting chloride concentration is the temperature of the metal surface. Temperature has a dual effect; first, elevated temperatures will cause water evaporation, which in turn concentrates the chloride salts, and, second, as the temperature increases, the rate of the corrosion reaction increases.

Finally, chlorides have been discussed because they are the most common and aggressive of the halogen family. Bromides and fluorides may also cause SCC, but are less common and probably less aggressive (Ref 27).

Water is the fourth necessary ingredient in SCC. Because SCC is an electrochemical reaction, it requires an electrolyte. As water penetrates the insulation system, it plays a key role at the metal surface, depending on the equipment operating conditions.

Examination of the phenomenon of corrosion of steel under insulation provides a better appreciation of the widespread intrusion of water (Ref 29, 30, 31). In effect, water must be expected to enter the metal/insulation annulus at joints or breaks in the insulation and its protective coating. The water then condenses or wets the metal surface, or if it is too hot, the water is vaporized (Ref 29).

This water vapor (steam) penetrates the entire insulation system and settles into places where it can recondense. Because the outer surface of the insulation is designed to keep water out, it also serves to keep water in. The thermal insulation does not have to be in poor condition or constantly water soaked. A common practice in chemical plants is to turn on the fire protection water systems on a regular basis. This deluges the equipment with chloride-bearing water. Some seacoast locations use seawater for the fire protection water. Hot food-processing equipment is regularly washed with tap water, which contains chlorides. All insulation system water barriers eventually develop defects. As the vessel/insulation system breathes, moist air contacts the metal surface. From the insulation standpoint, the outer covering acts as a weather barrier to protect the physical integrity of the insulation material. The outer coverings are not intended, nor can they be expected, to maintain an air- and water-tight system.

Other Problems. External SCC has been found in other situations similar to those that occur under thermal insulation. On of the more common locations is under slip-on flanges, which create crevices that often fill with rust from corrosion of the flanges. This rust pocket is an ideal place for the collection and holding of water and chlorides. Figure 15 shows a cracked type 316 stainless steel lap nozzle.

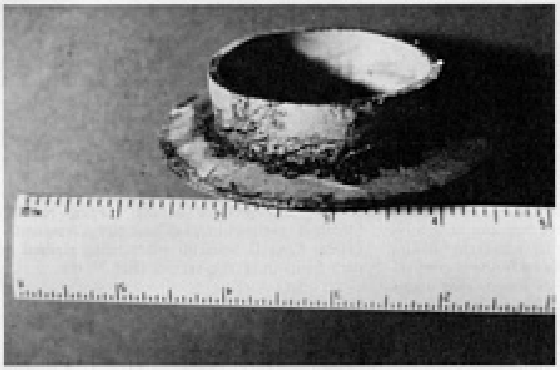

Fig. 15 Type 316 stainless steel pipe flange lap showing external SCC

Another example is the common instrument tube. Because these tubes often carry steam or hot process materials, it is necessary to wrap them for the protection of personnel. Figure 16 shows widespread external SCC of stainless steel tubing under asbestos tape wrapping.

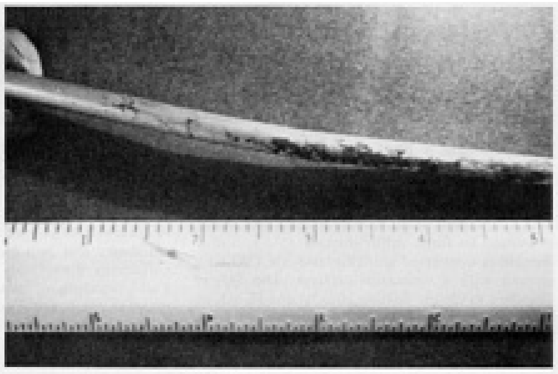

Fig. 16 Type 304 stainless steel instrument tube showing external SCC under an asbestos tape wrapping used to protect plant personnel

In yet another application, polyethylene tape was wrapped around a painted stainless steel line at each pipe support location. The hot line caused the tape to loosen, taking some of the paint with it. The loose tape also created pockets where water and chlorides collected, resulting in external SCC.

In a final example, a pipe fabricator affixed the company logo sticker onto the stainless steel pipe. The pipe was subsequently painted according to specifications, but without first removing the label. The label eventually peeled off, which exposed the bare pipe to a severe chloride-filled atmosphere. This situation resulted in external SCC (Fig. 17).

Fig. 17 External SCC under a logo sticker on a type 316 stainless steel pipe. The label was painted over, then came loose, allowing water to contact the bare steel. The label adhesive may also have been high in chlorides.

Prevention of External SCC. As an understanding of external SCC and its mechanisms developed, selection of a preventive method became much easier. Table 6 summarizes the possible methods of prevention that apply to each causative agent. As can be seen, application of a suitable protective coating system is generally the most economical method, although other methods are included and may be practical under certain circumstances.

Table 6 Guidelines for selecting external SCC preventive

Causative agent	Preventive method	Comments	Evaluation
Austenitic stainless steel	Change to SCC-resistant alloy	Stainless steel alloys with >30% Ni and the duplex stainless alloys are alternative choices, but cost considerably more and may not be readily available.	Extra cost compared to other preventive methods makes this an unwise choice.
Tensile stress	Thermal treatment (anneal or stress relieve)	Annealing at 1065 °C (1950 °F), followed by water quenching will distort and scale equipment severely.	Generally not practical for piping and vessels; may be used for small individual components.
		Stress relieving at 955 °C (1750 °F) and slow cooling will sensitize the grain structure and cause some warpage and scaling. Note: A stress-relieved vessel or pipe will be subjected to tensile stresses in assembly and under operatingconditions. May override the thermal treatment	
	Shot peen	Shot peening converts the surface stresses to compressive stress and is a proven SCC preventive method. It is a delicate process requiring specific skills and experience. May be costly or difficult to apply in the field	Should be considered, but may be more costly and difficult to obtain than other prevention methods.
Chlorides	Remove or eliminate Cl^- ion	Because of their widespread occurrence, highly soluble chloride salts are difficult to avoid or keep off of equipment.	Not practical
	Apply barrier coating to stainless steel	Use of a protective coating on the stainless steel surface can prevent Cl^- contact with the alloy.	This is a practical and proven preventive method.
		Wrap stainless steel with aluminum foil, which serves as both a barrier coating and cathodic protection anode.	Being used with success; extended life of the aluminum has not been determined.
Water	Improved waterproofing to prevent water entry	No type of coating, cementing, or wrapping of insulation can keep air and water from entering the insulation system, except for constructing an external pressure shell. Note: The application and maintenance of a weather barrier is important togood insulation performance and should have a high maintenance priority.	Not practical to expect a wrap of coating to keep water out
	Apply barrier coating to stainless steel	A carefully selected protective coating can provide long-term protection for stainless steel equipment.	This is a practical and proven preventive method.
		Use of aluminum foil wrap as above	Limited use, but with success
		Note: Use of inorganic zinc primer or paint system is not safe due to the possibility of liquid-metal embrittlement upon subsequent welding or exposure to extreme heat.	

The critical step then becomes the implementation of whichever preventive method have been selected. Assuming a protective coating has been chosen, it is necessary to convince project or operating managers of the benefits of painting stainless steel. Although painting stainless steel may at first seem unusual, experienced field personnel will usually understand the need for preventive measures.

Application of any protective coating requires a good specification and inspection. The use of manufacturer application guidelines and the knowledge of an experienced inspector are indispensable in producing an acceptable protective coating.

Fortunately, protective coatings work very well on stainless steel because the metallic substrate does not oxidize or rust. Therefore, coating adhesion failures are very rare. The main objective is to achieve a continuous coating at a reasonable cost that will resist the hot-water environment encountered under insulation.

Sulfuric acid is the largest volume inorganic acid currently in use and is generally considered to be the most important industrial chemical. Sulfuric acid is made by the contact process, in which elemental sulfur or sulfur-containing waste is burned to form sulfur dioxide (SO_2). Sulfur dioxide is converted to sulfur trioxide (SO_3) by contact with a vanadium catalyst. The SO_3 is absorbed in oleum (fuming H_2SO_4) and H_2SO_4 in a series of towers. Because of heightened environmental concerns, sources of sulfur, such as smelter or power plant stack gases, are now being converted into H_2SO_4.

The corrosiveness of H_2SO_4 depends on many factors, particularly temperature and concentration. Strong, hot conditions present the greatest problems, and few materials except platinum, tantalum, fluorocarbon plastic, and brick-lined steel will

resist 60 to 98% H_2SO_4 at 120 °C (250 °F). However, other variables also influence the resistance of materials to H_2SO_4. The presence of oxidizing or reducing contaminants, velocity effects, solids in suspension, and galvanic effects can alter the serviceability of a particular material of construction.

It is unwise to select materials of construction for equipment that will handle H_2SO_4 solely on the basis of published corrosion data unless the conditions involved are adequately and specifically covered by the reference data. Seemingly minor differences in impurities or environmental conditions may significantly affect actual service corrosion rates. Impurities such as halides generally increase corrosion. Aeration or the presence of oxidizing agents generally accelerates corrosion of nonferrous materials and reduces corrosion of stainless alloys, but the extent of these effects depends on specific conditions. Hot-wall effects are frequently overlooked, and heating coils made of the same material as the containing vessel can corrode rapidly while the condition of the vessel itself remains satisfactory.

It is, therefore, advisable to consider all general corrosion data only as an indicator of relative resistance and as a guide by which the limiting conditions of materials may be further reviewed. Final selection of materials for specific equipment depends, of course, on such factors as allowable corrosion rate, desired mechanical and physical properties, fabrication requirements, availability, and cost (Ref 32).

Corrosion Mechanisms

The corrosion of metals in H_2SO_4 is complex, and an understanding of electrochemical theory is useful. The electrochemical behavior of most metals falls into three categories: active, passive, or active-passive (Fig. 18).

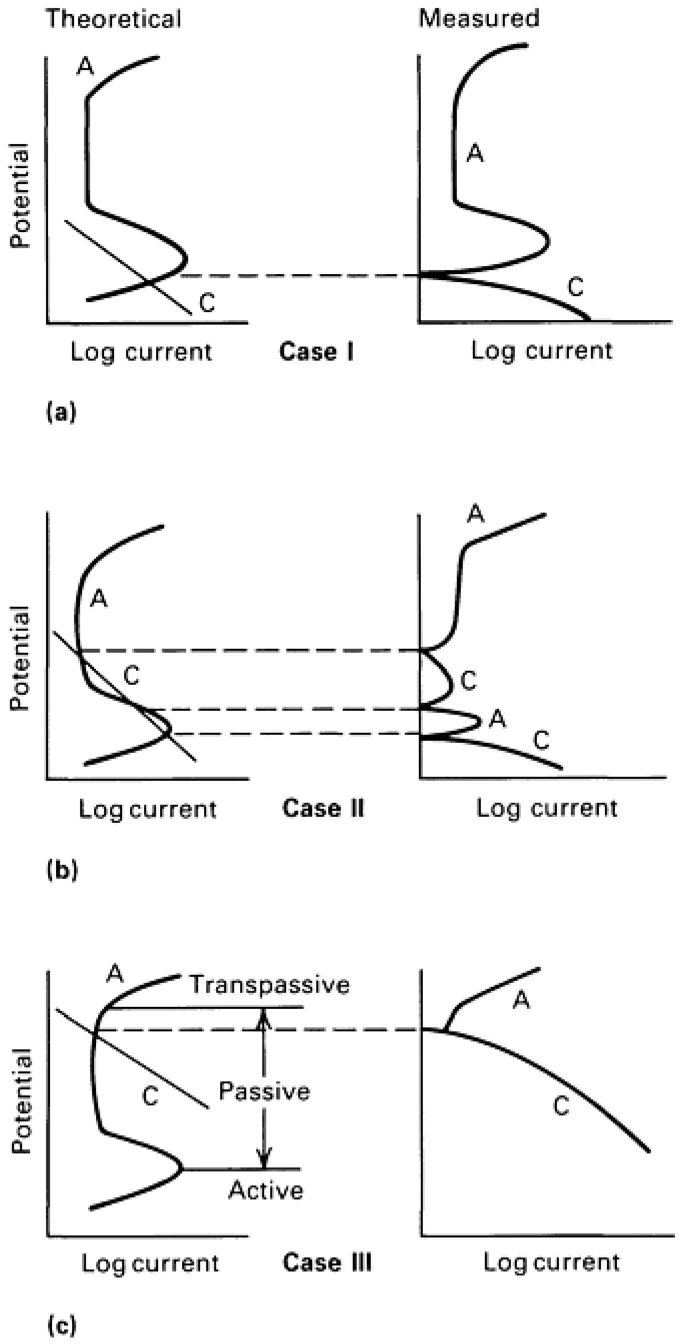

Fig. 18 Comparison of theoretical and measured anodic polarization curves for (a) active (Case I), (b) active-passive (Case II), and (c) passive (Case III) behavior. A, anodic current; C, cathodic current. Source: Ref 33

For active behavior (Case I), the corrosion potential is in the active region, and a wide range of corrosion rates are possible. For passive behavior (Case III), the anodic and cathodic current curves intersect in the most stable passive region; these alloys generally passivate spontaneously and exhibit low corrosion rates. For active-passive behavior (Case II), the cathodic curve intersects the anodic curve at three potentials: one in the active region and two in the the passive region. Because the middle region is not stable, the intersections indicate the possibility of unpredictable and erratic corrosion rates, depending on the environment. Slight changes in the environment may cause a shift to active behavior. In fact, a regular oscillation is often observed between active and passive behavior. Thus, Case II corrosion is difficult to study and presents the most risk for materials selection. Environmental conditions that appear identical from one lab to another, from one plant to another, and from one day to another can produce widely varying results. Stainless steels and nickel-base alloys frequently exhibit Case II behavior when being pushed to their limits in H_2SO_4 service (Ref 33, 34, 35).

Carbon Steel

General Resistance. Steel has long been used in handling concentrated H_2SO_4 at ambient temperatures under static and low-velocity conditions (<0.9 m/s, or 3 ft/s). A soft sulfate film forms that is highly protective unless physically disturbed. The actual corrosion rate of steel depends on temperature, acid concentration, iron content, and flow, because these parameters determine the dissolution rate of the protective sulfate film. Figure 19 shows the corrosion resistance of steel as a function of temperature for nonflowing conditions at concentrations above 65%. In the concentration range of 65 to 100%, steel is applicable for ambient-temperatures storage tanks and piping at low velocities. Within the 100 to 101% range, steel exhibits potentially catastrophic increases in corrosion rates as the temperature exceeds 25 °C (75 °F) and is not recommended, except where low temperatures and velocities can be ensured. Steel is used in oleum service above 101% acid concentration at ambient and moderate temperatures.

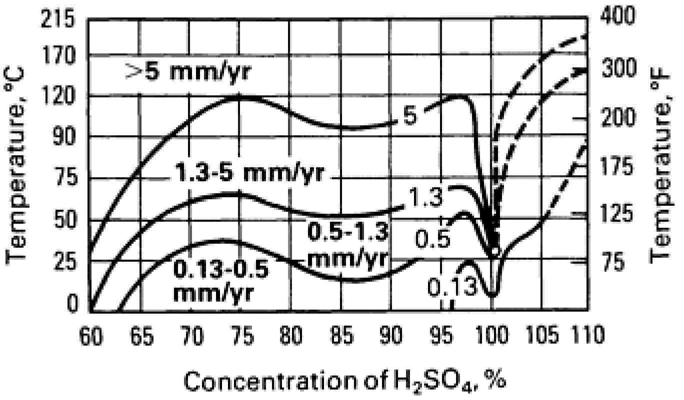

Fig. 19 Corrosion of steel by H_2SO_4 as a function of temperature and acid concentration. Source: Ref 35

Localized attack can occur even at flow velocities within the prescribed limits. Discontinuities such as short-radiused elbows, excessive penetration of welds, and pipe mismatch may cause sufficient downstream turbulence to disturb the protective sulfate film, resulting in high corrosion rates. Weldments must be thoroughly inspected to ensure that they contain no slag, surface porosity, laps, excessive penetration, or other welding defects that might initiate accelerated corrosion. In addition, steel vessels and piping should be free of mill scale, or serious pitting or nonuniform corrosion may occur.

Hydrogen grooving is another form of localized attack that occurs on vertical or inclined surfaces exposed to the liquid phase. During the corrosion of steel by H_2SO_4, atomic hydrogen is evolved. If produced in sufficient quantities, the hydrogen combines to form small bubbles that stream along preferred paths on vertical and inclined surfaces, disrupting the soft protective iron sulfate film. Channels and deep grooves may eventually be formed. Grooving is commonly observed in the tops of horizontal manways on the side of storage tanks and on the top 180° of horizontal pipe runs (Fig. 20). In piping, stagnant conditions promote grooving; therefore, a minimum velocity of 0.3 m/s (1 ft/s) is often recommended.

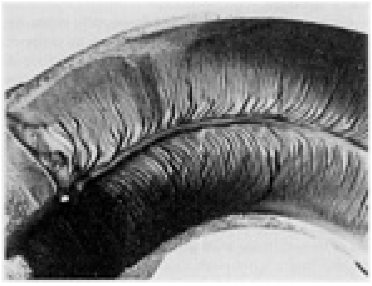

Fig. 20 Hydrogen grooving of a 75-mm (3-in.) diam steel elbow. The elbow was sectioned; the top half is

shown.

Grooving, combined with erosion-corrosion, also occurs on the sidewalls of tanks (Fig. 21). Location of the liquid inlet in the roof near the shell has, in at least two cases, resulted in combined erosion-corrosion and hydrogen grooving, which caused catastrophic rupture of large storage tanks (Ref 36).

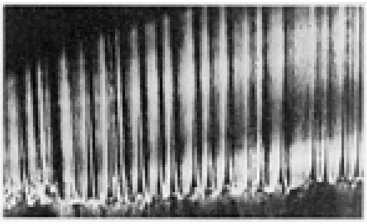

Fig. 21 Hydrogen grooving on the sidewall of an H_2SO_4 storage tank

Influence of Copper. The addition of copper to steels for improved resistance to H_2SO_4 is a controversial subject. Steels containing 0.02% Cu were reported to have rates 16 times higher than steels containing 0.10% Cu in 42 wt% H_2SO_4 (Ref 37). The associated electrochemical study showed that the effects of additional copper dissolved in steel reduced the exchange current of the cathodic reaction, thereby decreasing the corrosion rate. Another study confirmed the beneficial effect of 0.1 to 0.5% Cu in H_2SO_4 solutions up to about 55% (Ref 38). However, in concentrated H_2SO_4 solutions above 60%, the corrosion mechanism appears to differ, and the beneficial effect was not observed. It is generally believed that the advantages, if any, of the use of copper-bearing steels for handling strong H_2SO_4 are not sufficient to warrant the additional expense.

Anodic protection has been used to lower corrosion rates on steel tanks storing 93 to 99% H_2SO_4. The intent is to prolong tank life and to minimize iron pickup. Typically, corrosion rates can be lowered by 50 to 80%. In this process, the steel is electrochemically driven from the active to the passive region by the application of an applied potential between a cathode and the steel. If proper passivity is achieved, the corrosion rate decreases to less than 0.1 mm/yr (3.9 mils/yr) (Ref 39). The use of stainless steel and alloy 20Cb-3 in tanks being protected must be carefully analyzed because the passive protection potential for steel may overlap active regions for these alloys.

With improvements in the H_2SO_4 production process, acid with lower iron content is being produced. This acid is more corrosive to steel than the high-iron acid. Thus, the use of anodic protection will become increasingly important.

Mechanism of Corrosion Protection. Carbon steel corrodes in the active state at all concentrations up to 100% H_2SO_4. At concentrations below 50%, the iron sulfate corrosion product readily goes into solution, and corrosion rates are high. At higher concentrations, the initial corrosion rate is high, but is quickly reduced by the accumulation of iron sulfate corrosion product. It has been shown that the dissolution and diffusion of the ferrous sulfate from the surface is the rate-limiting step (Ref 40). The effects of velocity, concentration, and temperature on the corrosion process in piping and storage tanks have been modeled (Ref 41, 42). At concentrations from 65 to 100% and at ambient temperatures, the sulfate layer diffuses into solution sufficiently slowly for the use of steel as a material of construction. Corrosion rates are typically 0.15 to 1.0 mm/yr (5.9 to 39 mils/yr). In the oleum range above 101% H_2SO_4 concentration (4% free SO_3), steel corrodes in the passive region because of the oxidizing effect of SO_3. Corrosion rates are typically 0.1 mm/yr (3.9 mils/yr) at ambient temperature. In the 100 to 101% concentration range, the steel goes through an active-passive transition state, and measured corrosion rates are erratic and excessive above 25 °C (75 °F).

Cast Irons

Gray cast iron has been used for piping and coolers for H_2SO_4 since acid plants were first built. Cast iron is at least as resistant to corrosion as steel is in the 65 to 100% acid concentration range at ambient temperature. The higher carbon and silicon content of cast irons leads to conditions favoring superior resistance at higher velocities and elevated temperatures, at least in the concentration range of 90 to 100%. Gray cast iron is less sensitive to velocity than steel and is frequently used up to 1.7 m/s (5.6 ft/s) in larger-diameter piping. The superior resistance of cast iron may be due to interference of

the graphite flake network with reaction between the acid and the metallic matrix (Ref 43). Graphite flakes may act as cathodic areas and shift the corrosion potential to a more favorable region (Ref 44).

Gray cast iron normally should not be used in the oleum range because of a tendency toward violent cracking. Free SO_3 is thought to attack the graphite flakes. Corrosion products form in the voids and strain the structure by volumetric expansion. Cracking of gray cast iron has also occurred in concentrated H_2SO_4 service, in which the cast iron was attached to stainless steel coolers protected by anodic protection. It is theorized that the anodic current causes the cast iron to behave as though it is in oleum service. This problem has been solved by placing 3-m (10-ft) ductile iron pipe spool between the cooler and the gray cast iron pipe. Ductile cast iron is not subject to the same phenomena as gray cast iron, because the graphite is in form of isolated nodules and the metal matrix is substantially stronger.

Gray cast iron is brittle and frequently ruptures catastrophically. Care must be taken to support cast iron pipe properly and to replace it before it thins excessively because of corrosion. For replacement or new piping, ductile cast iron, stainless steels with and without anodic protection, and plastic-lined pipe are now favored.

Ductile cast iron is nearly as corrosion resistant as gray cast iron in concentrated H_2SO_4 service. Laboratory testing comparing the materials has been inconclusive, probably because chemical compositions vary considerably. Actual plant experiences with piping tend to indicate up to 50% higher corrosion rates for ductile cast iron versus gray cast iron, but this is usually compensated for by the additional corrosion allowance used with ductile cast iron.

A modified ductile cast iron was recently introduced that reportedly has twice the corrosion resistance of conventional ductile cast iron. This alloy has about 3.5% Si versus the 1.8 to 2.8% for standard ductile iron.

High-Silicon Cast Iron. Another material that has long been used for handling H_2SO_4 is high-silicon iron. Iron with 14.5% Si has exceptional resistance to H_2SO_4 in all concentrations to 100% up to the atmospheric boiling points. Corrosion rates are normally less than 0.12 mm/yr (5 mil/yr), as shown in Fig. 22.

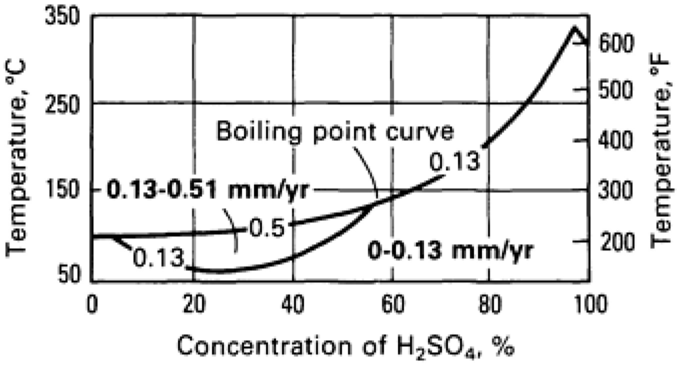

Fig. 22 Corrosion of high-silicon iron in H_2SO_4 as a function of temperature and acid concentration

The resistance of high-silicon iron derives from the formation of a strong silicon-rich abrasion-resistance film. Even the most severely abrasive slurries can be handled.

The high-silicon irons are available only in the cast form. In addition, they have low tensile strength and virtually no ductility. High-silicon irons are susceptible to thermal and mechanical shock. Sharp hammer blows and rapid temperature fluctuations have caused the material to fail. High-silicon irons are rapidly attacked in oleum or other services containing free SO_3. Only SO_3, SO_2, and fluorine contaminants are known to alter drastically the corrosion resistance of high-silicon iron to H_2SO_4.

Austenitic Stainless Steels

The resistance of austenitic stainless steels to H_2SO_4 is complex due to the active-passive nature of the alloys. An excellent summary that includes corrosion rate data is provided in Ref 45.

Mechanism of Protection. Stainless steels depend on electrochemical passivity--Case III behavior--for resistance to corrosion in H_2SO_4 solutions. Stable passivity is achieved at ambient temperatures in the very low and very high concentrations and in oleum.

Corrosion Resistance. At ambient temperatures, austenitic stainless steels, for example, type 304, exhibit stable Case III passivity in H_2SO_4 above 93% concentration and are frequently used for piping and tankage where product purity is desirable. The corrosion rates are essentially nil as compared with 0.15 to 1.0 mm/yr (5.9 to 39 mils/yr) for steel. Molybdenum stretches the passive region, making type 316 and 317 acceptable above 90% concentration at ambient temperature. The upper temperature limit for stable passivity for types 304 and 316 in 93% $H_2SO_4$is believed to be around 40 °C (105 °F). For 98.5% H_2SO_4, the upper stable passive limit is believed to be above 70 °C (160 °F) (Ref 46). As concentration increases above 99%, corrosivity decreases rapidly, allowing the use of stainless steels above 100 °C (210 °F).

In dilute acid, only the molybdenum grades, such as type 316 or 317, are useful, although type 304 may be used when only a trace of acid is present. Figure 23 shows corrosion data for these alloys in as-mixed and refluxed (aerated) H_2SO_4 solutions. Stainless steels have poor resistance to deaerated dilute solutions. Type 310 stainless steel with 25% Cr and no intentionally added molybdenum is more resistant than the molybdenum-bearing grades when oxidizing agents are present. This is attributed to the higher chromium content of the type 310.

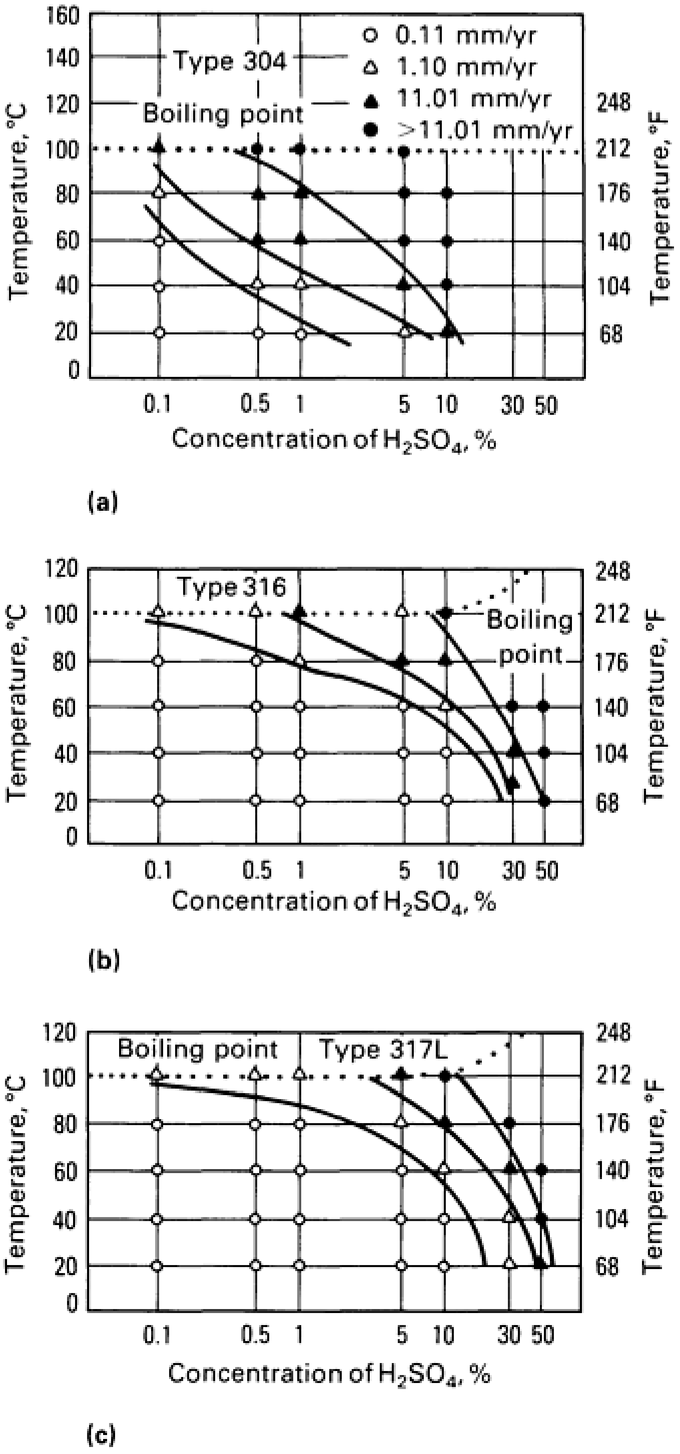

Fig. 23 Isocorrosion diagrams for (a) type 304, (b) type 316, and (c) type 317L stainless steels in aerated H_2SO_4 up to 50% concentration. Source: Ref 47

Effect of Velocity. If a stainless steel is solidly in Case III passive behavior, velocity appears to have little effect. Laboratory tests of type 304L with velocities to 6 m/s (20 ft/s) in 93% H_2SO_4 at ambient temperature have shown Case III passive behavior (Ref 46). However, once the alloy drops to Case II (active-passive) behavior, usually because of increasing temperature, velocity has a major effect. Under abrasive conditions, cast stainless steels have shown Case II active-passive behavior in 96% H_2SO_4 even at ambient temperatures (Ref 48).

Effect of Aeration and Oxidants. Highly aerated solutions are much more suitable for these alloys than air-free ones. Similarly, the presence of oxidizing impurities stabilizes the passive film, and the resistance to H_2SO_4 of austenitic

stainless steels improves markedly. Cations that are easily reducible, such as Fe^{3+}, Cu^{2+}, stannic (Sn^{4+}) and cerric (Ce^{4+}) ions, are oxidizing agents that can inhibit the attack of stainless steels in H_2SO_4 solutions. It was found that 0.19 g/L of Fe^{3+} ion was sufficient to cause passivity and low corrosion rates in boiling 10% H_2SO_4, but 0.115 g/L did not give inhibition (Ref 49).

Other oxidizing agents, such as H_2CrO_4 and HNO_3, were shown to be effective in reducing corrosion rates (Ref 50). Nitric acid concentrations as low as 1.5% were found to inhibit the corrosion of stainless steel over a wide range of H_2SO_4 concentrations at ambient and elevated temperatures (Ref 51). Oxidants in sufficient quantities were shown to reduce the corrosivity of H_2SO_4 on stainless steel by shifting the corrosion potential from an active to a passive state (Ref 52).

Effect of SO_3. In strong H_2SO_4 (above 97% concentration) and in oleum, the increased SO_3 content has a strong oxidizing effect, and corrosion rates are reduced dramatically. Figure 24 shows an isocorrosion diagram generated for type 304L stainless steel in an absorption tower environment (Ref 53, 54). Most stainless steels and nickel-base alloys likely have similar reductions in corrosion rates with increasing concentration. However, the molybdenum-containing alloys are distinctly inferior unless the chromium content is high, as is the case with E-Brite stainless steel (Table 7).

Table 7 Corrosion rates of various metals in 99% H_2SO_4 at 100-120 °C (212-250 °F)

Alloy	Corrosion rate	
	mm/yr	**mils/yr**
Steel	>2.4	94.5
Cast iron	0.12	4.7
Ductile iron	0.25	9.8
Type 304L	0.02	0.8
Type 316L	0.06	2.4
Alloy 904L	0.19	7.5
Alloy 20Cb-3	0.08	3.1
Alloy C-276	0.33	13.0
Alloy B-2	2.3	90.6
A-611	0.04	1.6

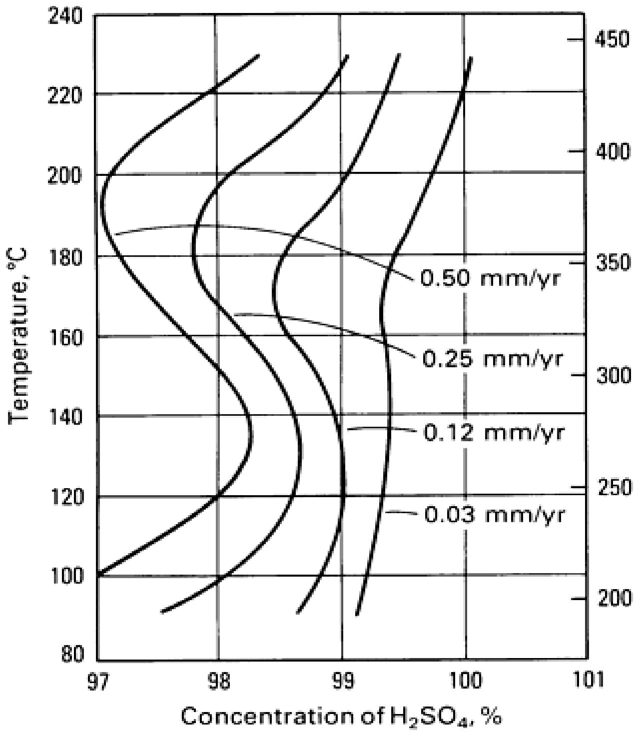

Fig. 24 Isocorrosion diagram of type 304 stainless steel in highly concentrated H_2SO_4. Source: Ref 54

Extreme care must be taken when using stainless steels in the 98 to 100% concentration at high temperatures; velocity conditions, reductions in acid concentration, or changes in oxidant levels may initiate high corrosion rates. For contrast, compare the corrosion data generated in flowing 98.7% H_2SO_4 at 100 °C (210 °F) shown in Table 8 with the data in Table 7. In the oleum range, stainless steels are free from the concerns about minor concentration variations and corrosion resistance is extended well in excess of 100 °C (210 °F).

Table 8 Corrosion test in flowing 98.7% H_2SO_4 at 100 °C (212 °F)

Alloy	Corrosion rate	
	mm/yr	**mils/yr**
Type 304	0.5	19.7
Type 316	3.44	135.0
Alloy 904L	2.3	90.6

Anodic protection is a practical method of extending the useful temperature and concentration range for stainless steels in H_2SO_4. With anodic protection, a stainless steel component (anode) is held in the passive (Case III) condition by an impressed current from a cathode.

Fortunately, H_2SO_4 is a good conductor of electricity and therefore has good throwing power. Complex shell sides of stainless steel shell and tube coolers handling concentrated H_2SO_4 can be easily protected using Hastelloy C-276 cathodes that extend the full length of the tube bundle. Piping is more difficult to protect because a cathode must throw the current a greater distance from the cathodes, which are typically located every 4.5 to 6 m (15 to 20 ft). Stainless steel may be protected in 93% H_2SO_4 up to 70 °C (160 °F) and in 98% H_2SO_4 up to 120 °C (250 °F). Corrosion rates can be reduced to 0.01 to 0.1 mm/yr (0.4 to 4 mils/yr). Approximately 400 anodically protected coolers have been installed in acid recirculation loops in H_2SO_4 plants throughout the world.

Silicon Stainless Steels. Austenitic stainless steels containing 5 to 6% Si have interesting corrosion characteristics in concentrated H_2SO_4 service. Cast and wrought versions are available. The cast version has a typical composition of Fe-5Si-21Cr-16Ni-0.02C (Ref 56). The wrought version of this alloy, A-611, has a typical composition of Fe-5.3Si-18Cr-18Ni-0.02C. The A-611 alloy has useful corrosion resistance in 99% H_2SO_4 up to 120 °C (250 °F) without anodic protection. Corrosion protection is obtained by the formation of a tenacious silicon-rich film formed on the surface during the initial days of corrosion. Corrosion resistance of the cast alloy is similar. Piping, distributors, and pump tanks handling hot 98 to 99% H_2SO_4 have been made from the A-611 alloy.

Cast Stainless Steels

Cast stainless steels have essentially the same corrosion resistance to H_2SO_4 as their wrought counterparts. Because the cast versions contain second-phase ferrite for castability, care must be taken that proper heat treatment is performed for maximum corrosion resistance. Preferential corrosion as the result of the duplex structure has been shown to be a problem. However, properly cast and heat-treated duplex materials perform well (Ref 45).

One cast alloy that does not have a close wrought counterpart is ACI CD-4MCu. Corrosion resistance lies between 20Cb-3 stainless steel and type 316. Figure 25 shows the isocorrosion diagram for this alloy. Corrosion resistance of CD-4MCu in H_2SO_4 extends over the entire concentration range at ambient temperatures, and the alloy is suitable above 100 °C (210 °F) in oleum service.

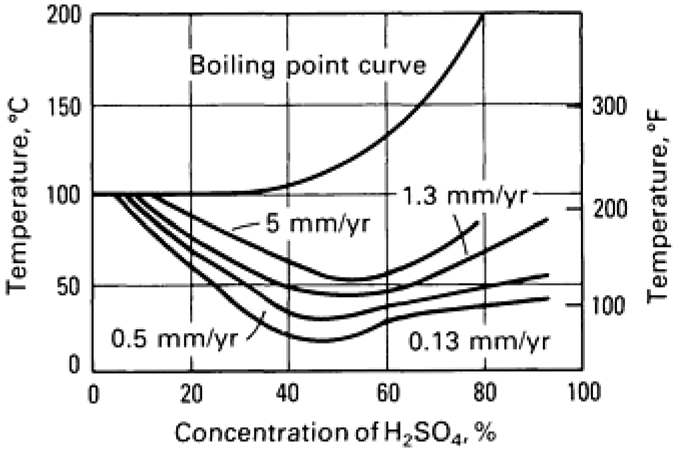

Fig. 25 Isocorrosion diagram for ACI CD-4MCu in H_2SO_4. Source: Ref 45

Higher Austenitic Stainless Steels

Like the austenitic stainless steels, the corrosion resistance of the higher austenitic stainless steels is also complex. However, the range of passivity and corrosion resistance is extended because of the higher alloy content. Like the stainless steels, Case I (active) and Case II (active-passive cyclic behavior) are the modes of corrosion. Resistance is achieved in the Case III (passive) state. A summary that includes corrosion data is provided in Ref 45.

Iron-base nickel-chromium-molybdenum alloys. This class of alloys contains approximately 25% Ni, 20% Cr, and 4.5% Mo; copper, titanium, and niobium are sometimes added as stabilizing elements. Alloys in this category that do not contain copper are generally more corrosion resistant than type 316 stainless steel and include Hastelloy M-532 and alloy JS-700 (Fe-25Cr-20Ni-3Mn-3Mo). Figure 26 shows an isocorrosion diagram of Hastelloy M-532. The temperature and concentration range of this alloy has been extended beyond that for type 316 as the result of the increased alloy content.

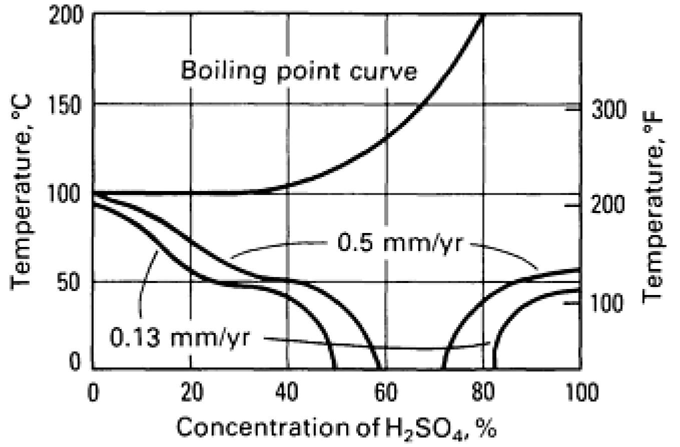

Fig. 26 Isocorrosion diagram for Hastelloy M-532 in H_2SO_4. Source: Ref 45

The copper-bearing alloys in this class are more resistant in H_2SO_4 than the copper-free alloys. Figure 27 shows an isocorrosion diagram for a 25Ni-20Cr-4.5Mo-1.5Cu alloy such as alloy 904L. The copper additions make the alloy suitable for the entire concentration range at ambient temperature.

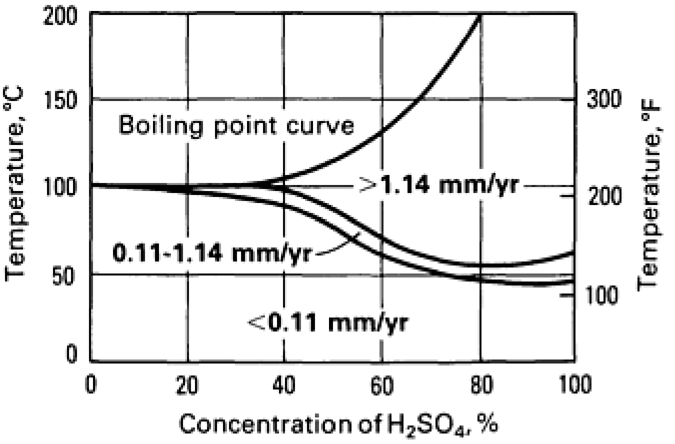

Fig. 27 Isocorrosion diagram for alloy 904L in H_2SO_4. Source: Ref 45

The 20-Type alloys are usually the first considered when an H_2SO_4 environment is too corrosive for the use of steel, 300-series stainless steels, or cast iron. This group contains both wrought (20Cb-3) and cast alloys (ACI CN-7M) that are roughly equivalent in resistance to H_2SO_4.

Cast ACI CN-7M. Figure 28 shows an isocorrosion diagram for cast ACI CN-7M. This alloy is generally suitable to 80 °C (175 °F) at concentrations to 50%. For higher concentrations, good corrosion resistance is expected to 65 °C (150 °F).

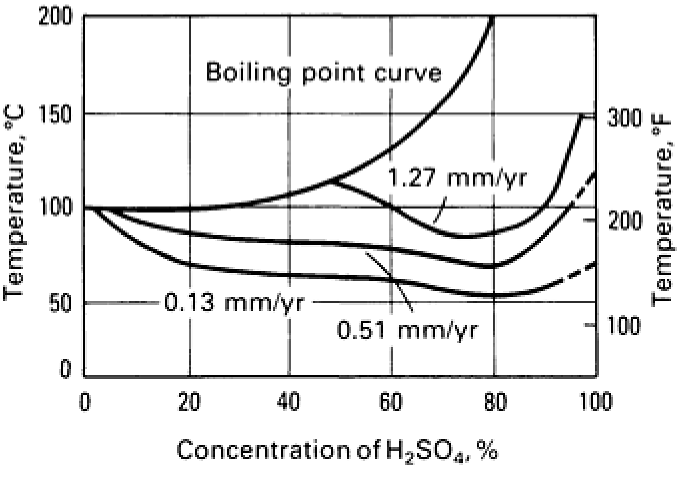

Fig. 28 Isocorrosion diagram for ACI CN-7M in H_2SO_4. Source: Ref 45

Wrought Alloy 20Cb-3. The wrought counterpart to cast ACI CN-7M was developed in 1947. In 1948, niobium was added to this alloy for stabilization against sensitization and intergranular attack. In 1963, the nickel content was raised to 33 to 35% in order to give greater resistance to chloride SCC and to improve resistance to boiling H_2SO_4 under heat transfer conditions. Minor changes were subsequently made to impart greater resistance to intergranular corrosion. This alloy is now known as 20Cb-3. A typical composition is Fe-34Ni-20Cr-3.3Cu-2.5 Mo. Corrosion resistance of 20Cb-3 is similar to that of CN-7M. Figure 29 shows an isocorrosion diagram for 20Cb-3.

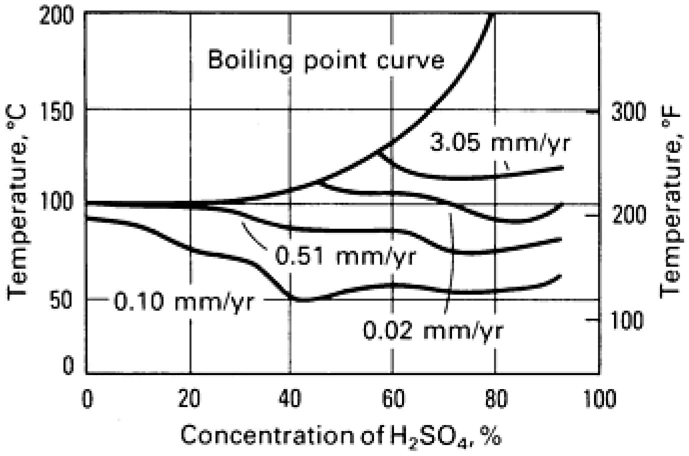

Fig. 29 Isocorrosion diagram for alloy 20Cb-3 in H_2SO_4. Source: Ref 45

Nickel-Base Alloys

The nickel-base austenitic alloys have superior resistance to corrosion in H_2SO_4 up to 95% concentration because of their high alloy content. Frequently, low corrosion rates occur in both the active and passive corrosion states. Thus, reliable corrosion behavior is achieved over a wide range of concentrations, temperatures, and impurity levels. Extensive discussion, data, and references are given in Ref 45, 57, 58.

Nickel-base iron-chromium-molybdenum-copper alloys. Incoloy 825 has excellent resistance to H_2SO_4 up to 40% concentration and in concentrated acid (Fig. 30). The higher nickel content of this alloy versus the 20-Type alloys offers slightly improved corrosion resistance at high temperatures in low and high concentrations of H_2SO_4.

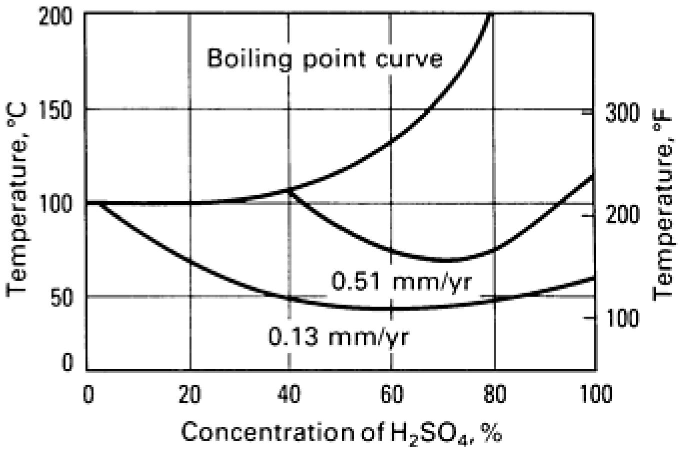

Fig. 30 Isocorrosion diagram for Incoloy 825 in H_2SO_4. Source: Ref 45

Hastelloy G and G-3 are modifications of the now obsolete Hastelloy G. A typical composition is 45Ni-22Cr-6.5Mo-2Cu. Hastelloy G-3 is a modified version of Hastelloy G with the same general corrosion resistance. It was modified to resist formation of grain-boundary precipitates during prolonged heating, such as stress relief. These alloys are promoted for their resistance to halide-contaminated H_2SO_4 environments. Figures 31 and 32 show isocorrosion diagrams for Hastelloy G.

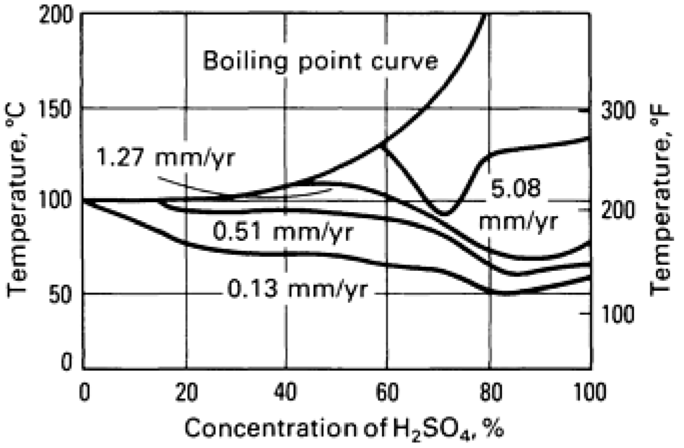

Fig. 31 Isocorrosion diagram for Hastelloy G in H_2SO_4. Source: Ref 45

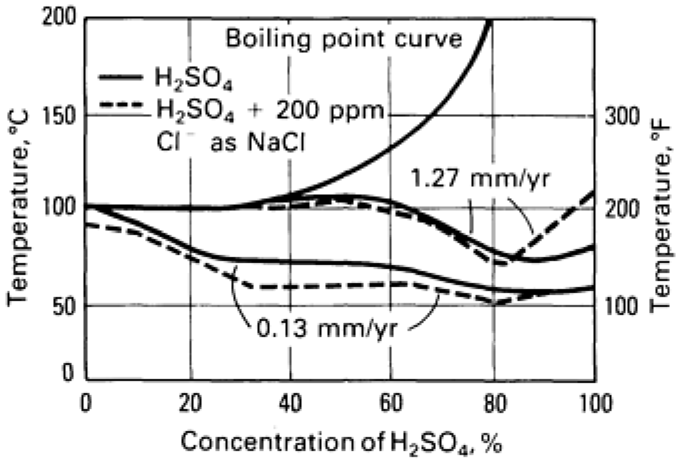

Fig. 32 Isocorrosion diagram for Hastelloy G in H_2SO_4 solutions contaminated with Cl^- ion. Source: Ref 45

Nickel-copper alloys. Monel 400 is used for handling H_2SO_4 under reducing conditions. Thus, this alloy offers an alternative to stainless steels and other alloys exhibiting active-passive behavior when H_2SO_4 solutions are not oxidizing, such as deaerated dilute acid. Monel 400 exhibits reasonably low corrosion rates in air-free H_2SO_4 up to 85% concentration at 30 °C (85 °F) and up to 60% concentration at 95 °C (205 °F).

Nickel-molybdenum-chromium-iron alloys. These nickel-base alloys, containing about 16% Mo, 16% Cr, and 3 to 5% Fe, are available in wrought (Hastelloy C-276 and C-4) and cast form (ASTM A494, grades CW-12MW and CW-7M). In general, the corrosion resistance is excellent (Fig. 33 and 34). At room temperature, the corrosion rate for all concentrations is less than 0.1 mm/yr (3.9 mils/yr). Because of the higher chromium content, these alloys are more resistant to H_2SO_4 containing oxidizing contaminants, for example, Fe^{3+} or Cu^{2+} ions, than to such materials as Monel 400 or Hastelloy B-2. Another material in this group is Inconel 625 (Fig. 35).

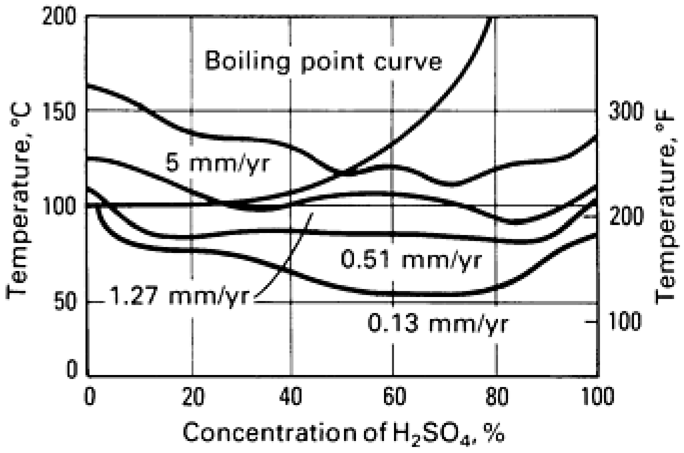

Fig. 33 Isocorrosion diagram for Hastelloy C-276 in H_2SO_4. Source: Ref 45

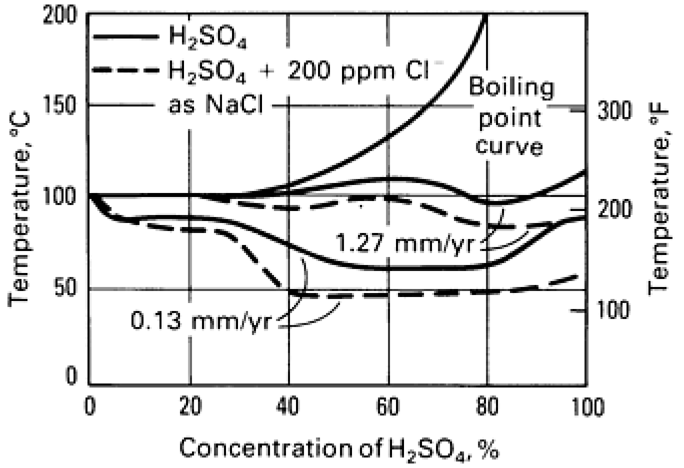

Fig. 34 Isocorrosion diagram for Hastelloy C-276 in H_2SO_4 and in H_2SO_4 contaminated with Cl^- ion. Source: Ref 45

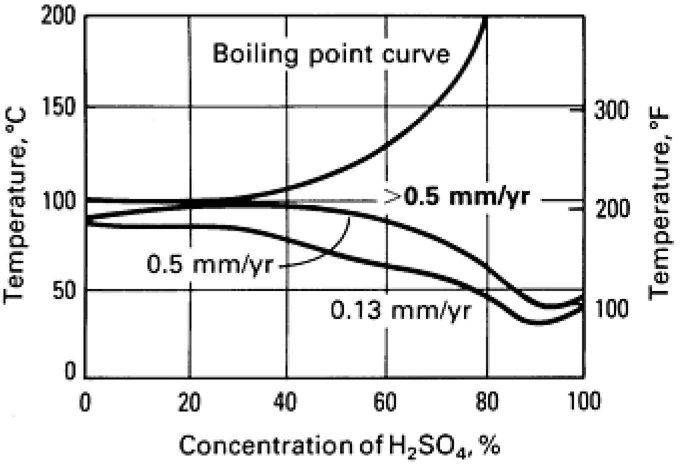

Fig. 35 Isocorrosion diagram for Inconel 625 in H_2SO_4. Source: Ref 58

Nickel-Base Molybdenum Alloys. These nickel-base alloys, containing about 30% Mo, 3 to 6% Fe, and 1% Cr, are available in the cast and wrought forms. The corrosion resistance of these alloys is excellent in pure H_2SO_4 over a wide range of temperatures and concentrations. However, oxidizing contaminants, such as Fe^{3+} ions, increase corrosion rates considerably and have caused premature failure. Chlorides also increase corrosion rates. Hastelloy B-2 is the wrought material in this alloy group (Fig. 36). The cast version with similar corrosion resistance is ASTM A494, grade N-12MV. Cast alloy ASTM A494, grade N-7M, also falls into this general grouping.

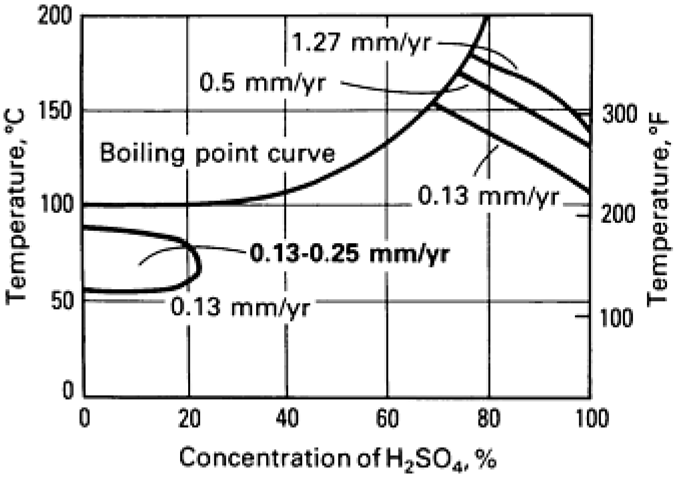

Fig. 36 Isocorrosion diagram for Hastelloy B-2 in H_2SO_4. Source: Ref 45

Nickel-base chromium-iron-cobalt-silicon alloys are proprietary alloys developed specifically for hot concentrated H_2SO_4 pump and valve applications. Alloy 55 is one such cast alloy (Fig. 37). Figure 38 shows the effect of temperature in 98% H_2SO_4 as determined by laboratory tests. Alloy 66 is a ductile cast alloy that can also be made in the wrought form. Both forms have excellent corrosion resistance in the 0 to 60% and 80 to 90% ranges, but performance is erratic in the 60 to 80% range (Fig. 39).

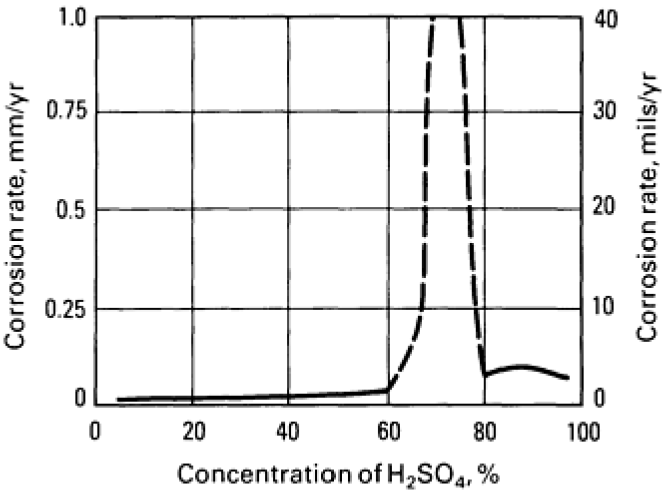

Fig. 39 Corrosion rates of alloy 66 in H_2SO_4 solutions of 100 °C (212 °F). Source: Ref 45

Nickel-base chromium-molybdenum-copper alloys are proprietary alloys designed to resist H_2SO_4 concentrations to 98% at temperatures to 100 °C (212 °F). Illium 98 is a weldable, machinable cast alloy. Illium B, also a cast alloy, is a version of 98 that has been modified for enhanced corrosion resistance; however, illium B is not easily welded (Fig. 40).

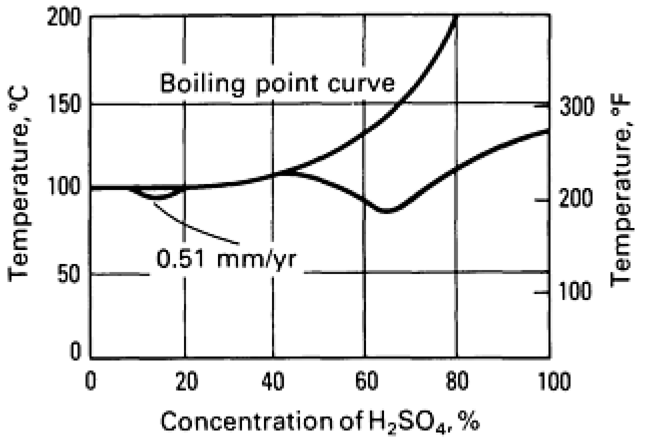

Fig. 40 Isocorrosion diagram for Illium B in H_2SO_4. Source: Ref 45

Zirconium

The most prevalent application of unalloyed zirconium in the chemical industry has been in hot H_2SO_4. Zirconium has excellent resistance to H_2SO_4 up to 50% concentration at temperatures to boiling and above. From 50 to 65% concentration, resistance is generally excellent at elevated temperatures, but the passive film is a less effective barrier. Experience has shown that welding and oxidizing species in more than 50% H_2SO_4 can encourage selective attack. In concentrated H_2SO_4 above 70%, the corrosion rate of zirconium increases rapidly with increasing concentration. Because welds are known to be slightly less resistant than the parent metal, zirconium is seldom used above 60 to 65% concentration in the welded condition unless it has been heat treated to maximize corrosion resistance (Fig. 41).

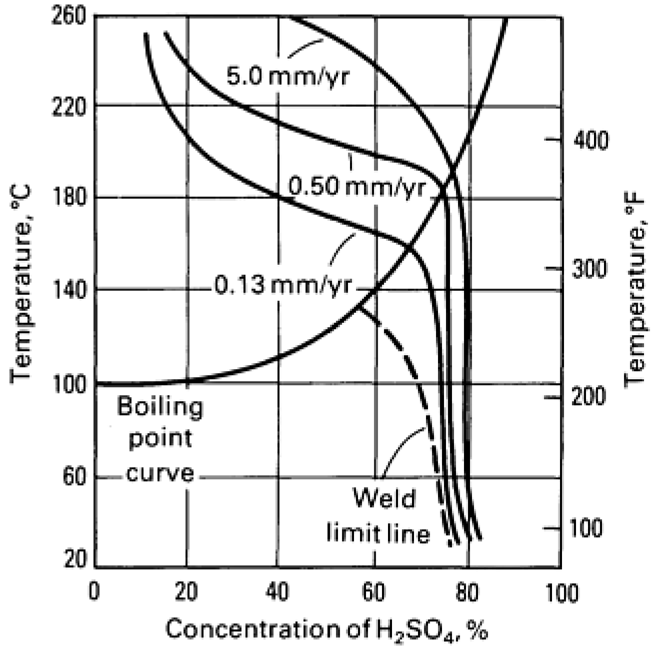

Fig. 41 Corrosion of zirconium by H_2SO_4 as a function of temperature and acid concentration. Source: Ref 59, 60

The corrosion resistance of zirconium in H_2SO_4 depends on the formation of a passive film. The protective film consists of predominantly cubic zirconium dioxide (ZrO_2), which is highly ordered and corrosion resistant. Electrochemical measurements show the corrosion potential of zirconium in H_2SO_4 to be located solidly in the passive region when it is resisting corrosion. However, as temperature and/or concentration increases, the transpassive (breakdown) potential

decreases, and there is less tolerance for oxidizing agents, such Fe^{3+}, Cu^{2+}, and nitrate (NO_3^-) ions. At high temperatures in concentrations exceeding 50%, oxidizing agents in sufficient quantities delete the passive region, causing zirconium to corrode actively.

Other Metals and Alloys

Unalloyed tantalum has resistance to H_2SO_4 over the entire range of concentration and temperature except for very strong and exceptionally hot conditions. Figure 42 shows the corrosion rates of tantalum in 98% acid and oleum. A common use is for reboilers and concentrators of H_2SO_4 in the 70% concentration range.

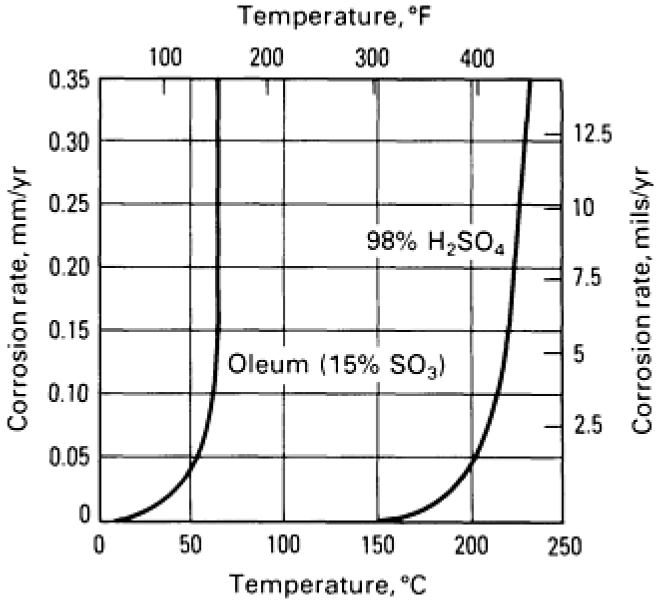

Fig. 42 Corrosion of tantalum in 98% H_2SO_4 and in oleum

Unalloyed titanium is rapidly attacked by all concentrations of H_2SO_4 except very dilute solutions. Impurities in the form of oxidizing agents may act as inhibitors; for example, titanium resists 0 to 50% concentrations of H_2SO_4 saturated with chlorine (Ref 61, 62). Titanium has also been used in the H_2SO_4 leaching of nickel ores. Resistance is attributed to the presence of heavy-metal oxidizing agents, such as Fe^{3+} and Cu^{2+}, ions (Ref 63, 64).

Lead resists H_2SO_4 but its protective sulfate film is increasingly solubilized above 90% concentration. The film is easily damaged by erosion or abrasion even at low velocities, with the rate at attack increasing rapidly with concentration. Lead is useful as a pan material to catch acid drippings. It is also used as a membrane behind brick in H_2SO_4 concentrating units and scrubbing units.

Copper and copper-base alloys are not widely used in relatively pure H_2SO_4 because of the drastic effect of oxidizing conditions. The resultant Cu^{2+} ions also cause autocatalytic corrosion. Brass is not often used, because of the potential for dezincification. Bronzes have the greatest applicability, with the normal copper-tin-bronzes showing acceptable service below 60% concentration at 79 °C (174 °F). The silicon-bronzes extend the suitable range to about 70% concentration. The aluminum-bronzes have resistance approaching that of Monel 400; however, dealuminification can be a problem, particularly with alloys containing more than 8% Al (Ref 18).

Nonmetals

Nonmetallic materials of construction have wide application in H_2SO_4. Most of these materials have good corrosion resistance to the pure acid, particularly in dilute concentrations, and are primarily restricted by their mechanical properties at temperature. They are relatively unaffected by most inorganic contaminants, except for such strongly oxidizing agents as HNO_3, peroxides, and dichromates.

Brick linings have been used for the most severe H_2SO_4 conditions. Under most conditions, acid-resistant fire clay brick can be used. For extreme conditions, silica brick is used. High-alumina (Al_2O_3) refractories are inferior at high temperatures and concentrations. At concentrations below 70% lead, plastic or elastomeric corrosion-resistant membranes are required behind the brick. The brick serves as a thermal and abrasion barrier. At higher concentrations, brick can be used directly on steel, although tetrafluoroethylene (TFE) or mortar barriers are often used. For moderate concentrations and temperatures, plastic mortars, such as furans and phenolics, are used. For high temperatures and concentrations, the silicate cements are required. Sodium silicate cement has been the most common type even though it slowly converts to sodium sulfate (Na_2SO_4), which hydrates and degrades. Potassium silicate (K_2SiO_3) is now preferred because its sulfate salt does not hydrate. Mortars based on pure colloidal silica are also available for extreme conditions.

Polyvinyl chloride has excellent resistance to H_2SO_4 to approximately 93% concentration at ambient temperature. Chlorinated PVC resists slightly higher concentrations and temperatures. These materials have been used for pipelines, but are not popular for longer runs, because they have high coefficients of expansion and require essentially continuous support. Many companies prohibit the use of solid plastic piping for safety considerations because of the potential for breakage.

Lined Pipe. Polyvinylidene chloride (PVDC), polypropylene (PP), polyvinylidene fluoride (PVDF), and PTFE all are used for linings in pipe for handling H_2SO_4. The range of usefulness is shown in Table 9. Although PP is shown as resistant to 98% H_2SO_4 at ambient temperatures, there is considerable controversy on this point because high concentrations can cause charring and SCC. To avoid this, the PP must either be kept in compression or a copolymer must be used.

Table 9 Suitability of plastic-lined piping systems in H_2SO_4

Material	Maximum temperature[(a)]		Concentration of H_2SO_4, %
	°C	**°F**	
PVDC	52	126	<16
	24	75	30
	NR		>60
PP	93	200	<60
	80	175	93
	65	150	96
	50	120	98
PVDF	120	250	<16
	105	220	30-60
	80	175	85-93
	65	150	94-98
TFE	260	500	0-100

(a) Temperature may be further limited by mechanical conditions under vacuum. NR, not rated

Polyethylene possesses a high degree of resistance to attack by H_2SO_4 up to 98% concentration at ambient temperature. The high-density resins show virtually no attack in 98% acid at temperatures to 50 °C (120 °F). The use of poly-ethylene equipment for handling H_2SO_4 must be restricted to relatively low temperatures and low loads unless continuously supported. Polyethylene is widely used in laboratories for beakers, bottles, and so on, which do not require heating over direct flames. Tanks constructed of molded, seamless, high-density, cross-linked polyethylene have been used to store relatively small volumes (3800 L, or 1000 gal.) of concentrated H_2SO_4 up to 96%.

Fluoroplastics. Fully fluorinated plastics, such as PTFE, fluorinated ethylene propylene (FEP), and perfluoroalkoxy (PFA), are unattacked by H_2SO_4 and oleum at all concentrations. Other fluoroplastics, including PVDF, ethylene-chlorotrifluoroethylene (ECTFE), and ethylene-tetrafluoroethylene (ETFE), are resistant to acid up to 98% concentration, but have less resistance to oleum and SO_3. Table 10 lists temperature limitations and polymer designations.

Table 10 Suitability of nonmetal linings in H_2SO_4

Material	Maximum temperature		H_2SO_4 concentration, %
	°C	°F	
PTFE	260	500	0-100
PFA	260	500	0-100
FEP	205	400	0-100
ECTFE	150	300	<98
ETFE	150	300	<98
PVDF	120	250	<16
	105	220	30-60
	80	175	85-93
	65	150	94-98

Fluoroplastics are being increasingly used for H_2SO_4 applications, such as linings in pumps and valves. Sheet linings of FEP, ECTFE, and PVDF permit fabrication of large components, such as tanks. Spaghetti-type FEP heat exchangers have been used to cool concentrated H_2SO_4 in contact plants for more than two decades. In Europe, the heat recovered is often used for town heating. These units cannot be used to cool oleum, because the reaction of free SO_3 and water vapor permeating the FEP tubes causes excessive temperatures and destruction of the resin. Recently, PFA construction and design modifications have improved exchanger temperature and pressure capabilities. Dispersion of powder linings of PVDF, ECTFE, and PFA, with or without fiber reinforcement, are applied to a broad range of steel equipment (Ref 65). Equipment size is limited only by available ovens.

Polyester Resins. Polyester and vinyl-ester resins, normally used to form a fiberglass-reinforced laminate, show virtually no attack in dilute H_2SO_4 at 90 °C (200 °F) and are used in pickling operations where 15 to 20% acid may be encountered at temperatures to 90 °C (195 °F). At 50% concentration, the polyesters can be safely used to 65 °C (150 °F) and can even find application in special cases where the temperature approaches 90 °C (200 °F). At 75% acid, the temperature must be restricted to less than 65 °C (150 °F). At 90%, most polyester and vinyl-ester resins are rapidly degraded even at ambient temperatures.

Phenol-formaldehyde and furfural alcohol resins are blended with reinforcing glass or other filler to make corrosion-resistant composite pipe and equipment. Some phenol-formaldehyde composites resist H_2SO_4 at concentrations to 50% at 150 °C (300 °F), to 70% at 100 °C (212 °F), and to 96% at ambient temperature. Furfural alcohol resin composites resist H_2SO_4 at concentrations to 50% at 90 °C% (195 °F) and to 70% at ambient temperature.

Carbon and Impervious Graphite. Impervious graphite has excellent corrosion resistance to all but highly oxidizing concentrations of H_2SO_4. Impervious graphite coolers are used in 93% H_2SO_4 (Ref 66). Care must be taken that the impregnant is resistant to the solution. Polyester, furan, and PTFE impregnants are available. Carbon is somewhat superior to graphite in the higher concentrations and is generally preferred for hot acid at concentrations above 60%. Carbon is less conductive and lacks strength and is therefore unsuitable for cooler construction. Both carbon and graphite are, of course, brittle (Ref 67, 68).

Coatings and Linings. Heat-cured phenolic linings on steel are often used to prevent iron contamination in 93% H_2SO_4 and have reasonable life in 98% H_2SO_4 at ambient temperature. These thin-film linings should not be used for concentrations below 70%, because of rapid corrosion of exposed steel substrate at pinholes.

Butyl rubber and Neoprene exhibit good resistance to 50% H_2SO_4 at modest temperatures and will resist 75% acid under ambient conditions. A sulfonated chlorinated polyethylene elastomer has been successfully used in plant applications involving dilute H_2SO_4 as well as hoses handling 93% H_2SO_4 acid.

Glass and glass-lined equipment is widely used in H_2SO_4 service. For severe H_2SO_4 applications, glass-lined steel is a popular material of construction.

Corrosion by Nitric Acid

Ronald D. Crooks, Hercules, Inc.

Nitric acid is typically produced by the air oxidation of NH_3. This catalyzed reaction takes place at very high temperatures. The gaseous oxidation product is condensed to an aqueous liquid of about 65% concentration. During the high-temperature oxidation, corrosion of the plant materials is of secondary concern. The elevated operating temperatures dictate that the high-temperature properties of the materials are the primary design consideration. Corrosion considerations prevail during and after condensation and at lower temperatures.

The concentration of HNO_3 up to 99% requires secondary processing to remove excess water. This involves mixing 65% HNO_3 with another substance having a greater affinity for water (such as H_2SO_4), then separating the mixed acids by distillation and condensation processes.

The basic materials of construction used for equipment to carry out the process described above are reasonably standardized and are listed below:

Equipment	Material
Ammonia converter	Austenitic stainless steel or nickel-base alloy
Acid coolers and condensers	Type 304L (a very low-carbon 0.030 max, version of type 304 stainless steel
65% acid storage	Type 304L
Acid concentrator	Type 304L
Distillation column	Corrosion-resistant cast iron or glass-lined steel
Concentrated acid condensers	Aluminum, glass/PTFE/Alloy 610
Concentrated acid storage	Aluminum alloy 3003, glass-lined steel

Additional information is available in Ref 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81.

Commercially produced HNO_3 is available in concentrations from 52 to 99%. Nitric acid over 86% is described as fuming. Nitric acid up to 95% is stored and shipped in type 304 stainless steel. Concentrated acid above 95% is handled in Aluminum Association (AA) aluminum alloys 1100 or 3003. Figure 43 shows the reason for this; the corrosion rate of type 304 stainless steel increases rapidly above 95% concentration, while that of aluminum 3003 remains essentially constant to 100%. A new stainless steel containing 4% Si--alloy A-610--shows excellent resistance to concentrated HNO_3 (Fig. 48); unfortunately, this advantage does not extend to lower concentrations.

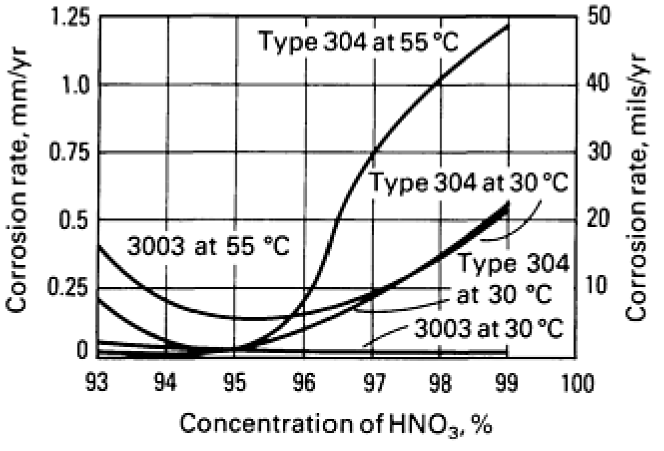

Fig. 43 Comparison of corrosion of aluminum alloy 3003 and type 304 stainless steel in HNO_3

Nitric acid a strong oxidizing agent and attacks most metals, such as iron, by oxidizing the metal to the oxide. A secondary effect of oxidation is the generation of hydrogen at the metal/acid interface, which can cause hydrogen embrittlement of some materials, for example, high-strength steels. Metals and alloys that are able to form adherent oxide films, such as austenitic stainless steels and aluminum alloys, are protected by their oxide films from corrosion by HNO_3.

Metals

Austenitic Stainless Steels. The basic corrosion data for the austenitic (300-series) stainless steels have been reduced to the isocorrosion diagram format (Fig. 44). This diagram shows the effect of temperature and HNO_3 concentration on the corrosion of type 304 stainless steel. Increasing either or both raises the corrosion rate; nevertheless, there is a large useful are extending from 0 to 90% concentration and up to the boiling point below 50% concentration in which the predicted corrosion rate is less than 0.13 mm/yr (5 mils/yr).

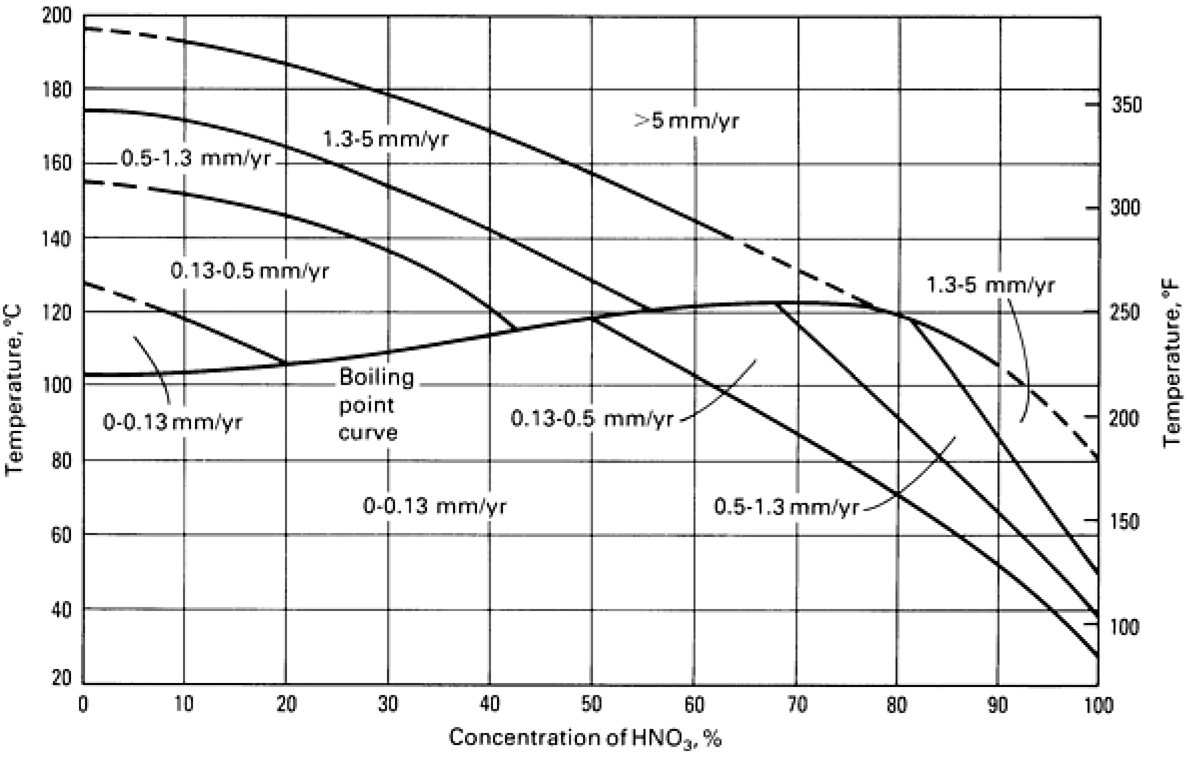

Fig. 44 Isocorrosion diagram for annealed type 304 stainless in HNO_3. Source: Ref 43

Experience has shown that, although all austenitic stainless steels behave in this fashion, types 304 and 304L, when welded, are clearly superior to the others. Therefore, they are the most popular grades for HNO_3 service.

Figure 44 also applies in general to the cast equivalents of wrought stainless steels. However, the generally higher carbon content of cast alloys and the propensity of castings to have high-carbon surfaces often leads to selective intergranular corrosion in strong HNO_3.

Although austenitic stainless steels are commonly used in HNO_3, they are not without problems. One of the most prevalent is selective corrosion associated with chromium carbides precipitated around grain boundaries in the weld HAZ. Because few pieces of industrial equipment are made without welding, this is a serious shortcoming. There are three methods of avoiding this problem:

- Use low or extra-low carbon content (Fig. 45)
- Add carbide stabilizers to the alloy, as in types 321 and 347
- Solution anneal after welding to reduce the chromium carbide gradient

Of these alternatives, solution annealing is frequently not practical, and the choice of stabilized alloys is not always an option. Therefore, when welding is planned, use of low-carbon stainless steels is the most popular alternative.

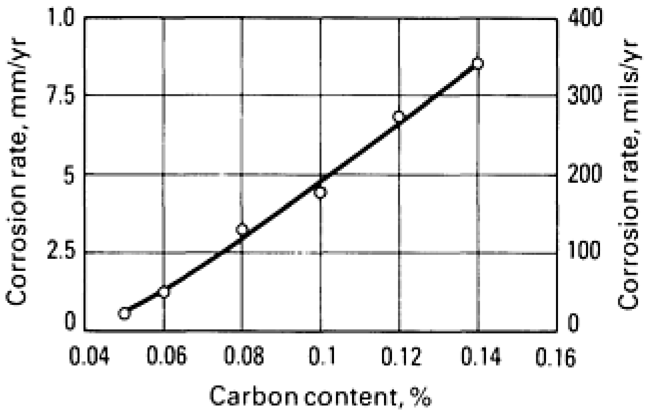

Fig. 45 Effect of carbon content on corrosion rate of type 304 stainless steel in boiling 65% HNO_3. Source: Ref 82

Sensitization of stainless steel refers to the precipitation of chromium carbides and the resultant depletion of the matrix of chromium as a result of heating from 480 to 760 °C (900 to 1400 °F). Figure 46 shows that the effect of such heating on corrosion rate in 65% HNO_3 is detrimental in all cases. Sigma phase, which may also form during prolonged heating of austenitic stainless steels, is preferentially and rapidly attacked by 65% HNO_3. Solution heat treating the alloy will restore corrosion resistance.

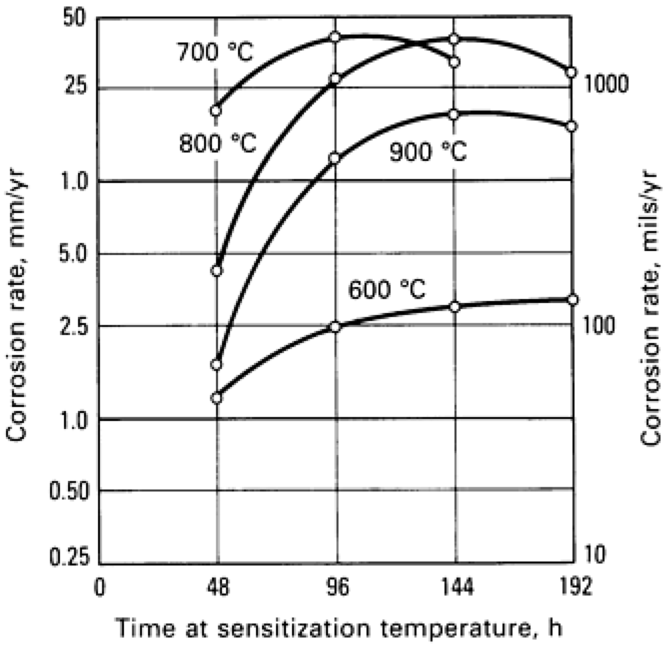

Fig. 46 Effect of sensitization time and temperature on the corrosion of type 304 stainless steel in boiling 65% HNO_3. Source: Ref 78

The corrosion of austenitic stainless steels in HNO_3 is accompanied by the formation of hexavalent chromium (Cr^{6+}), a complex chromium compound that increases the corrosivity of HNO_3 solutions. The effect of Cr^{6+} buildup is shown in Fig. 47 to be clearly detrimental. In general, the presence of chlorides and fluorides in HNO_3 solutions tends to increase the corrosion rate of stainless steels.

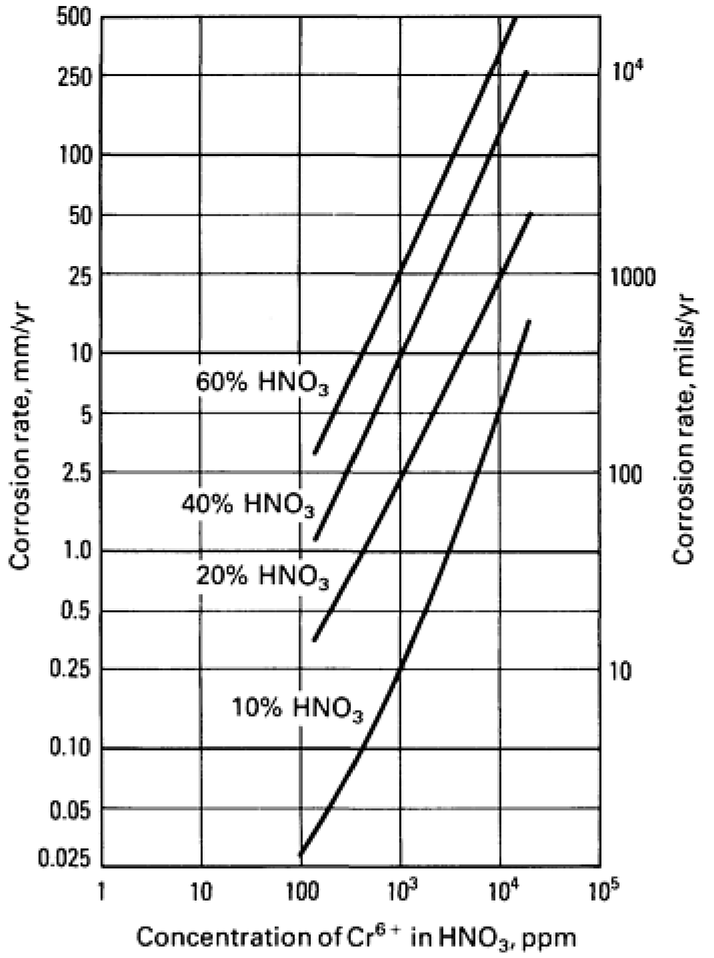

Fig. 47 Effect of hexavalent Cr^{6+} contamination on the corrosion rate of type 304 stainless steel in HNO_3. Test duration: 40 h. Source: Ref 79

Selective corrosion along grain boundaries is common in austenitic stainless steels exposed to HNO_3, especially strong acid. There is some evidence to support the view that this cannot be entirely prevented; however, maintaining low carbon and avoiding sensitization will help.

For very concentrated acid (>95%), the addition of silicon to iron and to austenitic stainless steels is beneficial. Cast iron with 14% Si is very resistant to acid over 50% concentration. Recently, two new stainless alloys of 4 and 6% Si--alloys A-610 and A-611--have been produced (Ref 83). These new alloys have remarkable resistance to HNO_3 above 95% (Fig. 48). At lower concentrations, they offer no advantage over type 304.

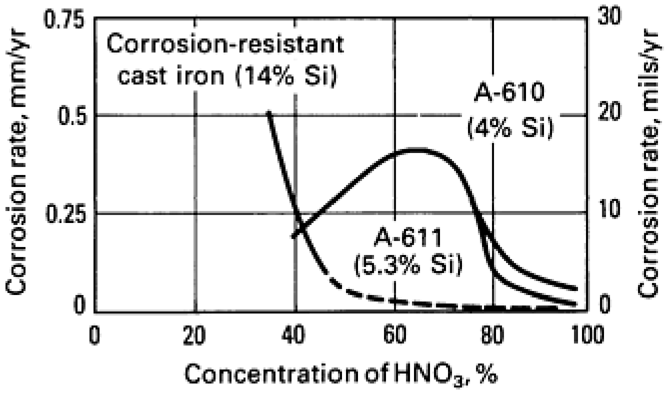

Fig. 48 Effect of silicon content on the corrosion of iron and iron-chromium-nickel alloys in boiling HNO_3. Source: Ref 84

Aluminum, as previously mentioned, shows an advantage over type 304 at acid concentrations exceeding 95% (Fig. 43). However, if acid concentration falls below 80% or if temperature rises above 40 °C (100 °F), much higher corrosion rates can be expected. This relationship is clearly shown in the isocorrosion diagram for aluminum (Fig. 49).

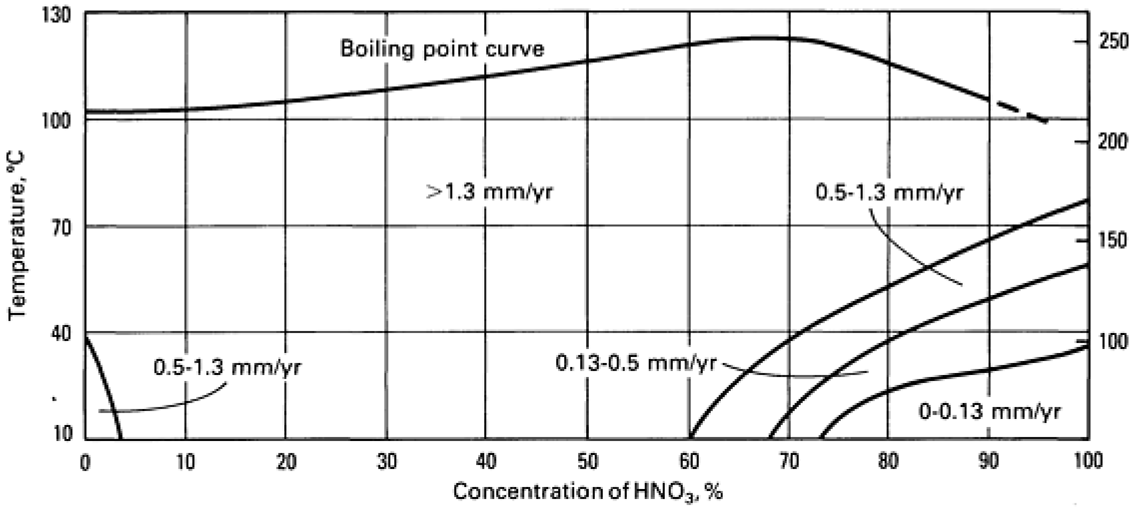

Fig. 49 Isocorrosion diagram for aluminum alloy 1100 in HNO_3. Source: Ref 43

The preferred aluminum alloys for HNO_3 service are alloys 1100 and 3003 (Ref 85). If higher strength is required, alloys 5052 or 5454 can be used.

Aluminum alloys may also suffer degradation by improper welding or by using an incorrect filler metal, which leads to selective weld corrosion. To avoid these problems, the filler metals listed below should be used for the indicated alloy:

Aluminum alloy	Filler metal
1100	1100
3003	1100
5052	5356
5454	5356

Higher-alloy materials, such as 20Cb-3 stainless steel, Hastelloy C-276, Chlorimet 3, Illium 98, and Incoloy 825, are adequately resistant to HNO_3 but are not often used, because the more economical austenitic stainless steels are just as good. Some exception where the higher alloys are useful include very high velocities, mixed acids (especially HF), or the presence of other contaminants in the HNO_3 tending to increase the corrosivity, for example, Cl^- and F^- ions.

Titanium and titanium-palladium alloys resist concentrated HNO_3 from 65 to 90% and dilute acid of less than 10% (Fig. 50). At concentrations above 90%, however, titanium is subject to SCC. Titanium is never used in red fuming HNO_3, because a pyrophoric reaction can occur if water content is less than 1.34% and nitrous oxide (N_2O) exceeds 6%.

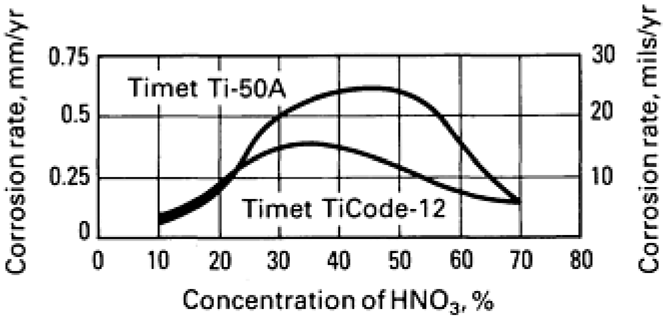

Fig. 50 Corrosion of titanium in boiling HNO_3. Source: Ref 80

Zirconium is even more resistant to HNO_3 than titanium is. Zirconium has a corrosion rate of less than 0.025 mm/yr (1 mil/yr) at all concentrations up to the boiling point. This corrosion resistance extends to 230 °C (450 °F) at concentrations under 65%. The response of zirconium to concentrations exceeding 65% and above the boiling point is uncertain. Unfortunately, zirconium is subject to SCC in HNO_3 at high concentrations and therefore must be used with caution in stronger acids (Ref 86, 87).

Nonmetals

Glass and ceramic materials, unlike most metals, do not corrode in acid, but they are changed by exposure to it. Elements such as iron and silica may leach out, resulting in decreases in strength and density. Glass-coated steel equipment is fully resistant to HNO_3 up to 70% concentration and to 125 °C (260 °F). Exposure to conditions beyond these limits will reduce the life of glass-coated equipment (Ref 88).

Nitric acid attacks most nonmetals, but some can be used to a limited degree in immersion service (Table 11). The temperature limits given in Table 11 apply to tank linings and coatings as well as composite structures embodying these resins.

Table 11 Maximum-use temperatures for plastics in HNO_3 service

Material	Concentration of HNO_3	Temperature	
		°C	**°F**
PTFE	70	232	450
Polyethylene	30	60	140
PVDC	50	52	125
PVDF	50	52	125
Polyester	50	43	110
Vinyl-esters	20	49	120
Furan	5	66	150

Coatings

Frequently, there are requirements for coatings resistant to splash and spillage of HNO_3, which is frequently washed down. None will withstand concentrated acid, but for 50% concentration or less, epoxies, epoxy-phenolics, chlorinated rubber, and aliphatic urethanes have given good service.

Corrosion by Organic Acids

G.B. Elder, Union Carbide Corporation

Organic acids constitute a group of the most important chemicals currently in use in industry. The acids are produced more as precursors for other chemicals than for end use as organic acids. Acetic acid is the best known member of the group and is produced in the largest volume, but the other organic acids are also important for the preparation of compounds used in daily life--compounds from aspirin to plastics and fibers.

The subject of corrosion by organic acids is complicated not only by the numerous acids to be considered but also because the acids typically are not handled as a pure chemical but as process mixtures, with inorganic acids, organic solvents, salts, and mixtures of several organic acids. They are even used as solvents for other chemical reactions.

This section will present some of the corrosion characteristics shared by the organic acids, will detail information on corrosion by formic acid (HCOOH), acetic acid (CH_3COOH), and propionic acid (CH_3CH_2COOH), and will provide selected data no longer-chain organic acids.

Corrosion Characteristics

Organic acids are weak acids, but provide sufficient protons to act as true acids toward most metals. Because most organic acids are neither oxidizing nor reducing to metals, they are handled successfully in such metals as copper, which do not directly displace hydrogen from acids. In organic acids, the corrosion behavior of the 400-series or type 304 stainless steels, which are protected by oxide films, is mixed. This makes contaminants extremely important, because they tend to shift the oxidizing capacity of the acid mixture. Air, Fe^{3+} ions, peracids, or peroxides will cause rapid attack of copper, and the presence of chlorides can have disastrous effects on stainless steels. Additional information on the role of contaminants in CH_3COOH corrosion is provided in Ref 89.

Corrosion testing can be difficult in organic acid media. Electrochemical measurements are most successful in dilute aqueous solutions of the acids because the conductance is very low in high concentrations or in solutions in nonaqueous solvents. The addition of sodium or chloride salts is reported to allow electrochemical measurements (Ref 90). Reported electrochemical data obtained in strong CH_3COOH, acetic acid anhydride [$(CH_3CO)_2O$)], and HCOOH solutions showed active-passive behavior that is consistent with field experience (Ref 91).

Data obtained by immersion tests in the laboratory often show erroneous results unless the atmosphere is carefully controlled. Without atmospheric control, the solution will be saturated with air at the beginning of the test, but will lose air as the temperature is increased until, at boiling conditions, almost all of the air will be removed. This situation can lead

to results that vary widely, depending on the length of the test. Short tests of metals that exhibit active-passive behavior can also be misleading, because the metal may remain passive for a short time but may corrode actively after a longer exposure.

Truly anhydrous organic acids are usually much more corrosive to stainless steels than organic acids containing even traces of water. Corrosion rates reported for glacial (concentrated) acids often reflect this effect, because the acids may be truly anhydrous or may contain small amounts of water.

Formic Acid

Formic acid is the most highly ionized of the common organic acids and therefore the most corrosive. It reacts readily with many oxidizing and reducing compounds and is somewhat unstable as the concentration approaches 100%, decomposing to carbon monoxide and water. The following discussion is divided into metal and alloy groups used to handle HCOOH.

Steel is attacked quite rapidly by HCOOH at all concentrations and temperatures and is normally not considered for HCOOH service. Alloy steels that have been heat treated to high strengths and placed under stress fail by hydrogen cracking when exposed to inorganic acids. Stressed 18% Ni maraging steel cracks when exposed at ambient temperatures to 10% aqueous HCOOH, but does not crack in 91% HCOOH, or in either glacial acid or 10% CH_3COOH (Ref 92).

Aluminum shows fair resistance to HCOOH at any concentration at ambient temperatures as long as there is no contamination of the acid (Fig. 51). However, contamination with a wide variety of materials--for example, heavy-metal salts--can cause severe corrosion of aluminum. Aluminum has been used to ship concentrated HCOOH of about 95 to 99% concentration.

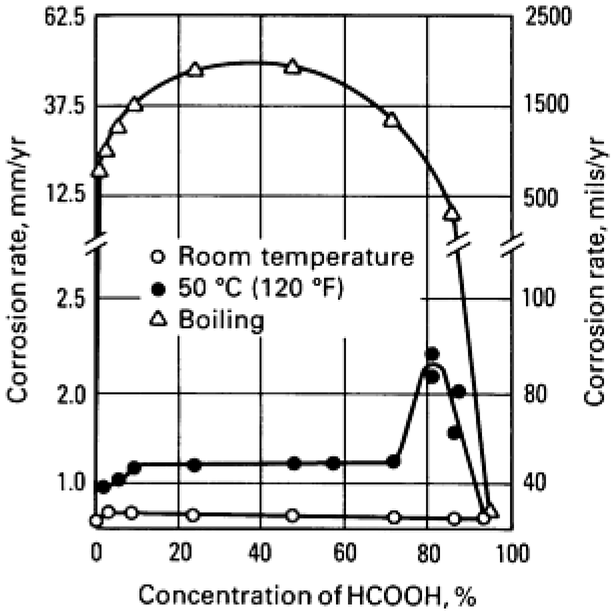

Fig. 51 Corrosion of aluminum alloy 1100-H14 in aqueous reagent grade HCOOH solutions. Sources: Ref 93

Typical rates of attack on aluminum alloy 5086 in HCOOH at 45 °C (115 °F) are shown in Fig. 52, which illustrates that the rate of attack increases rapidly with decreasing concentration at the maximum probable temperatures encountered during shipment. In addition, the acid used in the tests become turbid with aluminum salts, destroying the acid purity, and aluminum could not be used for shipment of this grade of HCOOH. Less meticulous grades of 95 to 99% acid could be shipped satisfactorily.

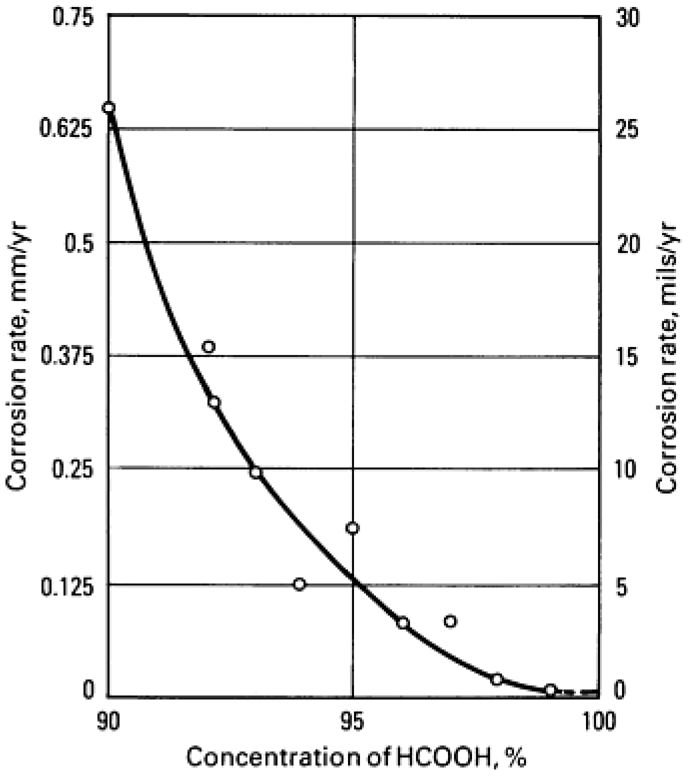

Fig. 52 Corrosion of aluminum alloy 5086 in HCOOH at 45 °C (115 °F). Source: Ref 93

Copper and its alloys, except yellow brasses, which dezincify, respond in approximately the same manner as aluminum to exposure to HCOOH. Table 12 shows typical corrosion rates for copper (C10300) and 90Cu-10Ni copper-nickel (C70600) in various concentrations of HCOOH. Aluminum bronze is reported to be a superior copper alloy for handing HCOOH (Ref 94).

Table 12 Corrosion of copper and copper-nickel by HCOOH

Laboratory tests in deaerated acid at atmospheric boiling temperature; test duration: 96 h

Acid concentration, %	Corrosion rate			
	Copper C10300		**Copper-nickel C70600**	
	mm/yr	**mils/yr**	**mm/yr**	**mils/yr**
1.0	0.02	0.8	0.02	0.9
5.0	0.02	0.7	0.02	0.9
10.0	0.02	0.6	0.02	0.7
20.0	0.20	7.8	0.40	15.7
40.0	0.14	5.5	0.34	13.3
50.0	0.26	10.2	0.54	21.2
60.0	0.05	2.0	0.03	1.3
70.0	0.76	30.0	0.76	30.0
80.0	0.20	7.8	0.13	5.0
90.0	0.22	8.7	0.19	7.6

The resistance of copper and its alloys to HCOOH depends on the presence or absence of oxygen or other oxidizing agents. If free air or other oxidants are present, high corrosion rates will be encountered; if the acid is free of air and other oxidants, copper will provide usable resistance to HCOOH at all concentrations to the atmospheric boiling point and even at higher temperatures. Copper and its alloys are probably the most widely used materials for handling HCOOH. The anomalies in the data shown in Table 12, such as the higher rate of attack in 50 and 70% HCOOH, are probably caused by incomplete deaeration during laboratory tests, although some increase in the rate of corrosion in intermediate acid strengths is to be expected because of maximum dissociation in these concentrations.

Stainless steels. The 400-series stainless steels are usually resistant to HCOOH, except for very dilute, cool solutions, and they are seldom used in HCOOH service. Type 304 stainless steel has excellent resistance to HCOOH at all concentrations at ambient temperatures, and it is the preferred material of construction for storage of the acid. However, type 304 stainless steel is resistant to only 1 or 2% HCOOH at the atmospheric boiling temperature, and corrosion tests are advisable whenever type 304 stainless steel is considered for handling HCOOH at elevated temperatures. Table 13 shows typical rates of attack on various stainless steels in several concentrations of HCOOH at the atmospheric boiling temperature.

(c) 48-h exposure.

(d) Low-carbon molybdenum-bearing version of type 446

Type 316 stainless steel shows excellent resistance to HCOOH in all concentrations at ambient temperatures and is resistant to at least 5% HCOOH acid at the atmospheric boiling temperature. However, type 316 stainless steel can be seriously attack by intermediate strengths of HCOOH at higher temperatures, and corrosion tests are advisable.

The 20-type alloys, such as 20Cb-3, are more resistant to HCOOH than type 316 stainless steel is, and their use should be considered in higher concentrations at higher temperatures. Other alloys with chromium and nickel contents higher than those in type 316 stainless steel also show superior resistance to mixtures of HCOOH and CH_3COOH and would be expected to perform better in HCOOH itself. Duplex alloys are also reported to be superior to type 316 stainless steel (Ref 94). Weld overlays of 20-type alloys have also been used to alleviate the crevice corrosion of type 316 stainless steel--for example, under gaskets.

A low-carbon niobium-bearing variant of type 446 stainless steel--alloy S44627--appears to have exceptional corrosion resistance to HCOOH in preliminary laboratory studies and plant usage. This alloy should be considered for handling HCOOH.

Titanium has shown outstanding resistance to HCOOH in laboratory tests and in field usage. However, titanium can be attacked at truly catastrophic rates by anhydrous HCOOH. Additional work is needed to determine the precise conditions under which titanium is attacked in HCOOH, and until these parameters have been established, titanium should be tested very carefully before use in HCOOH approaching 100% concentration at elevated temperatures.

Other Alloys. Several of the high-nickel alloys, such as Hastelloy B, Hastelloy C-276, and Hastelloy C-4, have shown outstanding resistance to HCOOH in process equipment and are reported to exhibit very good resistance even at temperatures above the atmospheric boiling point. Figure 53 shows corrosion data for Hastelloy C. Lead is substantially nonresistant to HCOOH and other organic acids. The refractory metals tantalum, niobium, and zirconium resist HCOOH, as does silver.

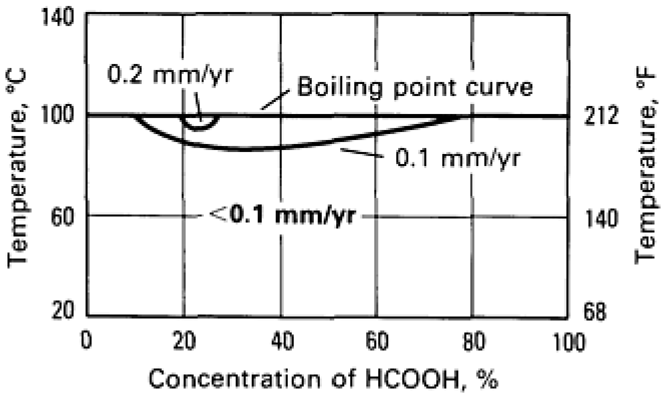

Fig. 53 Corrosion of Hastelloy C in HCOOH

Nonmetals. Formic acid is an excellent solvent and is destructive to most plastic materials and coatings. Therefore, plastics are not normally considered for handling HCOOH. Exceptions are the polyolefins, which are sometimes used to handle small quantities of acid; fluorocarbons, which are resistant; and some rubber linings, which can be used if discoloration of the acid is not critical. All coatings are normally unsatisfactory for strong HCOOH service.

Acetic Acid

Acetic acid, as well as its derivatives, is produced in large quantities. It is the most important organic acid and is frequently encountered as a contaminant in other organic chemical processes. Acetic acid is even used as a solvent for some organic reactions. Consequently, knowledge of its corrosivity is essential. Additional information on corrosion by CH_3COOH is provided in Ref 91 and 95.

Acetic acid is classified as a weak acid, but the effective acidity in aqueous streams increases rapidly with concentration (Fig. 54). The following sections discuss the resistance of various materials to CH_3COOH.

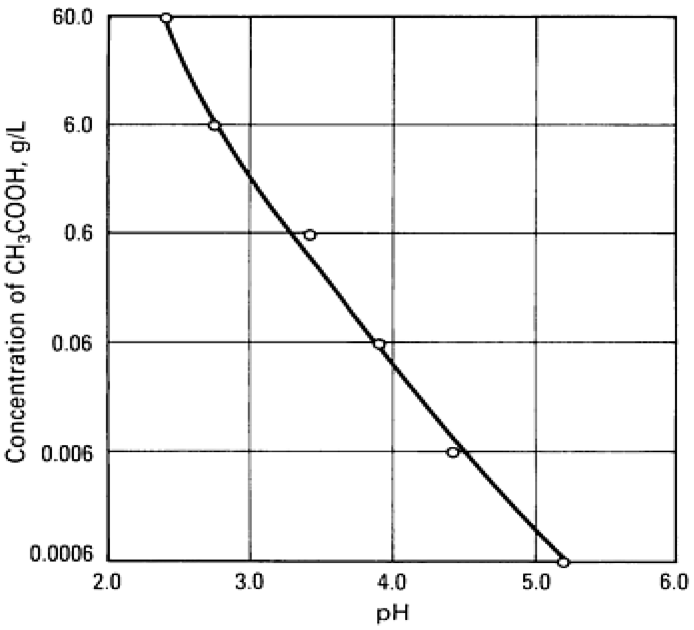

Fig. 54 Concentration versus pH of aqueous CH_3COOH solutions

Steel is attacked quite rapidly by all concentrations of CH_3COOH, even at room temperature. Glacial CH_3COOH at room temperature is less aggressive than aqueous solutions of the acid, but still gives a rate of attack of 0.8 to 1.3 mm/yr (30 to 50 mils/yr). Therefore, steel is normally unacceptable for use in CH_3COOH service.

Aluminum exhibits good resistance to nearly all concentrations of CH_3COOH at room temperature and has been used extensively for storage and shipment. It is fairly resistant to 97 to 99% CH_3COOH to the boiling point, but is attacked very rapidly in concentrations near 100% or containing excess $(CH_3CO)_2O$. Aluminum again becomes resistant to pure $(CH_3CO)_2O$, although it causes contamination of the anhydride due to formation of a white crystalline solid, aluminum triacetate ($Al(C_2H_3O_2)_3$), which precipitates in the liquid.

An excellent summary of the use of aluminum in CH_3COOH and $(CH_3CO)_2O$ is available in Ref 96. Figures 55 and 56 show the resistance of aluminum in CH_3COOH and $(CH_3CO)_2O$. The data are for aluminum alloy 1100, but similar rates would be expected for such alloys as 3003, 6063, and 5086.

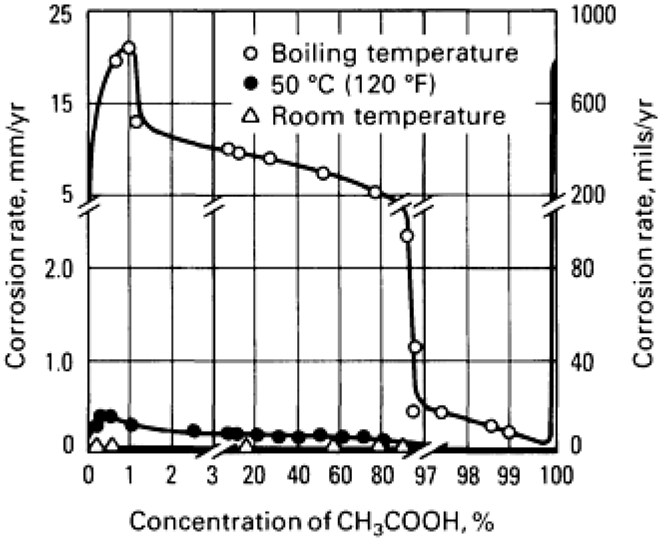

Fig. 55 Effect of acid concentration and temperature on the corrosion of aluminum alloy 1100-H14 in CH_3COOH

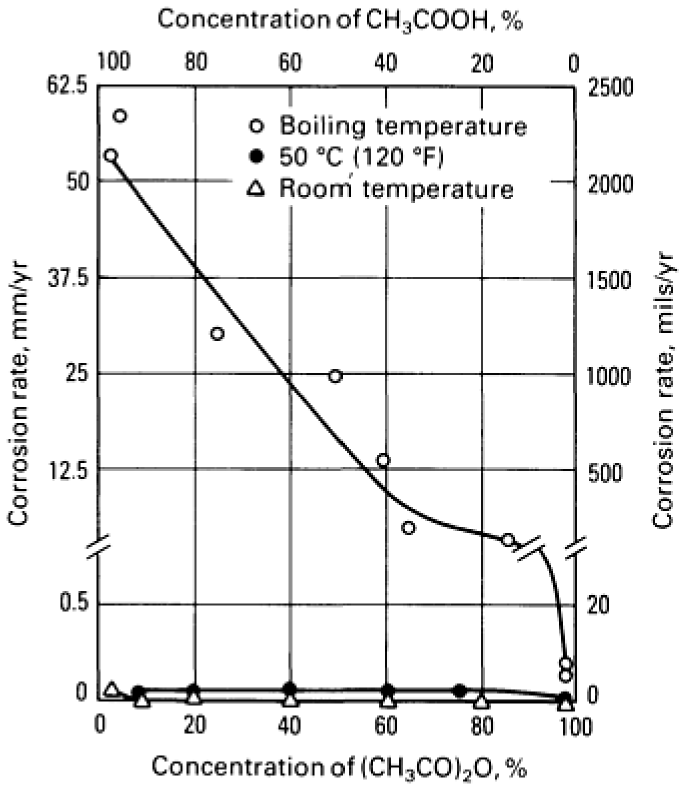

Fig. 56 Metal loss of aluminum alloy 1100-H14 in CH_3COOH-$(CH_3CO)_2O$ solutions at atmospheric boiling temperature

The corrosion resistance of aluminum in CH_3COOH is strongly affected by contaminants. Aluminum can corrode in almost any concentration of CH_3COOH at any temperature if the acid is contaminated with the proper species.

Copper and its alloys, except those with high zinc content (>15% Zn), show good resistance to all concentrations of CH_3COOH up to and even above the atmospheric boiling temperature in the absence of oxygen or other oxidants. Copper was used almost exclusively to handle CH_3COOH until the advent of the stainless steels, but today, type 316 stainless steel and higher alloys are often used.

The absence of oxidizing agents is essential for copper to resist attack by CH_3COOH and other organic acids. Copper is nearly immune to attack by pure, uncontaminated CH_3COOH, yet slight contamination with air through storage under an air atmosphere or by entry of air through a pump seal can increase the rate of attack in a copper column to hundreds of mils per year. One set of laboratory tests at room temperature in 50% CH_3COOH showed corrosion rates of 1.8 mm/yr (71.5 mils/yr) when the solution was sparged with oxygen, but only 0.08 mm/yr (3.1 mils/yr) when the solution was nitrogen sparged.

The addition of nickel to copper moderates the effect of oxidants. Tests in boiling 50% CH_3COOH sparged with air for 120 h gave rates of 7.9 mm/yr (310 mils/yr) for copper, 4.8 mm/yr (188 mils/yr) for copper alloy C71500 (copper-nickel, 30%), and 2.1 mm/yr (84 mils/yr) for copper containing 67% Ni. Similar reductions with increasing nickel content were noted when Fe^{3+} ion was added to the solution; however, rates still remained quite high.

Stainless Steels. The chromium stainless steels of the 400 series occasionally exhibit low corrosion rates in laboratory tests in dilute CH_3COOH. However, because field experience with these materials indicates high corrosion rates and pitting attack, they are rarely used for CH_3COOH production equipment. Type 304 stainless steel is the lowest grade commonly used. Exceptions include the high-purity ferritic stainless steels, which show good resistance.

Type 304 stainless steel finds wide application in dilute CH_3COOH and in the shipment and storage of concentrated CH_3COOH. Data show that glacial CH_3COOH can be handled in type 304 stainless steel to a temperature of about 80 °C (175 °F) and that type 304 has been satisfactory for lower concentrations to the boiling point of the acid (Ref 92). At

temperatures above 60 °C (140 °F), use of the low-carbon type 304L is advisable for welded construction in order to prevent intergranular attack of heat-affected zones (HAZs).

Type 316 stainless steel is the alloy most commonly used in CH_3COOH processing equipment. It will resist glacial acid to temperatures above the atmospheric boiling point. As with type 304 stainless steel, the low-carbon grade (type 316L) is required for the higher-temperature application.

Acetic anhydride was produced as a coproduct in the old acetaldehyde oxidation process for CH_3COOH and is found in other acid streams. When CH_3COOH is truly anhydrous or contains small quantities of $(CH_3CO)_2O$, the rate of attack on type 316 stainless steel increases dramatically. Experience has shown that the introduction of a few tenths of a percent of water will reduce the corrosion. Figure 57 illustrates the reduction in corrosion rate as $(CH_3CO)_2O$ is added.

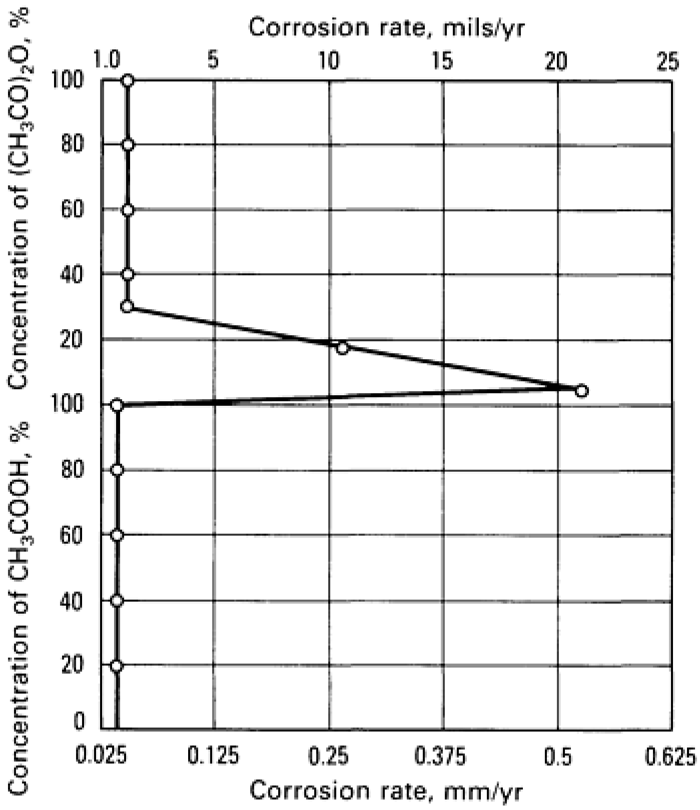

Fig. 57 Corrosion of type 316 stainless steel in CH_3COOH and in CH_3COOH-$(CH_3CO)_2O$ mixtures

Contamination with chloride can cause pitting, rapid SCC, and accelerated corrosion of type 316 stainless steel. Up to 20 ppm of chloride can be tolerated (Ref 9), but higher concentrations are likely to cause rapid equipment failure.

Transferring heat through a metal wall, as in heat exchangers, can drastically alter the corrosion characteristics of the metal. A method to test metals under heat transfer conditions and data on stainless steels and some nickel alloys in HCOOH and CH_3COOH under heat transfer conditions are given in Ref 97. Higher alloys, such as 20Cb-3 and Incoloy 825, show better resistance to CH_3COOH than type 316 stainless steel does.

Titanium resists all concentrations of CH_3COOH up to the atmospheric boiling point. Electrochemical studies in CH_3COOH solutions suggest that it is possible to attack titanium in anhydrous CH_3COOH, but titanium has been used very successfully (Ref 98). The high-strength titanium alloys should not be used, because of their susceptibility to SCC.

Other alloys. Hastelloy alloys C-276 and B resist CH_3COOH solutions at all concentrations and normal temperatures. These materials are sometimes used where the acid is used in conjunction with inorganic acids and salts that limit the use of stainless steels or copper alloys. Hastelloy B is used under reducing conditions, such as with combinations of CH_3COOH and H_2SO_4, while Hastelloy C-276 is commonly used in highly oxidizing CH_3COOH solutions.

Silver has been frequently used in Europe to handle CH_3COOH, and it is quite resistant to all concentrations at normal temperatures. Because of cost, silver has been used very little in the United States.

Lead has very limited resistance to CH_3COOH. It has been used to store glacial CH_3COOH where temperature, degree of aeration, and velocity are low, but dilute CH_3COOH, even at room temperature, attacks lead at rates exceeding 1.3 mm/yr (50 mils/yr). These rates increase rapidly with increasing aeration and velocity.

Wood tanks have been extensively used for the storage of dilute CH_3COOH, but stainless steels are now normally used. Many wooden tanks are still in use after many years of service.

Rubber linings, either hard or semihard, have been used successfully in CH_3COOH storage tanks and for those applications where discoloration of the acid is not objectionable. Glass linings have also been used to handle CH_3COOH. No attack on alkaline borosilicate glass has been reported below about 150 to 175 °C (300 to 350 °F) (Ref 99).

Propionic Acid

CH_3CH_2COOH has corrosion characteristics very similar to, but somewhat less aggressive than, those of CH_3COOH. The following sections will discuss various materials for use in CH_3CH_2COOH.

Steel is attacked at rates of about 0.6 mm/yr (25 mils/yr) in pure CH_3CH_2COOH at room temperature and at much higher rates in aqueous solutions of the acid. Therefore, steel has very limited use in handling CH_3CH_2COOH.

Aluminum. The corrosion characteristics of aluminum in CH_3CH_2COOH are shown in Fig. 58. The rates of attack are very similar to those in CH_3COOH. Again, the rates can be significantly affected by contamination.

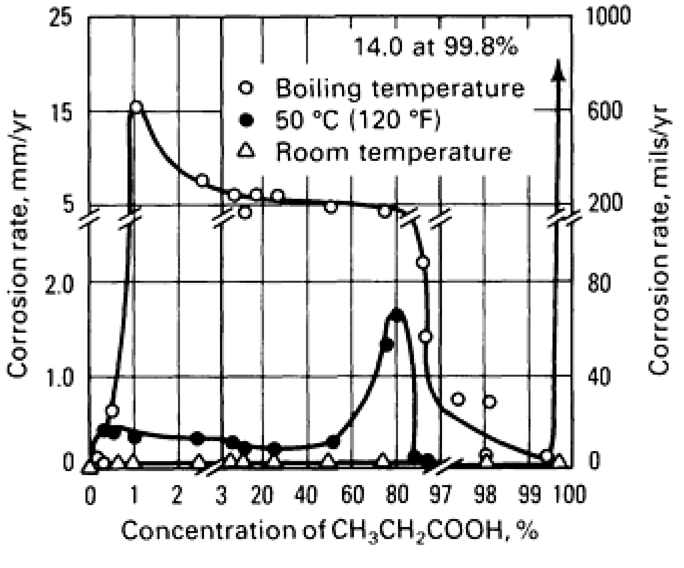

Fig. 58 Corrosion of aluminum alloy 1100-H14 in CH_3CH_2COOH solutions at various temperatures

Copper and copper alloys are excellent for handling all concentrations of CH_3CH_2COOH. The data shown in Fig. 59 indicate attack on copper in boiling 100% CH_3CH_2COOH, but this is believed to be an anomaly caused by incomplete deaeration of the solution. As with $HCOOH$ and CH_3COOH, copper and its alloys are satisfactory only if the solutions are completely deaerated and do not contain other oxidizing agents.

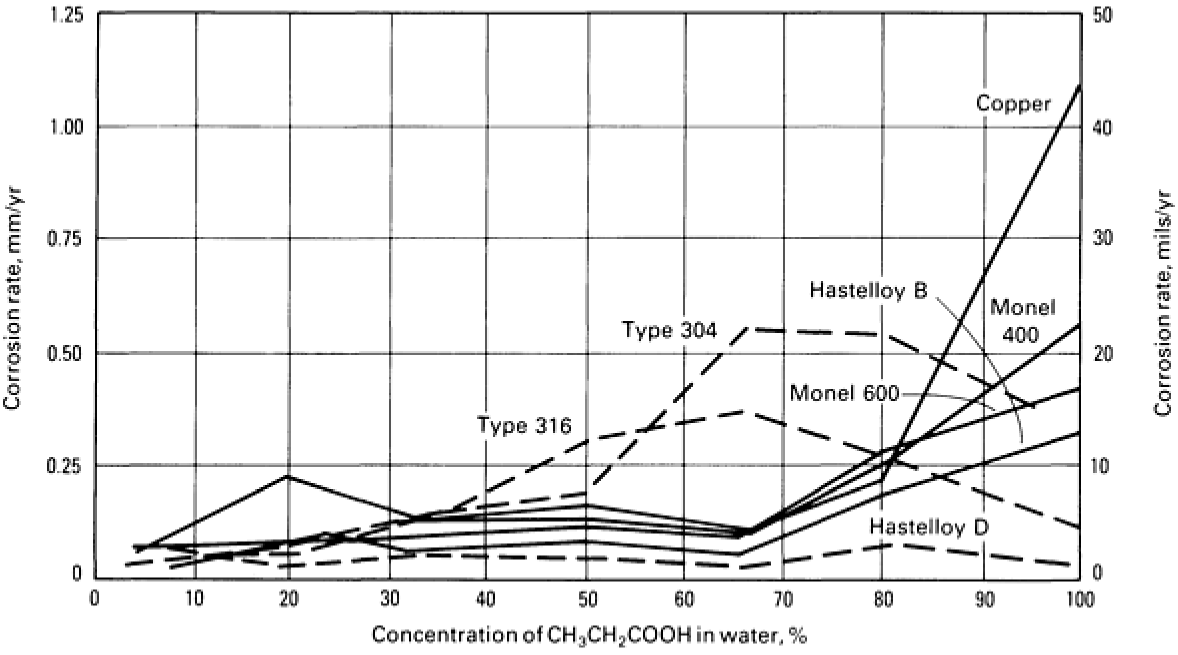

Fig. 59 Corrosion of metals in CH_3CH_2COOH at boiling temperature

Stainless Steels. The 400-series stainless steels are not used in CH_3CH_2COOH, because of their propensity for pitting. They should be thoroughly tested in the exact environment for which their use is proposed. Type 304 stainless steel shows good resistance to CH_3CH_2COOH at room temperature and to aqueous solutions up to about 50% concentration at boiling temperature.

The atmosphere over the laboratory test solutions (Fig. 59) was not controlled, and the tests were of short duration (24 to 75 h), which caused two misleading results. The rate of corrosion of copper was found to increase rapidly above 65% concentration, which is true with air present in the solution, but copper would have very acceptable rates of corrosion in all concentrations of acid in the absence of air or other oxidants. Type 304 stainless steel was shown to have decreasing corrosion rates between 80 and 100% concentration; field experience indicates that type 304 stainless steel exhibits borderline passivity in this range of concentrations at the boiling temperature and should not be considered for such service.

Type 316 stainless steel is the preferred material for handling hot concentrated CH_3CH_2COOH solutions. The low-carbon grade (type 316L) should be used to avoid possible intergranular attack, unless corrosion tests in the exact environment show that intergranular attack is not a problem.

Other Metals. Hastelloy alloys B and C show excellent resistance to CH_3CH_2COOH solutions under reducing and oxidizing conditions, respectively. Other nickel alloys exhibit good resistance to low concentrations of CH_3CH_2COOH, but are not normally as good as type 316L stainless steel for the higher concentrations at high temperatures.

Other Organic Acids

It is impossible to cover each of the remaining hundreds of organic acids. However, Table 14 lists the corrosion rates of various metals in several of the longer-chain aliphatic acids and aromatic acids and some dicarboxylic acids. Table 15 provides data on the corrosion of some less familiar alloys in various organic acids. It is possible to make some generalized statements concerning materials for use in the higher molecular weight acids.

(a) Low-carbon molybdenum-containing variant of type 446

Steel is usable at ambient temperatures in the higher molecular weight acids, and it is used conventionally to store many of the acids and their corresponding anhydrides.

Aluminum shows good resistance to the acids at room temperature and is widely used for their handling. Some of the higher molecular weight acids cause severe attack of aluminum at highly elevated temperatures; therefore, the use of aluminum must be considered for the specific acid and temperature desired.

Copper and copper alloys exhibit good resistance to all of the higher molecular weight acids and can be used quite widely to handle the acids, even at elevated temperatures in the absence of oxidants.

Stainless Steels Type 304 stainless steel has excellent resistance to the higher molecular weight organic acids at room temperature and at lower concentrations at high temperatures. With the concentrated acids, type 304 is sometimes severely corroded. Type 316 stainless steel is then required and is usable in almost all of the acids, even at elevated temperatures.

Other Alloys The nickel-molybdenum and nickel-molybdenum-chromium alloys shows excellent resistance to the higher molecular weight acids, but the expense of these alloys is rarely justified unless other contaminants, such as inorganic acids, are also present. The nickel alloys, particularly nickel-copper, have been used to process the higher molecular weight acids at elevated temperatures. They can be particularly useful when contamination of the acids prohibits the use of the type 316 stainless steel.

Corrosion by Hydrogen Chloride and Hydrochloric Acid

Thomas F. Degnan, Consultant

Hydrochloric acid is an important mineral acid with many uses, including acid pickling of steel, acid treatment of oil wells, chemical cleaning, the chemical processing. It is made by absorbing hydrogen chloride in water. Most acid is the by-product of chlorinations. Pure acid is produced by burning chlorine and hydrogen. Hydrochloric acid is available in technical, recovered, food-processing and reagent grades. Reagent grade is normally 37.1% (Ref 100).

Hydrochloric acid is a corrosive, hazardous liquid that reacts with most metals to form explosive hydrogen gas and causes severe burns and irritation of eyes and mucous membranes. Safe handling procedures for HCl are described in Ref 101. Additional safety information is available from the manufacturer.

Concentrated HCl is transported and stored in rubber-lined tanks, although plastic-fabricated polyester reinforced thermoset plastic (RTP) storage tanks have been used. Pipelines are usually plastic-lined steel. Processes involving aqueous acid are commonly carried out in glass-lined steel equipment. Nonmetallic materials are normally preferred because of the corrosive action of this strongest of acids on most metals.

Candidate metals and alloys for handling HCl are shown in Fig. 60. Suitable materials are judged to be those with a corrosion rate under 0.5 mm/yr (20 mils/yr) when exposed to uncontaminated HCl. In practice, contamination is not uncommon and can be catastrophic. Selection of a candidate metal should be based on extensive corrosion testing or, preferably, field experience, using the grade of acid that will be available.

Effect of Impurities

Fluorides. Acid recovered from the manufacture of fluorocarbons may contain trace amounts of HF. It has been reported that such acids may contain more than 0.5% HF (Ref 103). Commercial suppliers remove most of the fluoride from HCl by selective absorption, and it is unlikely that an unsuspecting customer would receive acid containing as much as 0.5%. However, glass-lined steel and the refractory metals, such as zirconium, niobium, tantalum, and titanium (but not molybdenum), have very low tolerance levels for fluorides. Zirconium is reported to tolerate less than 10 ppm (Ref 104). Tantalum may tolerate 10 ppm or more. The limits are undefined except for a few specific cases, and it is best to consider all of these metals and glass-lined steel to be essentially nonresistant of fluorides and to know the source and specification limits of the acid if these materials are used.

Ferric Salts. The presence of Fe^{3+} ions in HCl has a profound effect on the corrosion of many metals and alloys otherwise resistant to HCl. Nickel-base alloys, including Hastelloy B-2, the copper alloys, and unalloyed zirconium, are affected. Although the acid specification may be low in iron, acid can easily become contaminated during shipment and handling.

Cupric Salts. Cupric ions have an accelerating effect on the corrosion of many metals that is similar to that of Fe^{3+} ions. Like Fe^{3+} ions, Cu^{2+} ions can cause pitting and SCC of zirconium. The presence of Cu^{2+} ions can also lead to the autocatalytic acceleration of nickel-copper and copper-nickel alloys. It is unlikely that commercial acid would contain Cu^{2+} salts. This is more of a problem of in-process contamination by exposure of copper-containing metals or introduction as an impurity in a chemical or raw material used in the process.

Aeration, although less damaging than the presence of oxidizing metal salts, accelerates the corrosion of many metals. Figure 61 shows the effect of aeration on the corrosion rate of Nickel 200 and Monel 400.

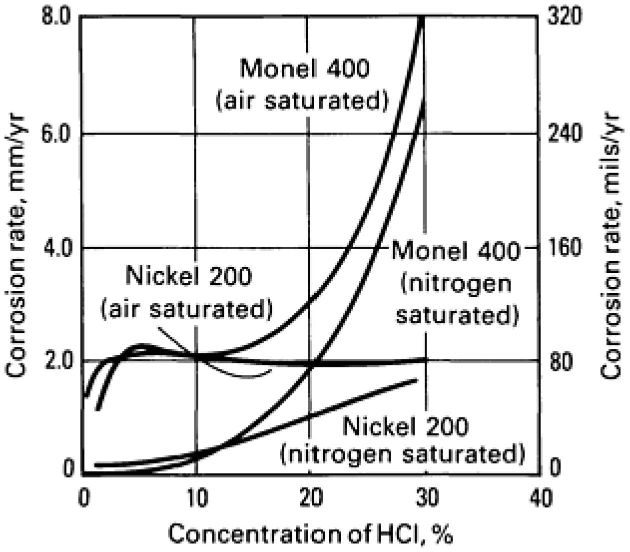

Fig. 61 Corrosion of Nickel 200 and Monel 400 in HCl solutions at 30 °C (85 °F). Source: Ref 104

Chlorine contamination accelerates the corrosion of all metals except unalloyed tantalum and noble metals; however, unalloyed, titanium can be protected by the presence of chlorine in dilute HCl (Ref 105). Chlorine may be present in acid recovered from a chlorination process, but would be removed before sale.

Organics. Hydrochloric acid can become contaminated with organic solvents, such as carbon tetrachloride (CCl_4) or chlorobenzene (C_6H_5Cl), when recovered as a by-product of a chlorination process. Even a few parts per million of organic contaminants can, over a period of time, destroy rubber linings, elastomer membranes behind brick linings, and certain plastics and elastomers. It is unlikely that such acid would be shipped, although organic contamination is often encountered in plant processes.

Corrosion of Metals in HCl

Most corrosion data and graphical information published by metal suppliers and others are based on tests conducted in reagent grade HCl. In some cases, as in Fig. 60, limitations will be noted regarding the presence of aeration or impurities. As mentioned above, these data should be used only as a guide in selecting metals for further testing and evaluation.

Carbon and alloy steels are unsuitable for exposure to HCl except during acid cleaning.

Austenitic Stainless Steels. The commonly used austenitic stainless steels, such as types 304 and 316, are nonresistant to HCl at any concentration and temperature. At ambient temperatures and above, corrosion rates are high. Nickel, molybdenum, and, to a lesser extent, copper impart some resistance to dilute acid, but pitting, local attack, and SCC may result (Ref 106). Subambient temperatures will slow the corrosion rate, but will invite SCC. Type 316 stainless steel has been known to crack in 5% HCl at 0 °C (32 °F) (Ref 107). At high corrosion rates (>0.25 mm/yr, or 10 mils/yr), SCC is unlikely to occur. However, the corrosion products, particularly $FeCl_3$, will cause cracking. Chlorides can penetrate and destroy the passivity (oxide film) that is responsible for the corrosion resistance of stainless steels, and the corrosion engineer should resist every attempt to use stainless steels in environments containing chlorides.

The standard ferritic stainless steels, such as types 410 and 430, should not be considered, because their corrosion resistance to HCl is lower than that of carbon steel. An exception is 29-4-2 stainless steel, which reportedly resists up to 1.5% HCl to the boiling point and remains passive (Ref 108). However, it is not suitable at higher concentrations, and the alloy is susceptible to SCC, although its resistance is reported to be high.

Some stainless steels--such as 20Cb-3, with its high nickel content (32 to 38%), 2 to 3% Mo, and 3 to 4% Cu--resist dilute HCl at ambient temperatures. However, 20Cb-3 is susceptible to pitting and crevice attack in acid chlorides and should be used with caution.

Nickel and Nickel Alloys. Nickel 200 and Monel 400 have good resistance (<0.25 mm/yr, or 10 mils/yr) to dilute (<10%) HCl in the absence of air or oxidizing agents at ambient temperatures. Monel 400 has been used at concentrations below 20% at ambient temperatures under air-free conditions and under 10% concentration aerated, but penetration rates generally exceed 0.25 mm/yr (10 mils/yr) and may approach 1 mm/yr (40 mils/yr).

Increasing the temperature affects the corrosion rate of Nickel 200 more than that of Monel 400 in 5% HCl (Fig. 62). When HCl is formed by hydrolysis of chlorinated hydrocarbons, acid concentrations are often less than 0.5%. Under theseconditions, Nickel 200 and Monel 400 have found application at temperatures below 200 °C (390 °F) (Ref 104).

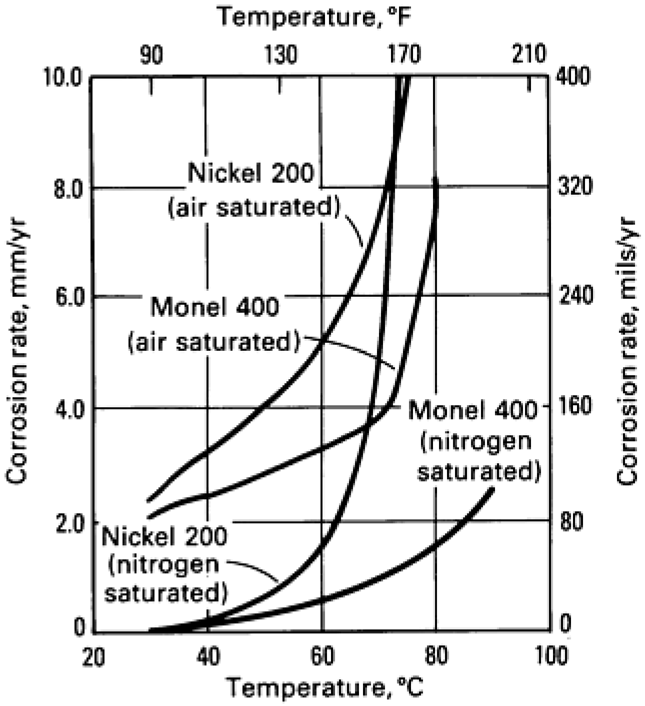

Fig. 62 Effect of temperature on the corrosion of Nickel 200 and Monel 400 in 5% HCl. Source: Ref 104

Inconel 600, although it has useful resistance to cold dilute HCl, exhibits corrosion resistance which is inferior to that of Nickel 200 and Monel 400. However, this alloy is useful in handling wet halogenated solvents, because it has little, if any, catalytic effect on hydrolysis.

Inconel 825, Hastelloy G, and Inconel 625 contain appreciable amounts of chromium and increasing amounts of molybdenum, and they have useful resistance to all concentrations of HCl below 40 °C (100 °F). Inconel 625 has good resistance to concentrated reagent grade acid at ambient temperatures. Corrosion data on Inconel 825 and 625 in various concentrations are given in Tables 16 and 17.

Table 16 Laboratory corrosion tests of Inconel 625 in HCl solutions at 66 °C (150 °F)

Acid concentration, wt%	Corrosion rate	
	mm/yr	**mils/yr**

Source: Ref 104

These alloys have good resistance to dilute (<5%) acid at higher temperatures and are less affected by aeration than Nickel 200 and Monel 400. They are all very resistant to chloride SCC. Resistance to pitting and crevice corrosion in acid chloride solutions improves with increasing chromium and molybdenum contents. Thus, Inconel 625 (22Cr-9Mo) is more resistant than Hastelloy G (22Cr-6.5Mo), which in turn is more resistant than Inconel 825 (21Cr-3Mo). Figure 63 shows an isocorrosion diagram of Hastelloy G in HCl.

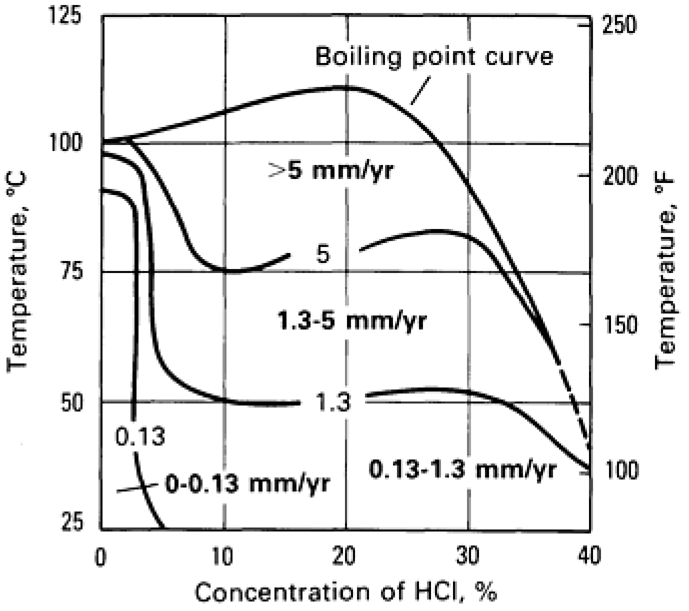

Fig. 63 Isocorrosion diagram for Hastelloy G in HCl

The most corrosion resistant of the nickel-base alloys to HCl are Hastelloy B-2 (Ni-28Mo) and Hastelloy C-276 (Ni-16Cr-15.5Mo). Hastelloy B-2 is one of the few metals with a corrosion rate under 0.5 mm/yr (20 mils/yr) in all concentrations and temperatures up to the atmospheric boiling point in nonaerated acid in the absence of oxidizing agents. Solution heat treatment after welding is required for maximum corrosion resistance. Figures 64 and 65 show isocorrosion diagrams for unaerated and oxygen-purged HCl.

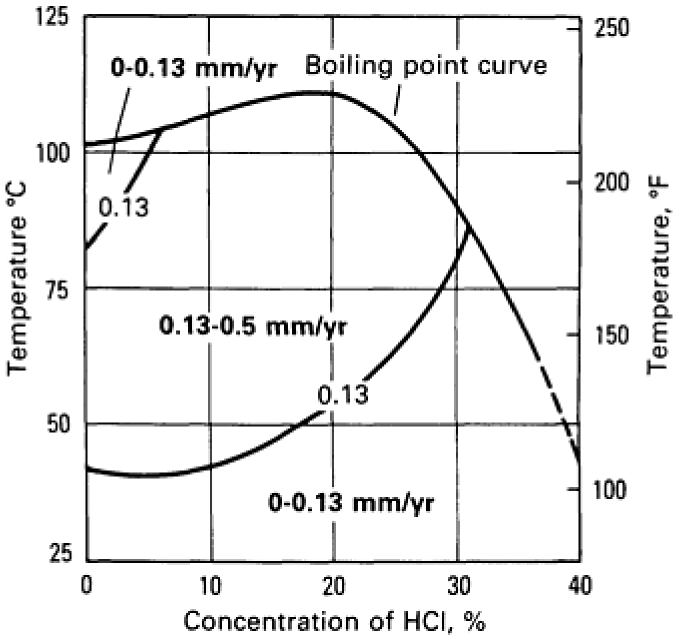

Fig. 64 Isocorrosion diagram for Hastelloy B-2 in HCl

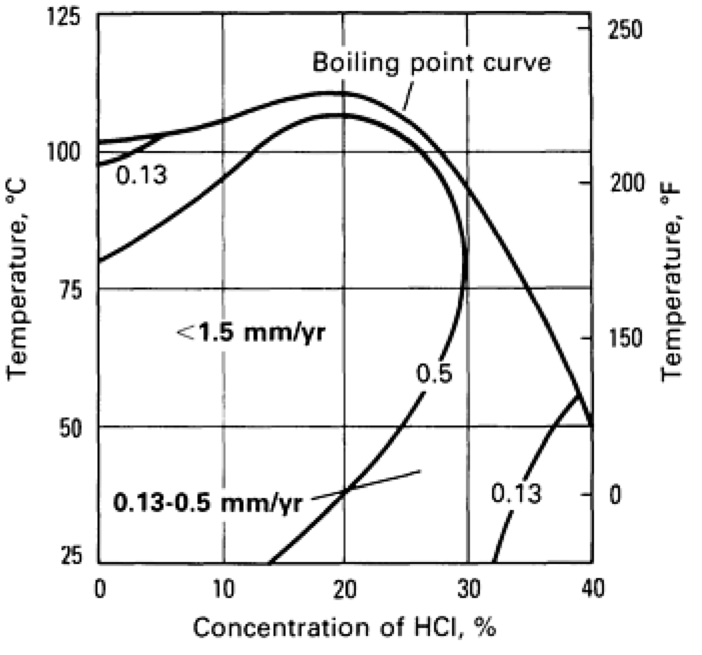

Fig. 65 Isocorrosion diagram for Hastelloy B-2 in oxygen-purged HCl

Hastelloy C-276 has excellent corrosion resistance (<0.13 mm/yr, or 5 mils/yr) in all concentrations of HCl at room temperatures and good resistance (<0.5 mm/yr, or 20 mils/yr) to all concentrations up to 50 °C (120 °F). At concentrations under 10%, its resistance often exceeds that of Hastelloy B-2. Figure 66 shows an isocorrosion diagram for

Hastelloy C-276 in unaerated HCl. Oxygen and strong oxidizing agents accelerate corrosion, although markedly less than for Hastelloy B-2.

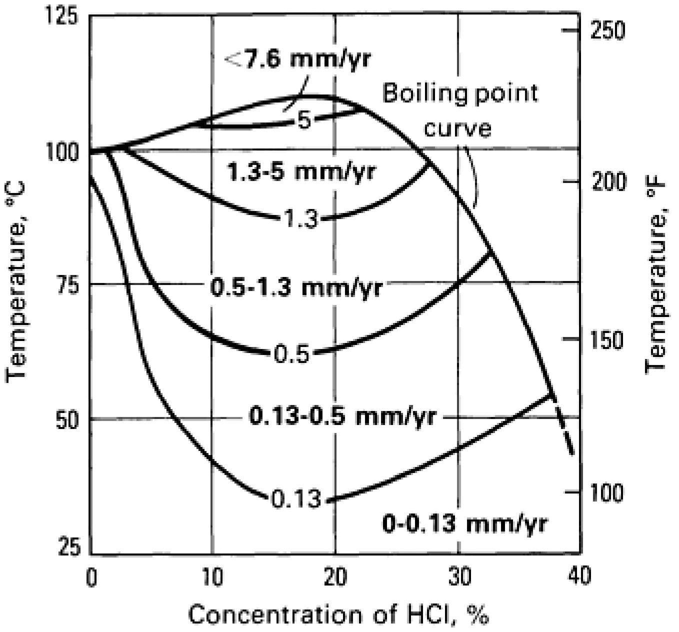

Fig. 66 Isocorrosion diagram for Hastelloy C-276 in HCl

Copper and copper alloys have limited utility in HCl service because they are so sensitive to velocity, aeration, and oxidizing impurities. However, copper is one of the few common metals above hydrogen in the electromotive force (emf) series, and under reducing conditions, it can have low corrosion rates. An example is the use of silicon-bronze (CDA C65500) agitators and hardware in the manufacture of $ZnCl_2$ by dissolving zinc in HCl (Ref 107), with the evolution of hydrogen.

Typical corrosion rates for silicon-bronze in HCl under nonaerated nonoxidizing conditions are 0.08 to 0.1 mm/yr (3 to 4 mils/yr) in up to 20% acid and 0.5 mm/yr (20 mils/yr) in concentrated acid at 25 °C (75 °F). At 70 °C (160 °F), rates are approximately 1 mm/yr (40 mils/yr) in up to 20% acid and over 6.4 mm/yr (250 mils/yr) in concentrated (35 to 37%) acid.

Corrosion-Resistant Cast Iron. A high-silicon iron alloyed with small amounts of molybdenum, chromium, and copper has good resistance to all concentrations of HCl to temperatures as high as 95 °C (200 °F). It is one of the few metals commonly used for pumps and valves in handling commercial grades of acid (Ref 106). Fluoride impurities are damaging.

Zirconium. The corrosion resistance of zirconium to HCl exceeds that of most metals, except tantalum and such noble metals as gold and platinum. Aeration does not have an appreciable effect. Corrosion rates are less than 0.13 mm/yr (5 mils/yr) at all concentrations to the atmospheric boiling point and above (Ref 109). However, chlorine and relatively small amounts of Cu^{2+} and Fe^{3+} ions accelerate corrosion and can cause pitting and embrittlement. Figure 67 shows an isocorrosion diagram of zirconium in HCl.

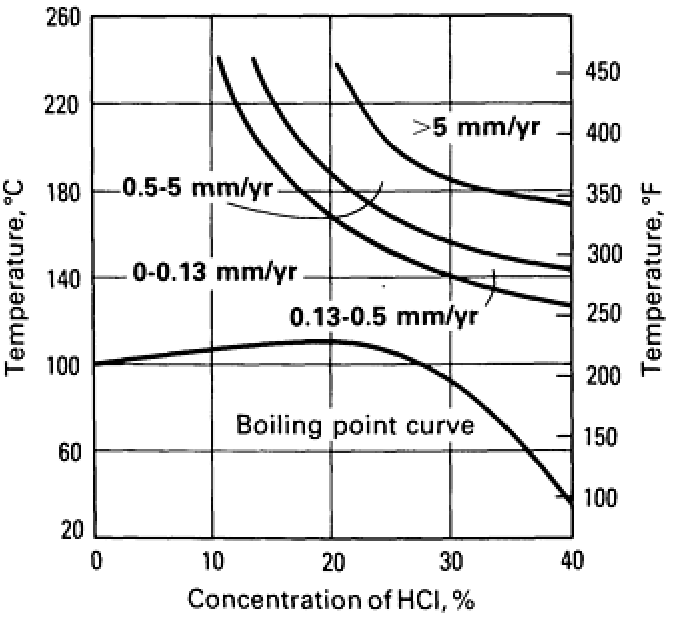

Fig. 67 Isocorrosion diagram for zirconium in HCl solutions. Source: Ref 109

It is important to avoid galvanic effects when connecting zirconium to other metals immersed in an electrolyte, because zirconium, like all the reactive metals, is sensitive to hydrogen embrittlement when it is the cathode of an electrochemical cell. Applications of zirconium equipment in HCl include pumps, valves, piping, and heat exchangers (Ref 109).

Titanium and Titanium Alloys. Although titanium has limited resistance to HCl, it is, unlike other metals, passivated rather than corroded by the presence of dissolved oxygen, Fe^{3+} and Cu^{2+} ions, nitrates, chromates, chlorine, and other oxidizing impurities (Ref 105). In commercial applications involving hot, dilute acid, enough impurities are often present to provide a high degree of protection. For example, the corrosion rate of unalloyed titanium in boiling 4% HCl was lowered from 21.4 mm/yr (843 mils/yr) to 0.01 mm/yr (0.4 mils/yr) by the addition of 0.2% $FeCl_3$ (Ref 105).

An isocorrosion diagram for unalloyed titanium and two titanium alloys is shown in Fig. 68. No titanium alloy has resistance to concentrated grades of HCl.

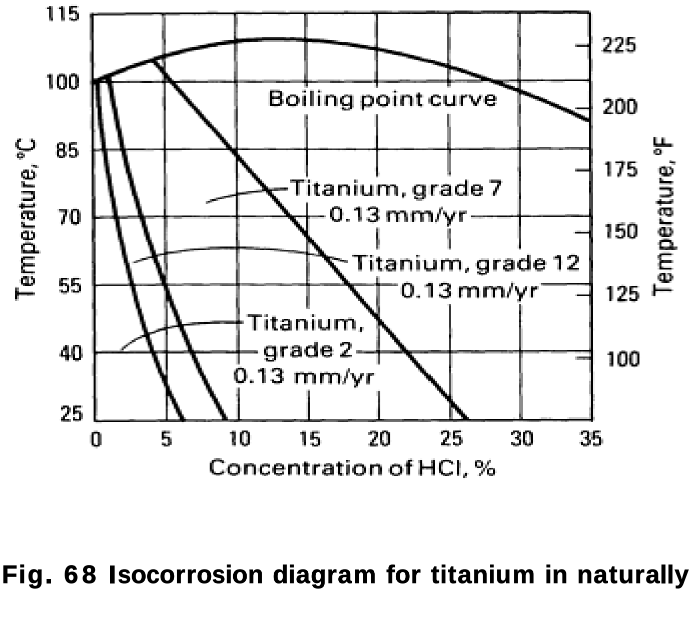

Fig. 68 Isocorrosion diagram for titanium in naturally aerated HCl solutions. Source: Ref 104

Tantalum and its alloys are the most resistant to HCl. Tantalum resists concentrations below 25% up to 190 °C (375 °F) and concentrations to 37% at temperatures to 150 °C (300 °F) (Ref 110). It was found that tantalum is embrittled by concentrations of 25% or higher at 190 °C (375 °F) (Ref 110). Corrosion rates at that temperature were less than 0.025 mm/yr (<1 mil/yr) at 25% concentration or less, 0.01 mm/yr (3.9 mils/yr) at 30%, and 0.29 mm/yr (11.6 mils/yr) at 37%. Embrittlement was most pronounced in 37% acid. It also was found that corrosion and embrittlement could be avoided by coupling tantalum with platinum. This discovery formed the basis for the later development of the titanium-palladium alloy.

Tantalum, like zirconium and titanium, is embrittled by the absorption of atomic hydrogen. This occurs if the metal is corroded in a nonoxidizing chemical or if it becomes the cathode of an electrolytic cell. For example, it is possible to embrittle tantalum plugs in a glass-lined vessel, if the vessel is equipped with an agitator of a metal lower in the emf series.

Noble Metals. Silver forms a protective chloride film in HCl and is resistant as long as the film is not dissolved or disturbed. At ambient temperatures, in the absence of oxidizing agents, silver resists all concentrations, with a corrosion rate of less than 0.025 mm/yr (<1 mil/yr) at concentrations of 20% or lower. At the boiling point, corrosion rates vary from 0.025 mm/yr (1 mil/yr) at 5% to 0.5 mm/yr (20 mils/yr) at 20%. Increasing the temperatures, aeration, and velocities will increase corrosion rates (Ref 106).

Refined gold is extremely resistant to all concentrations of HCl to and above the atmospheric boiling point. Oxidizing agents such as $FeCl_3$ and HNO_3 cause attack (Ref 106).

Refined platinum is almost as resistant as gold. It is slightly attacked by 36% acid at 100 °C (212 °F), the point at which gold shows no appreciable attack (Ref 106).

Nonmetallic Materials

Elastomers used in HCl service include natural rubber, neoprene, and others.

Natural rubber is used to line steel tanks, tank cars, and piping for handling commercial, uncontaminated, concentrated HCl (Ref 100). Natural rubber forms a protective rubber hydro-chloride surface that slows further penetration, and a life expectancy of 20 years at ambient temperature is not uncommon. The lining must be properly compounded for the service, must be of sufficient thickness (a minimum of 6.4 mm, or 0.25 in.), and must be properly applied and inspected. Soft rubber linings are recommended to 40 to 45 °C (100 to 110 °F), depending on the manufacturer (Ref 111, 112). A three-ply construction (soft-hard-soft) is often used to take advantage of the impermeability of the harder rubber and the resistance to damage, thermal shock, and abrasion of the soft rubber. Three-ply construction is recommended to temperatures of 55 °C (130 °F) (Ref 111). For higher temperatures, semihard rubber is recommended to 70 °C (150 °F), and hard rubber or flexible ebonite to a maximum temperature of 95 °C (200 °F) (Ref 113). The latter must be protected against exposure to sunlight and thermal and mechanical shock.

Natural rubber is severely affected by many organic contaminants, some of which may be present in by-product acid. Because the effect is cumulative, even trace amounts will eventually cause failure.

Neoprene. Although relatively unaffected by ambient-temperature HCl, neoprene is not recommended for linings, because of its permeability to concentrated acid (Ref 111, 112).

Other Elastomers. A number of elastomers have resistance to HCl that is as good as or better than that of rubber, but they are seldom used as linings for this service because of economics and difficulty of application. However, they should be considered for exposure to sunlight, organics, higher temperatures, or flexing (the hard rubber hydrochloride surface cracks when flexed). These include butyl rubber, nitrite butyl rubber (NBR), ethylene propylene diene monomer (EPDM), and chlorosulfonated polyethylene elastomer (Ref 113, 114). Fluoroelastomers have good resistance to hot acid, but because of high cost, are limited to small parts, such as gaskets and O-rings.

Thermoplastics. A large number of thermoplastics are suitable for handling all concentrations of HCl. Some of the most commercially important are described below.

Polypropylene. Polypropylene-lined steel pipe has largely replaced rubber-lined pipe for commercial HCl service, primarily because of economics and ease of field fit-up. Lined pipe is recommended for all concentrations of HCl to

temperatures of 110 °C (225 °F) (Ref 115). Polyproplyene is also available in small-to-moderate size tanks and various molded shapes.

Polyethylene is unaffected by ambient-temperature acid, but its lack of stiffness, high thermal coefficient of expansion, and rapid falloff of strength with increasing temperature limit its use to underground or continuously supported pipelines. High-density cross-linked polyethylene is stronger and stiffer and is available in tanks up to 3785 L (1000 gal).

Polyvinyl Chloride. Both plasticized and unplasticized PVC have good resistance to HCl at ambient temperature. Unplasticized PVC piping systems are practical for complex systems that can be properly supported.

Polyvinylidine chloride has been used for many years as a lining for HCl pipelines. It is recommended for all concentrations to 80 °C (175 °F) (Ref 115). It has better resistance than rubber or polypropylene to certain hydrocarbons that may be present in process streams.

Polyvinylidine Fluoride. Pipe lined with PVDF is recommended for all concentrations of HCl to 135 °C (275 °F) (Ref 115). Polyvinylidine fluoride is also available in lined valves and pumps. It resists a wide variety of other chemicals and solvents that may be present in process streams or in recovered acid. Linings, frequently reinforced with graphite, glasscloth, or veil, have been applied with multiple thermally fused layers with varying degrees of success. Each case should be approached with caution.

Fluoroplastics. In addition to PVDF, a number of other fluorocarbon plastics resist all concentrations of HCl at temperatures as high as 260 °C (500 °F) (Ref 115). The fully fluorinated PTFE and PFA have the highest temperature resistance and are the most expensive. Fluorinated ethylene propylene is limited to about 200 °C (400 °F), but is more easily molded than PTFE. Ethylene-chlorotrifluoroethylene and ETFE are limited to 150 °C (300 °F), but have superior abrasion and permeability resistance (Ref 116). Most fluoro-plastics are available as lined pipe, valves, and pumps (Ref 116).

Other Thermoplastics. Other plastics, such as acrylonitrile-butadiene-styrene (ABS), polysulfone, polyphenylene sulfide, and polyphenylsulfone, are resistant to HCl. Nonresistant thermoplastics include such polyimides as nylon and methacrylates.

Reinforced thermoset plastics for HCl service include polyester, epoxy, phenolic, and furan resins.

Polyester Resins. There have been a number of failures of glass-reinforced polyester resin storage tanks in concentrated HCl service. A life expectancy of 5 to 10 years has been reported (Ref 117). However, there are custom-built glass-reinforced plastic storage tanks that have given satisfactory service in concentrated HCl for 10 to 20 years and longer (Ref 107).

Standard, filament wound storage tanks are not suitable for concentrated acid. Vessels should be fabricated in accordance with the standards detailed in Ref 118. The inner resin-rich layer should be thicker than 0.8 mm ($\frac{1}{32}$ in.) with two layers of veil (Ref 107). Bubbles and porosity are not acceptable, because they will cause blistering, which will lead to degradation. The novalac epoxy vinyl-ester resins resist blistering better than other resins, although none are recommended for storage of concentrated acid (Ref 117).

In Europe, glass-reinforced plastic tanks for storing concentrated acid are frequently lined with PVC sheet. The novalac resins have superior resistance to some chlorinated hydrocarbons (Ref 119). Custom-built storage tanks using this resin have been in service for over 10 years in concentrated acid containing CCl_4 in excess of solubility (Ref 107). Pumps and piping systems of polyester glass-reinforced plastic are also used for moving concentrated acid.

The epoxy resins are generally less resistant to HCl than the resistant grades of polyesters. Manufacturers of glass-reinforced plastic pipe limit recommendations for their epoxy pipe to concentrations of 10 or 20% at ambient temperatures, while the polyester pipe is recommended for all concentrations at higher than ambient temperatures. Recommendations by a leading manufacture are given in Table 18. It should be noted, however, that a noted pump manufacture makes a silica-filled epoxy pump that is widely used for pumping concentrated HCl.

Table 18 Recommended maximum temperature limits for fiberglass-reinforced plastic piping in HCl

Acid concentration, wt%	Maximum recommended temperature

36.5 (conc)	NR		66	150[(a)]

NR, Not recommended.

Source: Ref 120

(a) Maximum temperature tested; could be suitable at higher temperature.

Phenolic Resins. Vessels, ducts, and piping systems fabricated of suitably filled phenolic resins will resist all concentrations of acid to temperatures as high as 175 to 200 °C (350 to 390 °F) (Ref 121). The phenolics are also resistant to many solvents. Because phenolic resins are weak in tension, equipment and pipe are often armored with epoxy-impregnated glass cloth or are filament wound. Piping systems must be carefully designed and installed with adequate support to minimize tensile stresses. Phenolic resins are often used as cements for brick linings.

Furan resins are also used to construct vessel duct and piping systems that are resistant to all concentrations of wet HCl (Ref 121). The solvent and alkali resistance of furan resins exceeds that of phenolics, and they are easier to handle during fabrication. Thus, furan glass-reinforced plastic vessels are available, and furan-glass membranes are used in brick-lined equipment. Temperature resistance is somewhat lower than that of the phenolics. Furans are the most common of the plastic cements used for brick linings.

Other nonmetallic materials for HCl service include impervious graphite, carbon, glass, glass-lined steel, and wood.

Impervious graphite is the most commonly used material of construction for HCl absorption and refining equipment. Resin-impregnated graphite equipment resists all concentrations of HCl to temperatures of 165 to 185 °C (330 to 365 °F), depending on impregnating resin and manufacturer. Polytetrafluoroethylene-impregnated graphite is reported to be resistant to a maximum temperature of 230 °C (450 °F) (Ref 122). By using graphite impregnated with pure carbon, it is possible to increase the maximum-use temperature in air to 400 °C (750 °F) (Ref 122). Graphite has excellent thermal conductivity and chemical resistance (except to strong oxidants and concentrated H_2SO_4). However, it is extremely weak in tension and is seldom used for piping. Heat exchangers are available in block and crossbore construction to obtain more rugged units than shell and tube designs.

Carbon has poor heat transfer but excellent abrasion resistance. It is available as bricks for brick-lined construction. Like graphite, carbon resists all concentrations of HCl to 400 °C (750 °F) in air.

Glass. Complete small chemical plants are available in glassware. Piping systems can be obtained armored with glass fabric. Piping systems must be properly supported, because tensile stresses can result in delayed fracture.

Glass-Lined Steel. The corrosion resistance of a proprietary glass lining in HCl is shown in Fig. 69. The minimum thickness of high voltage tested glass linings is about 1 mm (40 mils). The calculated life expectancy may occasionally be somewhat greater than actual experience because of localized chains of bubbles. However, these data provide a reasonably realistic design basis.

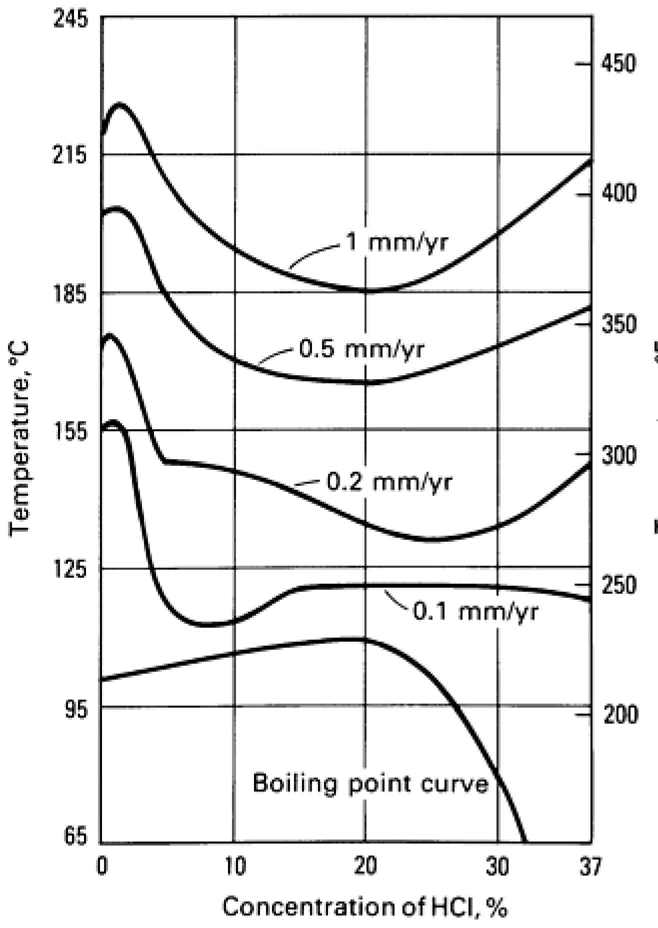

Fig. 69 Isocorrosion diagram for Glasteel 5000 in HCl. Source: Ref 123

Wood is an economical material for handling dilute acids. Tanks and large-diameter piping cost appreciably less than rubber-lined steel or thermosetting plastic construction. Although unsuitable for concentrated HCl, wood has excellent resistance up to 10% concentration. The National Wood Tank Institute (NWTI) recommends wood in 2% HCl to temperatures of 60 °C (140 °F) and 10% HCl to 70 °C (160 °F) (Ref 124). Cypress and fir were unaffected after 31 days of exposure in both 5 and 10% acid at room temperature and showed slight fiber disintegration and slight embrittlement and softening after 8 h in boiling 10% HCl (Ref 125).

Hydrogen Chloride Gas

The recommended upper temperature limits for various metals in HCl gas are shown in Table 19. These guidelines were developed from short-term tests. Because corrosion rates generally decrease with time as films and scales form, these limits have proved to be conservative. Temperature versus design corrosion rates for steel and several alloys are shown in Fig. 70.

Table 19 Suggested upper temperature limits for continuous service in dry HCl gas

Material	Temperature	
	°C	°F
Platinum	1200	2190

Source: Ref 126

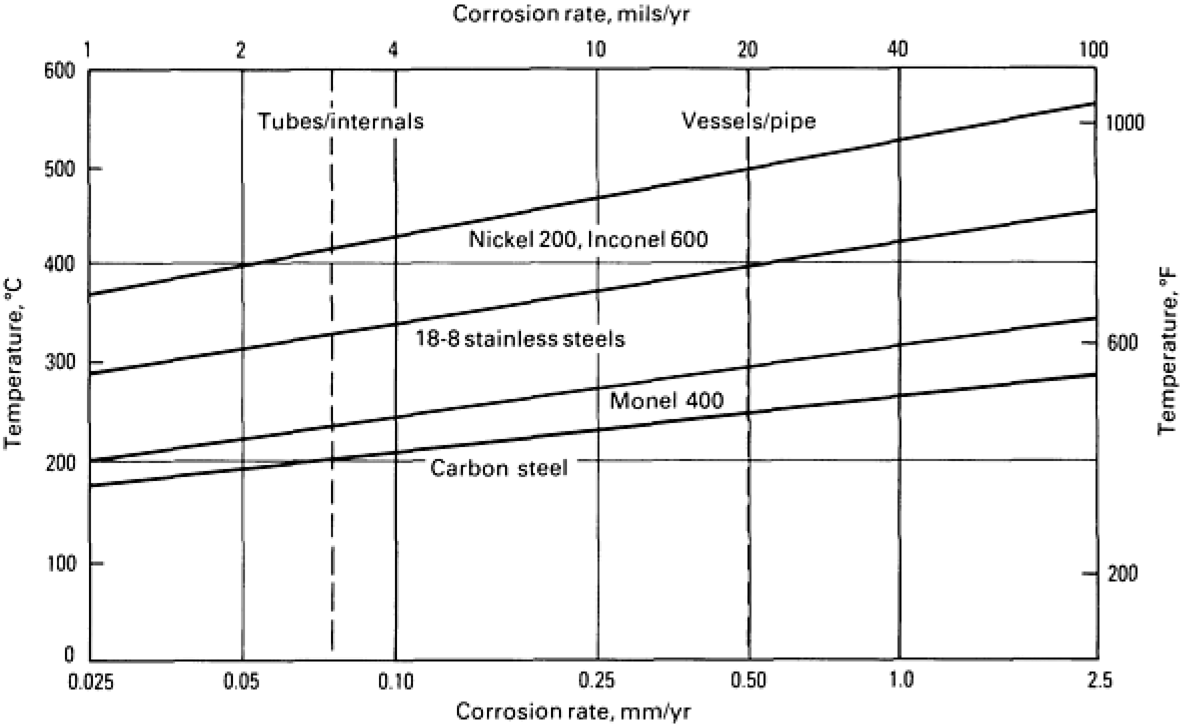

Fig. 70 Maximum temperature limits for various alloys in HCl service. Source: Ref 127

The addition of water vapor to HCl gas has little effect on upper temperature limits. The addition of 0.2% water vapor by weight has been found to have no effect (Ref 126). However, water vapor has a severe effect at lower temperatures.

In a recent study (Ref 128), the suggested lower limit for carbon steel in a 60% H_2O, 40% HCl environment was 200 °C (390 °F) or slightly lower. The lower temperature limits for nickel alloys were 115 °C (240 °F) for Hastelloy C-276, 140 °C (285 °F) for Inconel 625, and 260 °C (500 °F) for Nickel 200, Hastelloy B-2, and Inconel 600. Grade 7 (0.2% Pd) titanium had satisfactory resistance up to 120 °C (250 °F). None of the materials tested, including Nickel 200, titanium, zirconium, and cobalt-base alloys, was suitable at or slightly below the dew point. Minimum temperatures for metals ranged from 30 to 100 °C (85 to 210 °F) above the dew point, depending on the hygroscopicity of the corrosion products.

Corrosion by Hydrogen Fluoride and Hydrofluoric Acid

Thomas F. Degnan, Consultant

Anhydrous hydrogen fluoride (AHF) and aqueous HF are of great industrial importance. Anhydrous hydrogen fluoride is the foundation of the multibillion dollar fluorocarbon industry, which encompasses essentially all refrigerants, a fire-extinguishing agent, ultrasonic cleaning fluids, fluorocarbon plastics, and fluorocarbon elastomers. A popular process for alkylation of petroleum to enhance yields of gasoline depends on the use of AHF. Aqueous HF is used in large quantities to pickle stainless steels, to acid treat wells, and to etch glass.

Aqueous HF and AHF are hazardous chemicals. Fluoride salts, although added to potable waters to prevent tooth decay, are toxic in higher concentrations. Painful, persistent burns result from contact with aqueous HF or AHF, and inhalation of high concentrations of the vapors causes lung damage. The Occupational Safety and Health Administration has ruled that an employee's exposure to HF vapor in any 8-h work shift of a 40-h work week shall not exceed a time-weighted average of 3 ppm HF vapor by volume (Ref 129).

Essential information for the safe handling and use of HF is provided in Ref 130. Recommended respiratory protection guidelines are given in Ref 129. The latest product bulletins issued by the manufacturers contain current information.

Anhydrous hydrogen fluoride is manufactured by the reaction of H_2SO_4 and calcium fluoride (CaF_2) in horizontal kilnlike reactors, usually constructed of steel with a high-nickel alloy liner at the feed and discharge ends. The popular Buch process premixes the CaF_2 and H_2SO_4 in a high-nickel alloy mixer that reduces corrosion of the steel reactor. The reaction is endothermic and therefore requires a source of heat.

Information on suitable materials of construction for handling HF of various strengths and at various temperatures is given in Ref 131 and in the manufacturer's literature. However, many factors can influence the performance of these materials that are not shown in charts, and adequate experience or testing under the proposed conditions is necessary to avoid serious corrosion problems. The duration of the test is important because most metals form protective films or scales that decrease initially high rates to the low rates found in commercial use (Ref 132). Therefore, the validity of short-term rates should be discounted unless the validity of the short-term test has been confirmed by longer tests.

Table 20 lists data on the corrosion resistance of various metals in liquid AHF and AHF-hydrocarbon mixtures at temperatures of 15 to 90 °C (60 to 190 °F). Data on the corrosion resistance of various metals in selected concentrations of aqueous HF are shown in Tables 21 and 22.

Carbon and Low-Alloy Steels

Carbon steels have useful corrosion resistance from 64 to 100% HF. Resistance to aqueous acid is limited to ambient temperatures. Liquid AHF is commonly handled in carbon steel at temperatures to 65 °C (150 °F). Gaseous AHF is less corrosive and can be handled at temperatures to 300 °C (570 °F). Figure 71 shows a graph of corrosion rate versus temperature for liquid and gaseous AHF.

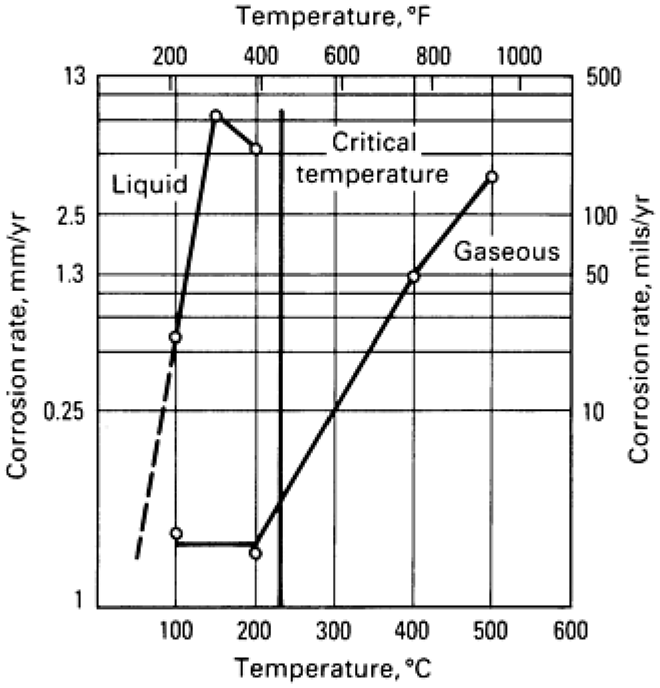

Fig. 71 Corrosion of steel in liquid and gaseous AHF. Source: Ref 135

Although Interstate Commerce Commission (ICC) regulations permitted transportation of aqueous HF of 60% or greater concentration in steel containers that were passivated with 58% acid, one study found that even passivated drums developed excessive hydrogen pressure from corrosion with 60% acid (Ref 136). The results of this testing, shown in Table 23, indicate that the minimum concentration should be 64%. In practice, the closest commercial grade is 70% HF, and the maximum recommended temperature for storage and handling is 30 °C (90 °F).

Source: Ref 136

Steel valves for AHF service often use high-nickel alloy trim. Closely fitting steel parts adhere to each other as a result of the nature of the corrosion products.

Alloy steels often have higher corrosion rates than carbon steel. In one case, a section of low-temperature pipe (ASTM A333, grade 9) containingnickel and copper was installed in a carbon steel piping system handling a mixture of organics and AHF at an above-ambient temperature. The section failed by uniform thinning, while the carbon steel fittings on either end were relatively unaffected (Ref 135).

It has been found that dilute acids (1.4 to 1.7 *N* HF, H_2SO_4, perchloric acid ($HClO_4$), and HCl) used for chemically cleaning heat exchangers corroded iron and carbon steel at about equivalent rates but that HF caused exceptionally high corrosion rates on steels containing 1.25 to 18% Cr (ASTM A335 grades and type 430 stainless steels) (Ref 137). Data comparing the corrosion rates in dilute HF, H_2SO_4, and HCl are given in Table 24.

Hydrogen Embrittlement and Blistering of Steels. Both HF and AHF cause hydrogen embrittlement of hardened carbon and alloy steels as well as hydrogen blistering and stepwise cracking of plate and pipelines.

When nonoxidizing acids, including HF, corrode steel, atomic hydrogen is formed. The atomic hydrogen may either combine to form gaseous molecular hydrogen or may be absorbed into the steel. Sulfides and arsenic, present in small quantities in HF, inhibit, or poison, the formation of molecular hydrogen and thus promote the entry of atomic hydrogen into the steel, where it may recombine at inclusion sites or laminations to form blisters or may migrate to dislocations in hardened steel to cause hydrogen embrittlement. Even purified (electronic) grade HF, however, exhibits similar but diminished hydrogen effects, as do other nonoxidizing acids to a lesser degree.

Hydrogen sulfide is the best known and most potent causative agent for hydrogen blistering and embrittlement; suitable materials and hardness levels to prevent embrittlement are covered in NACE standard MR-01-75 (Ref 138). Hydrofluoric acid is the second most potent agent for hydrogen blistering and embrittlement, with the added problem that some nickel-copper alloys, notably Monel 400 and Monel K500, acceptable in sulfide service, can fail by SCC in HF (Ref 139, 140).

To prevent hydrogen embrittlement in welded structures, the requirements of NACE Standard RP-04-72 should be followed (Ref 141). Contrary to a comment in the standard, shielded metal are welds have cracked, and welds produced by all welding methods should be hardness tested. As pointed out in the standard, stress-relief heat treatment, although desirable, will not necessarily reduce hardness, particularly that of high-manganese welds, and does not avoid the necessity for testing. Techniques such as the uphill welding of vertical seams and the use of temper beads are useful in controlling weld hardness. The hardness of the HAZ can be reduced by using pre- and postweld heating and lower carbon parent metal. Alloy steels and carbon steels with tensile strengths exceeding 483 MPa (70 ksi) should be avoided in welded structures.

Alloy steel fasteners have been a source of many failures in AHF service, particularly the use of ASTM A193, grade B7, a chromium-molybdenum steel. When a high-strength fastener must be used, grade B7M, the same steel tempered to a lower hardness of 201 to 235 HB, is a better choice. However, these bolts will crack if stressed beyond their yield point in an HF environment, and the hardness range has been a difficult one for manufacturers to meet and still comply with the minimum tensile requirements.

Hydrogen blistering and stepwise cracking of steel plates have been troublesome with HF as well as with sulfides in sour crudes (Ref 132, 133, 142). Figure 72 shows a photograph of the cross section of a blistered plate from an AHF storage sphere.

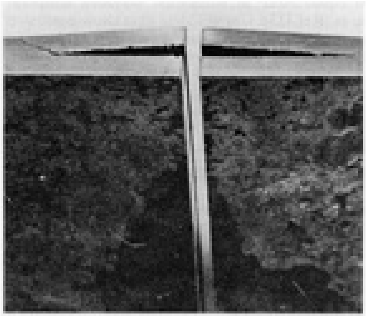

Fig. 72 Blister section from a sphere plate that was in HF service. Source: Ref 142

One study reported that blistering occurred in a semikilled steel containing many inclusions, but not in a cleaner fully killed steel. On the other hand, another researcher found no blistering in 43 semikilled ASTM A285, grade C, plates, nor in 54 fully silicon killed (ASTM A515, grade 70) plates in AHF tank cars and storage spheres. However, blistering was found in 55 of 442 plates of aluminum-silicon killed ASTM A516, grade 70, steel. Fine-grain practice (killed) steels are often preferred for ambient and lower-temperature service because their improved notch toughness, particularly when normalized or quenched and tempered, minimizes the possibility of brittle fracture.

Blistering occurs more readily in fine-grain practice steels because the added aluminum forms clusters of Al_2O_3 particles that segregate in the center of the plate and form sites for hydrogen accumulation. Type II manganese sulfide inclusions, which predominate in killed steels, flatten out and also serve as sites for hydrogen accumulation.

A promising solution to the problem of obtaining a clean steel with good notch toughness at a reasonable cost has been the availability in recent years of low-sulfur (0.005 to 0.010% maximum) steels with inclusion shape control. These steels are vacuum poured and then treated in the ladle with calcium or a rare earth, which removes the Al_2O_3 particles as calcium aluminate and spheroidizes the manganese sulfide particles. These steels were developed to prevent laminar tearing during welding by improving transverse strength and ductility.

Austenitic Stainless Steels

Austenitic stainless steels have good resistance to liquid AHF at somewhat elevated temperatures (Ref 133). Unpublished data show corrosion rates of less than 0.13 mm/yr (<5 mils/yr) for type 304 stainless steel at 100 °C (210 °F), but high corrosion rates at 150 °C (300 °F) (Ref 135). Type 304 stainless steel has good resistance to AHF gas to 200 °C (390 °F). Cast ACI CF-8M stainless steel is used for AHF pumps. However, both type 304 stainless steel and carbon steel have been known to fail by direct impingement of AHF steams.

Austenitic stainless steels have limited resistance to dilute HF. Type 304 stainless steel has poor resistance to any significant concentration, but type 316 has useful resistance at ambient temperatures and concentrations below 10%.

Cold-worked type 303 stainless steel failed rapidly when used as a fastener material in an HF plant. Cold-worked type 304 stainless steel fasteners (ASTM A193, grade B8, class 2) had few failures. The failed fasteners were strongly magnetic. It is believed that α-martensite is the susceptible phase. Alpha-martensite is formed when such alloys as type 301, type 303, and, to a lesser extent, type 304 stainless steels are cold worked. Figure 73 shows the effect of cold work on the magnetic permeability of common austenitic stainless steels. Type 316 is metallurgically stable, and type 304 only marginally, so.

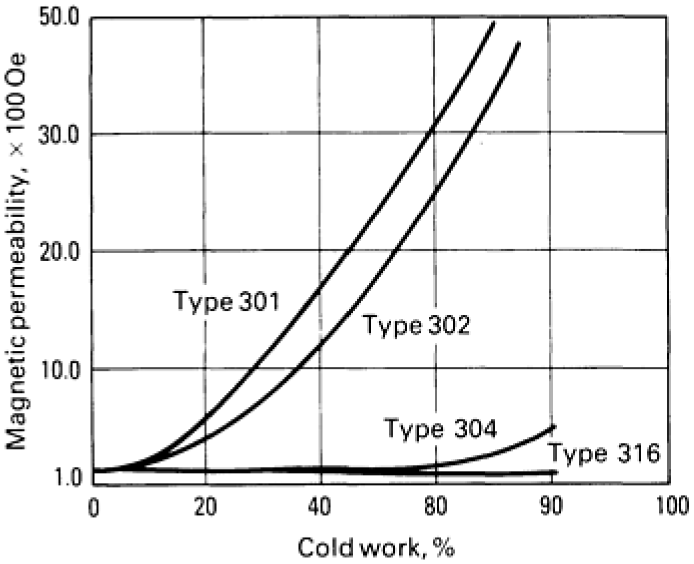

Fig. 73 Effect of cold work on the magnetic permeability of austenitic stainless steels.

Annealed austenitic stainless steels are resistant but not immune to SCC by HF. In one study, types 304 and 316 both failed from transgranular cracking in impure 12% HF at 70 °C (160 °F); type 304 failed in hot 40 to 50% HF (Ref 133). However, these conditions are more severe than are reasonable for the use of stainless steels in HF. This study also reported that cold-worked 18-8 stainless steel did not suffer SCC in a 7-day test in AHF at 70 °C (150 °F). Another study showed that the threshold Cl^- ion concentration necessary to cause intergranular SCC of sensitized type 304 stainless steel was greatly reduced by the presence of fluorides (Ref 143).

High-Alloy Stainless Steels and Superalloys

Higher alloys such as 20Cb-3 stainless steel and Incoloy 825 have good resistance to all concentrations of HF at ambient temperatures and to 0 to 10% concentrations at 70 °C (160 °F) (Ref 131). Corrosion data are shown in Table 25. The preferred material for pumps and valves for 70% HF at ambient temperatures and for valve trim for AHF is ACI CN-7M casting alloy.

Nickel and Nickel Alloys

Nickel 200 is less resistant than Monel 400 to aqueous HF. Also, oxygen has a greater accelerating effect on corrosion of Nickel 200. In aqueous HF, use of Nickel 200 is limited to completely air-free systems below 80 °C (175 °F). Although there are reports of SCC of Nickel 200 in aqueous HF, they appear to be related to such impurities as cupric fluoride (CuF_2) (Ref 144). Nickel 200 is one of the most resistant alloys to hot AHF vapor, but it may be embrittled by sulfur compound impurities.

Monel 400 is used extensively in HF alkylation units and in the manufacturer and handling of HF. It has excellent resistance to liquid HF over the entire concentration range in the absence of oxygen to at least 150 °C (300 °F).

Monel 400 is subject to SCC when exposed to wet vapors of HF in the presence of oxygen. Cracking is intergranular. Figure 74 shows a photomicrograph of SCC of a cold-bent Monel 400 instrument tubing that was inadvertently exposed to moist vapors and air during a shutdown. Stress-corrosion cracking of both Monel 400 and Monel K500 in moist vapor phase conditions has been widely reported in the literature (Ref 140).

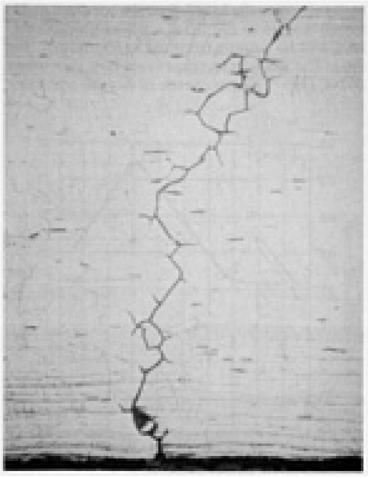

Fig. 74 SCC of a Monel 400 line in HF. 70×. Source: Ref 135

The mechanism of cracking was unknown until it was found that aqueous HF solutions containing appreciable concentrations of cupric chloride ($CuCl_2$) would cause rapid cracking of stressed Monel 400 (Ref 144). As shown in Fig. 75, the least resistant nickel-copper composition corresponds to that of Monel 400 (33% Cu). Copper-nickel alloys with 30% or less nickel are resistant.

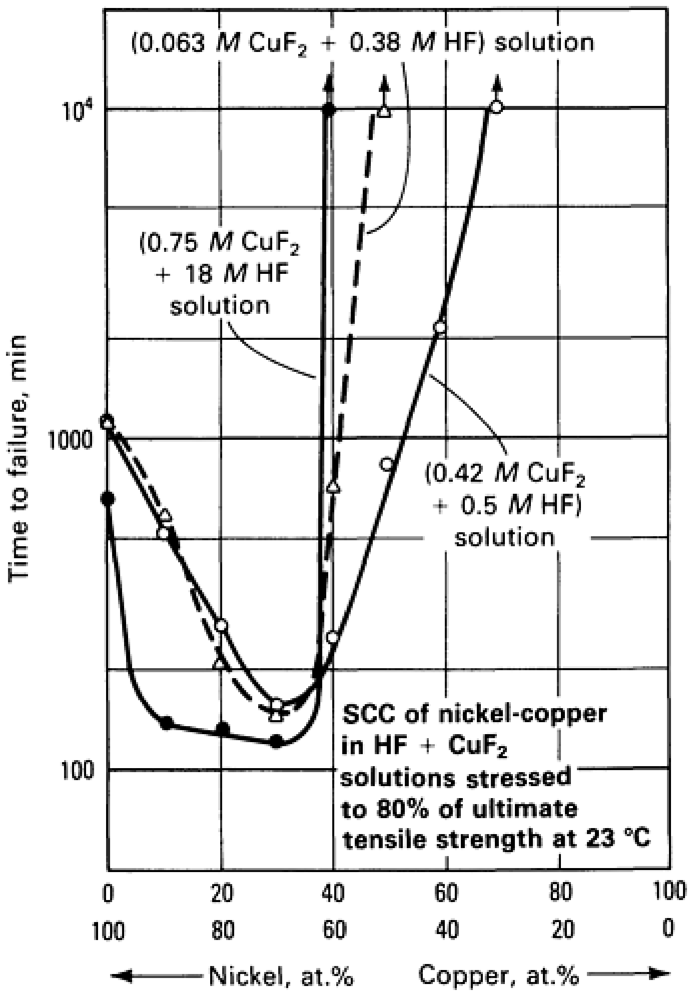

Fig. 75 Time to failure of stressed nickel-copper alloys in HF + CuF_2 solutions. Source: Ref 144

The reason that SCC is usually limited to the vapor phase rather than liquid is the enrichment of a thin layer of aqueous HF in the vapor with copper fluoride corrosion products. The presence of oxygen accelerates corrosion and forms CuF_2 from CuF. The much greater dilution of corrosion products prevents reaching a critical concentration of CuF_2 in the liquid phase.

Recommendations for prevention of SCC include immersion of all parts or purging of the vapor spaces with nitrogen. Thermal stress relief, although beneficial, has not always been successful in preventing SCC. As shown in Fig. 76, SCC can occur at relatively low stress levels.

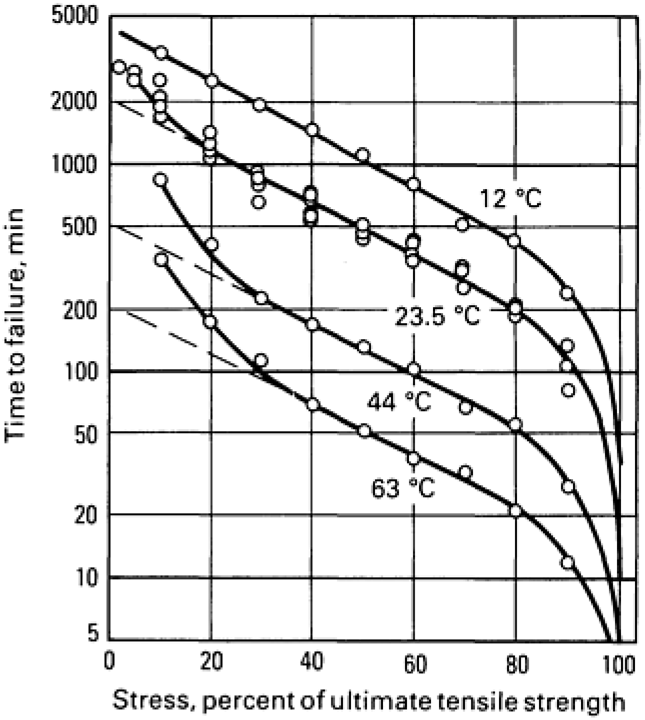

Fig. 76 Effect of stress and temperature on SCC resistance of Monel 400 in HF + CuF_2 solution. Source: Ref 144

Inconel 600 is resistant to dilute aqueous HF at ambient temperatures and to AHF. It has been used in valves and other equipment in place of Monel 400 to avoid possible SCC. It is the most widely used alloy for hot HF vapors, combining excellent chemical resistance and comparatively good metallurgical stability. Figure 77 shows the corrosion rate for Inconel 600 in dilute HF at 75 °C (165 °F).

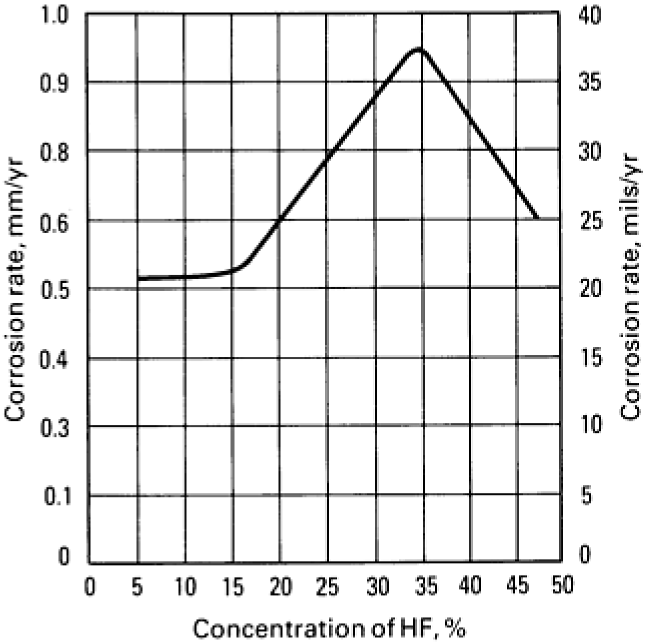

Fig. 77 Corrosion of Inconel 600 in HF at 75 °C (165 °F). Source: Ref 145

High-Performance Nickel Alloys. The Hastelloy alloys (C-276, B-2, G, and G-3) and Inconel 625 all have good-to-excellent resistance to aqueous and anhydrous HF and to high-temperature HF vapors. The presence of air or oxidizing agents can cause fairly high corrosion rates in hot aqueous acids. Table 26 gives corrosion data for the original (now obsolete) compositions of alloys of this type.

In one study, a series of corrosion tests was conducted in the liquid phase of 6.8 *M* (13.6%) HF-1.35 *M* zirconium fluoride (ZrF_4) and in the vapor phase of 6.8 *M* (13.6%) HF at 80 °C (175 °F) using 75-mm (3-in.) test vessels of Inconel 625 and Hastelloy C-4 (Ref 146). Welded, stressed U-bend samples of both materials were exposed. Previous screening tests showed that these alloys were the most promising of a group that included Hastelloy C-276 and G, Inconel 690, and Incoloy 825. Corrosion rates in the HF-ZrF_4 solution at 80 °C (165 °F) were 1.1 mm/yr (44 mils/yr) for Hastelloy C-4 and 2.4 mm/yr (96 mils/yr) for Inconel 625.

After evaluation of the results, Hastelloy C-4 with a carbon content of 0.006% maximum (versus the normal limit of 0.01%) was recommended. This was based on the observation of attack of the HAZs (weld decay) adjacent to a butt weld in the test vessel. Analysis of the vessel wall showed 0.011% C. Welded specimens with 0.001 to 0.006% C showed no such attack, nor did a replacement vessel made of pipe with 0.002% C.

Inconel 625 U-bend samples, which were exposed to the vapor phase, showed severe end grain attack and embrittlement within the first week of exposure, while Hastelloy C-4, although showing appreciable general corrosion, did not.Both alloys showed preferential weld attack. Neither alloy exhibited SCC. It should be noted that these high-performance alloys have good resistance to hot H_2SO_4-HF mixtures and are used in the manufacture of HF.

Other Metals and Alloys

Molybdenum has good resistance to both aqueous and anhydrous HF. The corrosion rates of molybdenum in 25 to 50% HF at 100 °C (210 °F) are 0.4 to 0.5 mm/yr (16 to 20 mils/yr) in aerated acid. Rates in the absence of air are so small as to be negligible (Ref 147).

Precious metals, including gold, silver, and platinum, are all more or less unaffected by AHF or by aqueous HF of any concentration at ambient temperatures and, in most cases, to the boiling point or higher (Ref 148, 149). Silver can be affected by the presence of sulfides and oxygen (Ref 149). Platinum and gold are unaffected at high temperatures.

Magnesium has good resistance to HF because the protective film formed is insoluble in aqueous acid.

Reactive and Refractory Metals. Tantalum, niobium, titanium, and zirconium are all nonresistant to HF and AHF in even trace amounts. Metals and welding products that contain appreciable amounts of these elements will suffer accelerated corrosion by HF under certain circumstances. The presence of several percent niobium in Monel 400 welds has been known to cause preferential weld attack. Titanium additions have been found to be less harmful (Ref 152).

Nonmetallic Materials

The uses and limitations of plastics, elastomers, carbon, and graphic are discussed in Ref 150.

Glass, materials reinforced with glass fibers, and materials rich in silica and silicon are nonresistant to HF.

Plastics. Polyethylene, PP, PVDF, and carbon-filled phenolics are limited to a maximum concentration of about 70% HF. Because the concentration of HF in the vapor phase above 70% HF is enriched, a limit of 60% is conservative. Polyvinyl chloride is limited to about 50% concentration. Silica-filled phenolics should be avoided. Furan resins are inferior to phenolics and may crack.

Butyl and chlorobutyl elastomers are used to line tank cars for 70% HF, but are attacked in the vapor phase of 70% acid at temperatures above 30 °C (90 °F). Chlorosulfonated polyethylene and EPDM elastomers also have useful resistance to aqueous HF at concentrations below 70%. Natural rubber and neoprene are useful up to 50% acid.

It should be noted that the resistance of elastomers to HF is strongly influenced by compounding. Silica and magnesia materials must be avoided. The supplier must be informed of the intended service. Anhydrous HF is resisted by many fluoroelastomers and fluoroplastics, including TFE, FEP, PFA, and monochlorotrifluoroethylene (CTFE).

High-Temperature Gas

A series of short-term corrosion tests was conducted on the rate of attack of hot, gaseous AHF on various metals (Ref 151). Results are shown in Table 27. Nickel 200, Monel 400, and Inconel 600 all have useful resistance to gaseous AHF at temperatures to 600 °C (1110 °F). Austenitic stainless steels are inferior to carbon steel in this regard. Although corrosion rates are exaggerated and distorted by the short 3- to 15-h test periods, other data confirm the general ranking of the materials. More realistic high-temperature data for nickel-containing alloys are shown in Table 28. Although the tests were run for only 36 h, the results agree with experience.

Source: Ref 152

Inconel 600 has been successfully used in the hydrofluorination of metal oxides at temperatures of 370 to 590 °C (700 to 1095 °F). Nickel 200 and the copper-nickel alloys are susceptible to intergranular embrittlement by sulfur compounds at temperatures above about 300 °C (570 °F) (Ref 152). Trace amounts of these compounds are present in commercial AHF. Inconel 600 resists embrittlement and has been successfully used at these temperatures in gaseous HF environments (Ref 152). It should be noted that many nickel alloys, including Hastelloy C-276 and Inconel 625, undergo metallurgical changes, such as aging or long-range ordering at temperatures above 400 to 500 °C (750 to 930 °F). Hardness and susceptibility to hydrogen embrittlement also increase. Inconel 600 is relatively unaffected.

Corrosion by Chlorine

E.L. Liening, The Dow Chemical Company

This Section considers corrosion of metals by dry chlorine in both the liquid and gaseous forms, moist chlorine, and chlorine-water. Materials (including nonmetals) used in chlorine-manufacturing environments are reviewed in Ref 153. Reference 154 is a good source for references on corrosion by chlorine published before 1976.

Dry Chlorine

Dry chlorine is not corrosive to steels, stainless steels, or nickel alloys at ambient temperatures. It is commonly shipped and handled in carbon steel equipment, with higher-alloy materials such as nickel, Monel 400, and Hastelloy C usually used for critical parts. Valves are frequently steel with Monel 400 or Hastelloy C trim and stem. Steel is usable up to about 150 °C (300 °F) and possibly higher under certain conditions. Stainless steels are usable up to about 300 °C (570 °F), and nickel is commonly used up to about 500 °C (930 °F). Inconel 600 or low-carbon nickel is often substituted for nickel at temperatures where graphitization may occur. Moisture will greatly accelerate attack on any of these materials, with the additional danger of SCC of stainless steels.

Iron and Steel. Eight-hour tests showed corrosion rates for steel to be below 0.0025 mm/yr (0.1 mils/yr) at up to 250 °C (475 °F), but ignition occurred at 250 °C (485 °F) (Ref 155). A slightly lower ignition temperature was reported for 16-and 20-h tests (Ref 156). Ignition of steel wool (grade 00) occurred at temperatures as low as 185 °C (365 °F) (Ref 155).

A maximum-use temperature for steel is given in Ref 156 and 157 as 205 °C (400 °F), but the discussion in Ref 157 suggests that a prudent maximum temperature may be nearer 150 °C (300 °) because of exotherms from reaction with grease-contaminated equipment. For grease-free and properly cleaned equipment, however, a maximum-use temperature of 200 °C (390 °F) may be acceptable.

Tests with various irons and steels in flowing chlorine indicated that ignition occurs at lower temperatures for steels with higher alloy contents, especially for carbon (Ref 158, 159). Ignition at temperatures as low as 200 °C (430 °F) was found

for iron containing 0.3% C and 6% other alloy content. This probably accounts for the lower use temperature for cast iron versus steel given in Ref 156. Iron alloys with silicon contents in the 10 to 15% range, however, reportedly resisted attack by dry chlorine (Ref 160, 161), but their poor impact properties limit practical applications in such critical service.

Below 250 °C (450 °F), the presence of oxygen and moisture had little effect on iron chlorination rates (Ref 162). Because iron is attacked less rapidly by hydrogen chloride than chlorine, the presence of hydrogen chloride in dry chlorine should have little effect on iron chlorination rates. In practice, however, the use of steel is avoided where moisture may be present.

The data in Ref 156, presented in Table 29, show corrosion rates and suggested upper temperature limits for use of steel and many other alloys in dry chlorine, based on 2-to 20-h tests. The temperature limits for many of the alloys correspond to higher corrosion rates than might usually be tolerated for expensive alloys. The rates shown, however, are in most cases higher than those that would occur in prolonged exposures. This is because, for most of the alloys, passivation occurs by the formation of a metal chloride film, after which corrosion decreases rapidly. In many cases, corrosion at higher temperatures is roughly proportional to the vapor pressure of the particular metal chlorides formed.

Table 29 Approximate temperatures at which the indicated corrosion rates occur in dry chlorine

Alloy	Temperature for corrosion rate, mm/yr (mils/yr)

(a) Suggested upper temperature limit for continuous service.

Suggested upper design limits for steel and some other alloys in dry chlorine are shown in Fig. 78, based on corrosion rates of approximately 0.08 mm/yr (3 mils/yr) for tubes and internals, and 0.5 mm/yr (20 mils/yr) for vessels and pipes. Similar design guidelines are discussed in Ref 127, 163, and Ref 164.

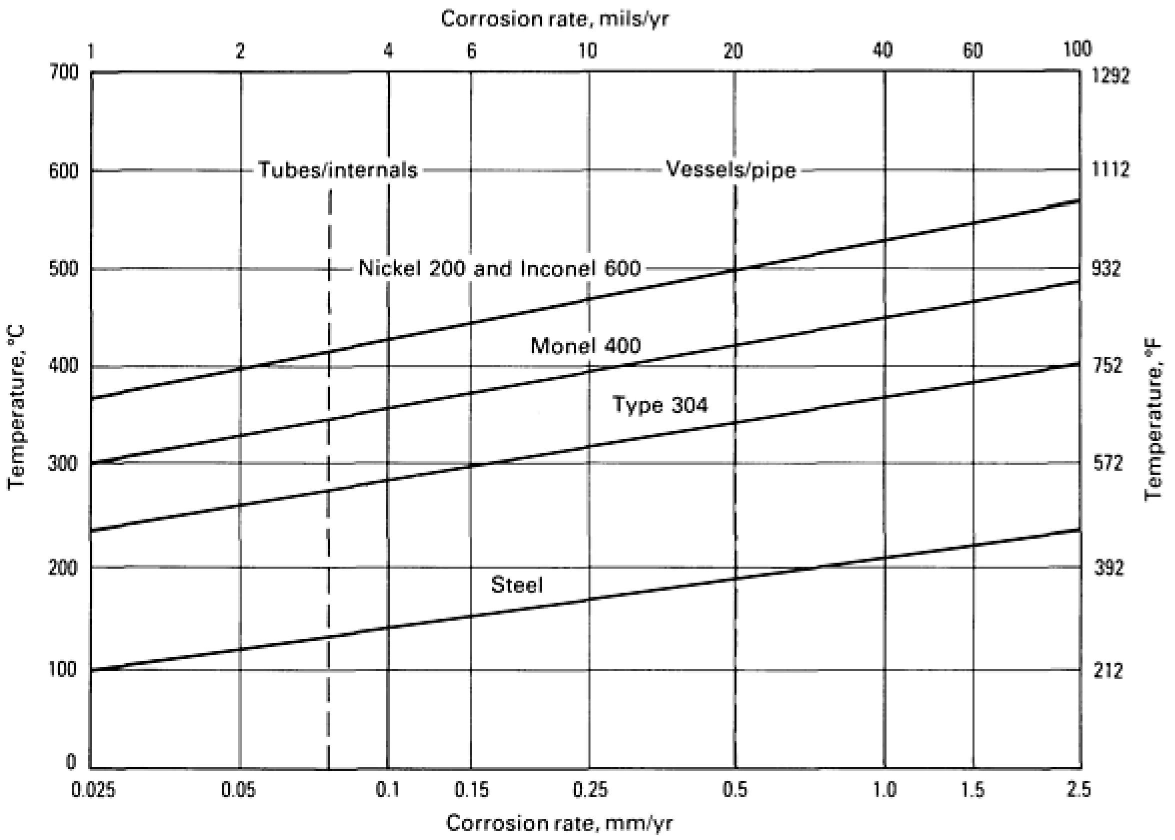

Fig. 78 Design guidelines for use in dry chlorine. Source: Ref 127

Aluminum. Care must be taken when evaluating results for aluminum because the protective aluminum oxide film may delay the onset of corrosion. In one study, there was a 5-h delay before reaction in dry chlorine at 500 °C (930 °F) (Ref 158). Aluminum was reported to be usable up to about 120 °C (250 °F) (Ref 156), and moisture in dry chlorine at room temperature increased attack (Ref 165). This is supported by the work documented in Ref 166 and is attributable to condensation. At higher temperatures (130 to 630 °C, or 265 to 1165 °F), the presence of water was reported to decrease attack on aluminum (Ref 167), as discussed in the section "Moist Chlorine" in this article.

Copper. A maximum-use temperature of 205 ° (400 °F) was suggested for copper in dry chlorine (Ref 156).

Ignition of copper was observed at temperatures as low as 260 to 300 °C (500 to 570 °F) at high velocities (Ref 168). Ignition occurred at 290 to 310 °C (555 to 590 °F) at a velocity of 250 mL/min, and no ignition occurred at 40 mL/min (Ref 162). The same researchers reported that below 200 °C (390 °F) the presence of oxygen and water vapor accelerates attack on copper, while above 250 °C (480 °F) they reduce the rate of attack and move the ignition temperature to near 350 °C (660 °F) (Ref 162, 169).

Stainless Steels. Austenitic stainless steels were shown to be significantly more resistant to dry chlorine than steel, aluminum, or copper (Ref 156, 158). Type 304 and type 316 stainless steels may be used up to 300 °C (570 °F). Moisture was reported to accelerate attack below 370 °C (700 °F) but to exert little effect or even decreased attack above the temperature (Ref 156, 167). The presence of moisture also increases the possibility of SCC.

Nickel and Nickel Alloys. Nickel 200 and nickel-base alloys show excellent resistance to dry chlorine, as indicated in Table 30. The good performance of nickel was supported by data in Ref 171 for tests in chlorine at a pressure of 13.2 kPa (0.13 atm) and in Ref 158 in flowing chlorine. However, the reports indicated higher corrosion rates (2.4 and 2 mm/yr, or 95 and 81 mils/yr) for nickel at 525 to 540 °C (975 to 1000 °F) than the study described in Ref 156. A temperature of 500 °C (930 °F) seems a wise upper limit for routine use of nickel in dry chlorine.

Table 30 Corrosion of cast alloys by water-saturated chlorine gas

Exposure for 6 weeks at room temperature

Alloy	Wrought version	Corrosion rate	
		mm/yr	**mils/yr**
ACI CF-8M	Type 316	0.79	31
ACI CN-7M	. . .	1.04	41
ACI CD-4MCu	Duplex stainless steel	1.24	49
ACI CW-12M	Hastelloy C	0.056	2.2

Water vapor was found to increase attack on nickel below 550 °C (1020 °F), but had little effect above that temperature (Ref 167). Between 425 and 760 °C (795 and 1400 °F), graphitization of Nickel 200 may occur, and a low-carbon version of nickel with a maximum of 0.02% C is normally used. When sulfur compounds are present, Inconel 600 is often substituted for nickel to avoid intergranular attack.

The data given in Table 29 indicate that Inconel 600 and Hastelloy B perform nearly as well as nickel in dry chlorine, and Hastelloy C somewhat less well. Chromel A and Monel 400 perform much better than stainless steels, but not as well as the other alloys mentioned above. Cast ACI alloy CW-12M (Ni-18Cr-18Mo) was reported to corrode in dry chlorine at 0 to 60 °C (32 to 140 °F) at about the same rate as Hastelloy C (Ref 62, 172).

Monel 400 is commonly used as trim on valves, but it should be used with care in refrigerated systems for the reasons discussed in the section "Refrigerated Liquid Chlorine" in this article. Water vapor in chlorine at temperatures below the dew point is corrosive to a wide variety of nickel, nickel-copper, nickel-chromium-iron, and nickel-chromium-molybdenum alloys (Ref 173).

Other Alloys. Limited information on the performance of various other alloys in dry chlorine is also available. Magnesium was found to perform as well as Chromel A, and actually better than Monel 400 (Ref 156). A maximum-use temperature of 455 °C (850 °F) was suggested, but use of magnesium in chlorine is not widespread.

Lead was found to be resistant in dry chlorine up to 275 °C (525 °F) (Ref 174). Average corrosion rates for lead in dry flowing chlorine were reported as 0.06 mm/yr (2.4 mils/yr) at 200 °C (390 °F), 0.13 mm/yr (5.1 mils/yr) at 250 °C (480 °F), 0.14 mm/yr (5.5 mils/yr) at 275 °C (525 °F), 1.5 mm/yr (59 mils/yr) at 295 °C (565 °F), and 2.5 mm/yr (98 mils/yr) at 310 °C (590 °F), (Ref 159, 167).

Unalloyed zirconium corrodes at less than 0.13 mm/yr (5 mils/yr) in dry chlorine near room temperature, but is not resistant in wet chlorine (Ref 62, 172, 175, 176, 177). Reactor grade zirconium tubing was reported to stress corrosion crack in 0.01 mg/cm^3 of chlorine gas at 360 to 400 °C (680 to 750 °F) (Ref 178).

Titanium was found to ignite in dry chlorine at temperatures as low as -18 °C (0 °F) (Ref 62, 172, 179, 180). However, small amounts of moisture in chlorine can passivate titanium (see the section "Moist Chlorine" in this article).

Niobium suffered no attack in dry chlorine up to approximately 200 °C (390 °F) (Ref 181). Tantalum performs well in dry chlorine at up to 250 °C (480 °F) (Ref 182, 183). Attack on tantalum was shown to begin at 250 °C (480 °F), to be violent after 35 min at 450 °C (840 °F), and to be instantaneous at 500 °C (930 °F) (Ref 184). This is consistent with the data given in Ref 167. Pitting of tantalum was reported in a mixture of dry chlorine and anhydrous methanol at 65 °C (150 °F), presumably caused by the presence of halogenated HCOOH contamination (Ref 178).

Refrigerated Liquid Chlorine

Refrigerated liquid chlorine can also be handled in steel, but special care should be taken at potential leak sites, such as at valves and nonwelded fittings. Because the chlorine is refrigerated, pipelines and associated equipment become encased in ice formed from the moisture in the air. Chlorine from even small leaks is then trapped beneath the ice, forming wet

chlorine gas that is corrosive even at low temperatures. Therefore, Alloy 20 materials are often used for valves and other fittings in refrigerated liquid chlorine equipment.

Similarly, ordinarily nonwetted parts, such as bonnet bolts in valves, are typically replaced by more resistant alloys. Nickel-copper alloys, such as Monel 400, have been used, but they are sensitive to oxidizing corrosives. Figure 79 shows an example of corrosion of Monel 400 bonnet bolts. Chlorine had leaked along the valve stem and was trapped beneath the ice, where it became wet and very corrosive. Nickel-chromium-molybdenum alloys, such as Hastelloy C-276, are used in order to avoid this type of attack on critical components such as bonnet bolts.

Fig. 79 Monel 400 bonnet bolt extensively corroded by chlorine gas trapped beneath ice covering a valve in liquid chlorine service

High-Temperature Mixed Gases

Several investigations were conducted on alloys in high-temperature mixed gases of chlorine, oxygen, and argon. Various alloys were tested in an atmosphere of argon, 20% O_2, and 2% Cl_2 at 900 °C (1650 °F) for 8 h (Ref 185). Alloy 214 performed the best, with metal loss of less than 0.025 mm/yr (1 mil/yr). Alloy R-41 was the next best performer, followed by Inconel 601 and 600, type 310 stainless steel, and Inconel 625. Hastelloy S was less resistant than the above group, followed by Incoloy, 800H, Hastelloy X, Hastelloy C-276, and alloy 188. Longer-term tests in a similar environment yielded the following in order of performance: alloys 214, 601, R-41, X, C-276, and 625.

Corrosion in argon-oxygen-chlorine mixtures was investigated on a more basic level (Ref 186). Work was performed in environments containing argon, 20% O_2, and 0.25% Cl_2 at 900 to 1000 °C (1650 to 1830 °F) and in air and 2% Cl_2 at the same temperatures (Ref 187, 188). A report on the corrosion at 260 to 425 °C (500 to 795 °F) of a variety of engineering alloys considered for use in a waste heat recovery system for a chlorinated hydrocarbon incinerator is given in Ref 189.

Moist Chlorine

Many industrial chlorine environments contain substantial water, particularly those in chlorine manufacture prior to the drying operation. Wet chlorine gas is extremely corrosive at temperatures below the dew point because the condensate is a very acidic and oxidizing mixture. One of the most commonly used metals for wet chlorine service is titanium,

especially for wet chlorine compressors. Titanium is perfectly passive if there is enough water in the chlorine, but it ignites if there is not enough. With sufficient water, titanium is resistant up to at least 175 °C (345 °F) and probably higher. Wet chlorine gas can be handled at room temperatures with stainless steels similar to Alloy 20 if condensation is not too great and if corrosion rates up to 1.3 mm/yr (50 mils/yr) are tolerable. Hastelloy C-276 is suitable to somewhat higher temperatures, and niobium or tantalum is required at even higher temperatures.

Nonmetals are frequently used in wet chlorine gas because of its corrosivity to most metals. Reinforced thermosetting plastics are widely used for handling wet chlorine gas, especially the gases coming from chlorine cells. Nonasbestos reinforcement is expected to predominate as asbestos becomes unavailable because of its toxicity. Glass and ceramics are also used, but thermal and mechanical shock problems must be dealt with. Reference 153, a summary of replies to a questionnaire on materials for handling industrial chlorine mixtures, discusses materials used for wet chlorine gases, particularly nonmetals. The materials used in equipment for the production of chlorine are reviewed in Ref 190.

Iron and Steel. The response of iron-base alloys to moisture in chlorine depends on the temperature range and particular class of alloys. At practical-use temperatures, small amounts of moisture and oxygen were reported to have little effect on iron chlorination rates; these contaminants were found to reduce chlorination rates above 300 °C (570 °F) (Ref 158, 169, 191). In practice, steel is generally avoided in any service where chlorine gas may collect water vapor.

Stainless Steels. Moisture has a significant effect on the corrosion of type 304 stainless steel in chlorine, as indicated in Ref 156, which documents tests conducted on type 304 stainless steel in chlorine containing 0.4% H_2O. Rates of approximately 30.5 mm/yr (1200 mils/yr) were found at 40 °C (105 °F), versus an estimated 0.3 mm/yr (12 mils/yr) at 100 °C (210 °F) in dry chlorine. Corrosion in wet chlorine decreased with increasing temperature until about 370 °C (700 °F), at which point the corrosion was about 4.6 mm/yr (180 mils/yr) and the effect of the moisture disappeared. The detrimental effect of moisture at low temperatures is believed to exist for chromium and austenitic stainless steels in general.

Several alloys were tested in water-saturated chlorine gas for 6 weeks at room temperature (Ref 170). The results (Table 30), show substantially higher rates than in dry chlorine. The data support the view that moisture in room-temperature chlorine gas increases corrosion rates on stainless steels, including cast stainless steels.

Aluminum. Aluminum alloy 1100 is more readily attacked by wet than dry chlorine at room temperature, especially if condensation is present. At temperatures above 130 °C (265 °F), however, the presence of moisture greatly reduces corrosion on aluminum. Data from Ref 167 (Table 31) show that larger amounts of water more effectively reduce corrosion on aluminum. Aluminum appears to be usable to 130 °C (265 °F) at 0.06% H_2O, 200 °C (390 °F) at 1.5% H_2O, and 545 °C (1015 °F) at 30% H_2O.

Table 31 Effect of water in chlorine gas on corrosion of aluminum alloy 1100

Temperature		Corrosion rate for amount of water in chlorine, wt %					
		0.06		**1.5**		**30**

Copper and copper alloys were found to suffer accelerated attack in chlorine gas saturated with water vapor (Ref 192). Copper alloys do not have adequate corrosion resistance for practical use in moist chlorine at temperatures above 200 °C (390 °F). Water vapor at room temperature was shown to accelerate attack on copper and copper alloys (Ref 193).

The same effect was reported on copper at temperatures below 200 °C (390 °F) (Ref 162). Above 250 °C (480 °F), however, water vapor and oxygen in chlorine was reported to reduce attack of copper and to move its ignition temperature from about 300 °C (570 °F) to about 350 °C (660 °F) (Ref 162, 169).

Nickel and nickel alloys are adversely affected by the presence of moisture in chlorine at temperatures up to their maximum-use temperatures in dry chlorine. Water vapor at 1.5% was found to double the reaction rate between chlorine and nickel, while 30% H_2O increased the rate from 2 to 20 times (Ref 162, 167). Above 550 °C (1020 °F), moisture was reported to have tittle effect, but the rates at that temperature even in dry chlorine make nickel marginal.

Hastelloy C-276 corrodes 2 to 1000 times faster, and Chlorimet 3 100 to 1000 times faster, in wet chlorine than in dry. Numerous other nickel, nickel-copper, nickel-chromium-iron, and nickel-chromium-molybdenum alloys are also reported to suffer greatly accelerated attack by wet chlorine at such temperatures.

Titanium is well known for its resistance to corrosion by wet chlorine and is widely used in various chlorine-manufacturing equipment, such as compressors that are exposed to wet chlorine. However, a minimum quantity of water is required to maintain the passivity of titanium. The amount of water required at temperatures between 25 and 175 °C (75 and 350 °F) was found to depend on chlorine pressure, temperature, flow rate, purity, and degree of surface abrasion of the titanium (Ref 179). Figure 80 shows a general guideline for water content needed to maintain passivity of commercial-purity titanium in chlorine at temperatures to 105 °C (220 °F).

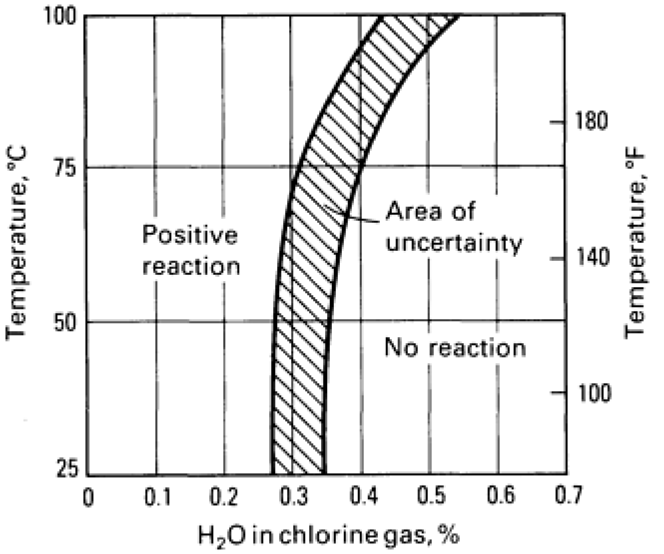

Fig. 80 Estimated water required to passivate unalloyed titanium in chlorine gas. Source: Ref 80

Crude cell chlorine tested under static conditions required about 0.5% H_2O at 125 °C (225 °F) and 1.2% H_2O at 175 °C (350 °F) (Ref 179). Less water was required at flow rates above 0.15 m/s (0.5 ft/s). Pure (99.5%) chlorine requires relatively more water: about 0.93% at room temperature and 1.5% at 200 °C (390 °F) under static conditions.

Other Alloys. Relatively limited information is available for other materials. Unalloyed zirconium was found to corrode in wet chlorine at a rate of 2 mm/yr (80 mils/yr) at 15 °C (60 °F) (Ref 62) and 4.9 mm/yr (192 mils/yr) at 25 °C (75 °F) (Ref 176). It also corroded at over 1.3 mm/yr (50 mils/yr) in room-temperature chlorine containing 0.3% H_2O (Ref 177).

Niobium was found to be resistant to wet chlorine at up to 100 °C (210 °F) and tantalum at up to 150 °C (300 °F) (Ref 161, 183, 194, 195). Tantalum reportedly performed well in chlorine plus 1.5% H_2O at up to 375 °C (705 °F) and in chlorine plus 30% H_2O at up to 400 °C (750 °F) (Ref 184). However, other studies indicated higher rates under these conditions (Ref 167). Another source reported corrosion of tantalum in wet chlorine at temperatures above 350 °C (660 °F), but the amount of water was not specified (Ref 194).

Chlorine-Water

Chlorine dissolved in water forms a mixture of HCl and hypochlorous acid (HClO). The latter is very oxidizing, which makes the mixture extremely corrosive. Relatively little information is available on corrosion in water containing substantial levels of chlorine, especially near saturation. Aluminum was reported to be unsuitable in HClO and to be attacked with extensive pitting in chlorine-water environments (Ref 166). Zirconium was found to corrode at less than 0.025 mm/yr (1 mil/yr) in chlorine-saturated water (Ref 175).

Corrosion of several alloys in chlorine-saturated water at 25 °C (75 °F) was investigated (Ref 170), and the results, presented in Table 32, show that rates are generally low for the chromium-containing alloys tested and for titanium. Only Monel 900 showed a very high rate (24 mm/yr, or 948 mils/yr), which is to be expected because of its sensitivity to oxidants. No large difference in performance between cast alloys and their wrought equivalents was found, except for crevice attack on ACI CF-8M, CN-7M, and CD-4MCu.

Table 32 Corrosion in chlorine-saturated water

Temperature: 25 °C (75 °F)

Alloy	Test duration, days	Corrosion rate	
		mm/yr	**mils/yr**

(a) Crevice corrosion.

Related tests were performed in chlorine ice at -20 °C (-4 °F) (Ref 170). The results, given in Table 33, show that corrosion rates for chromium-containing alloys are below 0.0025 mm/yr (0.1 mils/yr), except for ACI CW-12M at 0.0038 mm/yr (0.15 mils/yr). Higher, but not unacceptable, rates were found for steel, N-12M, and M-35. These alloys are sensitive to oxidants in acidic environments, which explains their poorer performance.

Table 33 Corrosion of alloys in chlorine-ice

147-day tests at -20 °C (-4 °F)

Corrosion by Alkalies and Hypochlorite

James K. Nelson, PPG Industries, Inc.

Caustic soda (NaOH), caustic potash (potassium hydroxide, KOH), and soda ash (Na_2CO_3) are true alkaline chemicals. They will be reviewed in this Section and will provide a basis for general discussion of various alkaline exposures. Technically, hypochlorites are alkaline oxidizing salts, but they exhibit behavior that is much different from alkalies. Some of the topics that will be addressed include:

- Applications for caustic and caustic-containing solutions in which carbon steel provides acceptable service with and without special treatments
- Use of austenitic stainless steels in alkaline solutions, addressing caustic embrittlement and SCC for alkaline chloride solutions
- Decomposition behavior of hypochlorites and its relationship to metallic corrosion and nonmetallic degradation

Sodium Hydroxide

Caustic soda is the most widely used and available alkaline chemical. Most NaOH is produced as a coproduct of chlorine through the use of electrolytic cells; the cells are of the diaphragm, mercury, or membrane type. Some NaOH is marketed as produced in the cells; most is evaporated and sold as 50 and 73% solutions or as anhydrous breads. Most caustic end uses require solutions of relatively low concentrations. The following materials discussions will present information on a spectrum of materials within a wide range of caustic temperatures and concentrations.

A number of reference tables provide resistance data for many metals; these data are included in Tables 34 35, 36, 37, 38, 39, 40, 41. Table 38 relates specifically to corrosivity relationships of diaphragm and mercury cell caustic.

Table 34 Corrosion of metals and alloys in caustic concentrations from 5 to 14%

(a) 75% NaOH concentrated to anhydrous; maximum temperature: 480 °C (900 °F).

(b) 73% NaOH concentrated to anhydrous; maximum temperature: 540 °C (1000 °F). Batch shaded with sulfur and Na_2NO_3; exposure time: 2.5 days.

No discussion of materials of construction for NaOH would be complete without stressing the need to consider safety in every application. Caustic solutions, especially when hot, are extremely damaging to the human body. Exposure can cause immediate and severe burns; eyes are an especially sensitive area. Frequently, the materials selection decisions must account for potential personnel exposure and dictate a more costly but completely reliable material.

Steel and Iron. The possibilities of product contamination or SCC (often called caustic embrittlement) are primary restrictions to the use of iron and steel in caustic service. These problems limit applications, yet low-carbon steel remains the most frequently used material. It is effective in caustic solutions of up to 50% concentration and at temperatures of 90 °C (190 °F).

The addition of OH^- ions to an aqueous medium decreases the corrosion rate of steel as well as that of other metals. Hydroxyl ions in solution decrease corrosion rates by acting as an anodic inhibitor, which increases anodic polarization by helping to form a protective film and keep it repaired. Figure 81 shows an alternative description of this effect. A pH of 12 is obtained by adding about 0.5 g/L NaOH. Benefits are increased by adding even larger quantities of caustic, up to 54% (Table 42).

Table 42 Corrosion of steel in NaOH solutions (22-day laboratory test at room temperature)

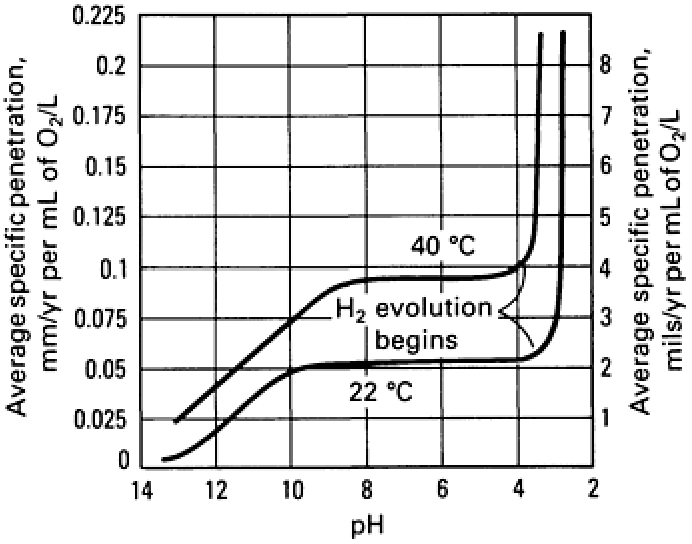

Fig. 81 Effect of pH on corrosion of low-carbon steel in aerated water containing NaOH and HCl. Source: Ref 200

Effective use is made of bare steel tanks storing 50% caustic at temperatures from ambient to 65 °C (150 °F). Iron contamination is frequently a concern because many caustic applications must limit the presence of iron to only a few parts per million.

When tanks are first filled, there is a sharp increase in the iron content of the caustic. If the tank contents remain relatively undisturbed for several weeks, the sampled iron content will decrease to levels of 4 ppm or less. This reduction is attributed to settling of precipitated ferric hydroxide ($Fe(OH)_3$), which then coats the steel with a gelatinous protective film. The preceding reactions would be an initial corrosion of the steel to form ferrous hydroxide ($Fe(OH)_2$), followed by oxidation to the less soluble $Fe(OH)_3$. As the caustic level is lowered, the protective hydroxide film further oxidizes to more voluminous ferric oxide (Fe_2O_3), which may be sloughed off or is redissolved as the tank level is raised.

It is easy to understand why bare steel is not acceptable if a low iron contaminant level is a requirement. In these cases, lined equipment is often used. If iron contamination is not a problem, the next limiting factor is SCC.

This problem has been discussed widely by producers and users debating practical and theoretical application limits. Figure 82 shows two of the more prominent studies on the stress-cracking range.

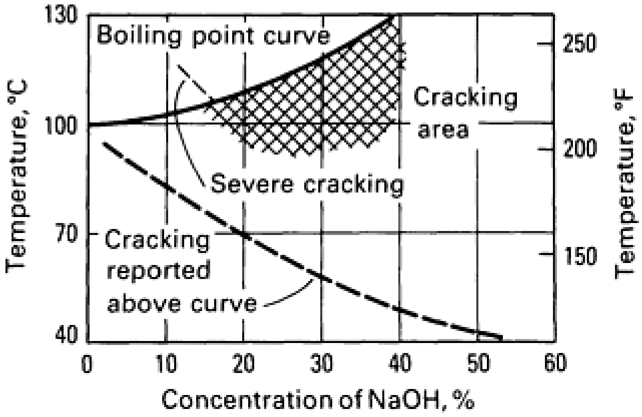

Fig. 82 Temperature and concentration of NaOH required to cause cracking of steel. Source: Ref 202, 203

The upper area, which was developed in the laboratory (Ref 203), showed no cracking below 100 °C (212 °F) over the 62-day stressed coupon test. The lower curve is based on information related to field service (Ref 202). Cracking was reported at temperatures as low as 50 °C (120 °F). In general, field experience is preferred to lab testing; however, in this case, the accuracy and completeness of field information assembled seemed to lead to an overly conservative result. A suggested practical limit is 65 °C (150 °F) at 50% concentration, allowing higher temperatures for dilute, nonconcentrating solutions.

Steel construction is suitable in NaOH concentrations of 10 to 20% at 90 °C (190 °F), where no potential exists for localized solution concentration or severely stressed conditions. Corrosion rates would be in the range of 0.05 to 0.4 mm/yr (2 to 15 mils/yr), depending on agitation, potential concentrating effects, high local surface (metal) temperature, and stress levels. Stress conditions can result from fabrication and joining procedures, such as forming, welding, or bending, and may occur from an externally applied load.

As the magnitude of stress increases, the time for stress cracking to occur will usually decrease when above the SCC threshold. It is generally accepted that stresses approaching the yield point are required, yet relatively small stresses have in some cases produced failure. Thermal stress relieving minimizes this phenomenon and should be implemented whenever there is a question regarding suitability of steel for the particular application.

Stress-relieving steel equipment used in cell liquor (a 10% NaOH, 15% NaCl solution) applications at 90 °C (190 °F) significantly reduces intergranular attack at weld areas. It should be noted that the presence or absence of salt has no apparent effect on caustic SCC of steel.

Other means of avoiding SCC are commonly implemented. Isolating the steel from caustic solutions with an organic lining, for example, is very effective. Stressed areas rarely, if ever, crack after the lining ultimately fails even though they may be exposed for months to hot, strong caustic. A possible explanation is that the steel undergoes a low-temperature stress relief during the life of the lining. There is evidence that the application of cathodic protection also prevents SCC and can even halt crack propagation. Practical applications of cathodic protection to prevent steel from cracking in caustic solutions are not known. The corrosion behavior of alloy steels, high-strength low-alloy construction steels, and abrasion-resistant steels does not differ significantly from that of carbon steel.

Cast iron also shows corrosion performance similar to steel and has proven quite useful in certain applications up to 70% concentration and 90 °C (190 °F). Stress-corrosion cracking is not a problem for cast irons. It is interesting to note that for many years cast iron pots were used to evaporate caustic to anhydrous NaOH at temperatures over 370 °C (700 °F). Corrosion rates in these cases were generally high (Table 41). The normal service life was several years, owing to the relatively thick-wall castings used. Nickel alloys were not applicable, because various color and clarity agents containing sulfur were routinely added.

Austenitic cast irons (Ni-Resist types) show superior resistance to caustic solutions up to 70% concentration and approaching boiling temperatures; corrosion rates are generally less than 0.25 mm/yr (10 mils/yr) (Ref 196). Nickel-containing cast irons generally benefit by additional nickel alloying as long as sulfur or sulfur compounds are not present (Table 43).

Table 43 Effect of nickel additions on corrosion of cast iron in boiling 50-65% NaOH

Stainless Steels. Austenitic and ferritic stainless steels are often used to fill an economic slot in what could be termed intermediate ranges of caustic service. Austenitic stainless steels, primarily types 304 and 316, are very resistant to caustic in concentrations up to 50% and temperatures to about 95 °C (200 °F) (Tables 35, 37, 38, 39, and 44). Usage in these ranges has increased in recent years for economic reasons even though some potential problems must be addressed.

Table 44 Corrosion of stainless steel in NaOH solutions

Type	Concentration of NaOH, %	Temperature		Test duration, days	Corrosion rate	
		°C	**°F**		**mm/yr**	**mils/yr**
302	20	50-60	120-140	134	<0.0025	<0.1

Source: Ref. 199

(a) Solution moderately agitated.

(b) No aeration.

Figure 83 shows corrosion rates and a stress-corrosion boundary for austenitic stainless steels exposed to NaOH solutions. No distinction is made between types 304 and 316, because their behaviors are so similar. Of significance is the SCC zone, based on known failures, which indicates potential cracking problems above about 105 °C (220 °F). It is generally accepted that this caustic SCC mechanism occurs regardless of austenitic alloy type (304 versus 316). Cracking is affected by stress level and temperature. To provide a measure of insurance, the suggested maximum service temperature is 95 °C (200 °F). Microscopic stress cracking has been reported in laboratory testing at concentrations as low as 10% with temperatures of 100 °C (210 °F) (Ref 204).

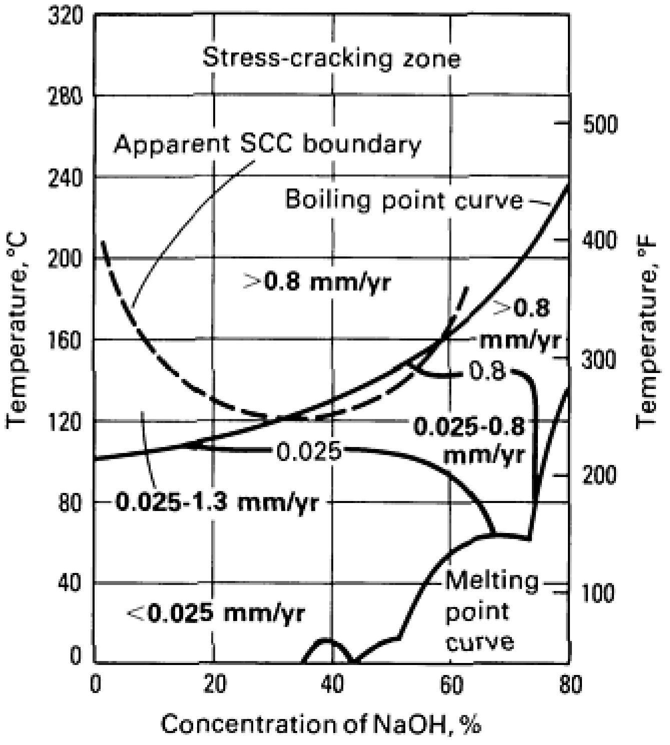

Fig. 83 Isocorrosion diagram for type 304 and 316 stainless steels in NaOH

Although the austenitic stainless steels crack readily in neutral and acid chlorides above 60 °C (140 °F), the effect of chlorides in an alkaline solution seems to be nil (Ref 205). As long as the solution remains alkaline, the mode of stress cracking is that of caustic embrittlement and continues to occur only in the range indicated in Fig. 83. A solution of 0.5 g/L NaOH with a pH of 12 is sufficiently alkaline. The concern for chloride contamination in caustic when using stainless steel equipment is not well founded.

More important concerns are those extraneous to the caustic solution. Failures resulting from such factors as external exposure, faulty insulation, contaminated test water, and improper cleaning and storage have produced more problems than handling caustic.

Because chloride pitting and/or chloride stress cracking are often primary concerns, alloy selection should consider relative performance in these areas. Although types 304 and 316 perform comparably in caustic and in standard stress-cracking tests, type 316 shows improved overall performance because of its pitting resistance (the role of dissolved oxygen may be significant in this effect) (Ref 206). In addition, the low-carbon grades perform marginally better because of their resistance to sensitization (Ref 205). This suggests that type 316L (molybdenum-containing low-carbon type 316) should be used unless significant controls are to be placed on the total exposure of the equipment. Painting the exteriors of stainless equipment is also recommended, especially if insulation will be applied (see the Section "Corrosion Under Thermal Insulation" in this article).

Applications of stainless steel for caustic services include piping, valves, pumps, and equipment. Transfer piping applications are quite common. Problems rarely occur whenever 10 to 20% solutions are involved, because clean-out and freezing considerations are minimal.

Another possible hazard involves introduction of mercury as a contaminant in mercury cell caustic. This can contribute to cracking or pitting of austenitic stainless with mercury concentrations as low as a few parts per million (see the article "Liquid-Metal Embrittlement" in this Volume). Also, there are cases in which stainless steels cannot be used, because of concern in returning Cr^{6+} ions to a mercury cell operation.

Cast stainless pumps and valves have performed very well in caustic applications. The nature of cast surfaces minimizes SCC problems, and castings are usually acceptable in situations considerably beyond the capabilities of wrought products. Corrosion rates are similar to those of the wrought products.

One other practical application of stainless steel in caustic service is in evaporation processes, in which high-purity alloy 26-1 (a low-carbon version of type 446 stainless steel containing niobium and molybdenum), heat-exchanger tubing has been used. Some high-temperature applications have proven effective where corrosion rates on nickel are excessive. This is probably due to the presence of hypochlorite or chlorate contaminants. The debate between nickel and ferrous alloys continues, yet both materials have shown satisfactory performance. The 26-1 alloy is useful up to 175 °C (350 °F), depending on the caustic, chloride, and contaminant concentrations (Ref 207). When 26-1 is attacked, the normal failure mode seems to be intergranular. At this time, there are no specific criteria to provide recommendations regarding the use of ferritic stainless steel. Decisions should be governed by economics, taking into account the impact of heat transfer coefficients as well as the cost of tubing.

A comprehensive summary of criteria for selection of stainless steel for process equipment is given in Ref 205. There probably are good applications for the new ferritic and duplex steels; however, little testing has been completed.

Nickel and Nickel Alloys. Nickel 200 or 201 and nickel-base Monel 400 and Inconel 600 have outstanding resistance to caustic solutions over a wide range of concentrations and temperatures. Nickel has a maximum corrosion rate of 0.025 mm/yr (1 mil/yr) for all concentrations up to 73% boiling solutions; corrosion rates are summarized in Tables 34, 35, 36, 37, 38, 39, 40, and 41. Some of the high nickel-chromium alloys and high-nickel austenitic cast irons perform very well, showing low corrosion rates in 73% NaOH up to 125 °C (255 °F) (Table 38).

Nickel or nickel-base alloys are extensively used in more severe applications. The very low corrosion rates also ensure low metal ion contamination. Nickel has the lowest corrosion rates, even in molten anhydrous NaOH up to 540 °C (1000 °F) and is essentially immune to caustic SCC.

Even with its high level of resistance, nickel is sometimes used in conjunction with cathodic protection. This technique is implemented in nickel concentrators and storage tanks when metal ion contamination must be minimized. Current densities as low as 0.11 A/m^2 (0.01 A/ft^2) have been effective.

When exposure in concentrated solutions above 315 °C (600 °F) is anticipated, low-carbon Nickel 201 (0.02% C maximum) should be selected. This material was specifically designed to avoid potential intergranular corrosion, which may occur in Nickel 200 (0.15% C maximum). In areas of high stress, this type of attack has resulted in cracking after intergranular corrosion, but is mechanically driven.

A common application of nickel and Monel 400 is in fabricating clad vessels and equipment. In these cases, special welding procedures are required to maintain iron contamination levels in welds within acceptable ranges. Typically, the nickel-clad thickness represents 20% or less of the base steel thickness. Nickel welds containing up to 25% Fe showed little change in corrosion rate in 73% caustic at 120 °C (250 °F) (Ref 208). Current welding practice has improved, and maximum iron levels of about 5% can be specified and maintained.

Repair welding of nickel and nickel alloys in caustic service is even more critical. It is absolutely necessary to remove corrosion products and any foreign material from the vicinity of the weld area. Chemical cleaning with a pickling acid is usually very effective; however, careful mechanical cleaning with a fine wheel or disk grinder is acceptable. If proper cleaning is not carried out, the weld will often become embrittled and crack.

The mercury contamination discussed earlier can also affect nickel and nickel alloys. Even though the mercury cell caustic is no more corrosive than diaphragm cell production under normal conditions (Table 38), a mercury-contaminated product could create cracking or pitting problems. The chances of this, however, have proven to be remote. The effect of oxidizable sulfur compounds can also be detrimental at higher temperatures and is probably encountered more frequently. The effects of sulfur, added for color shading, are given in Table 41 for nickel in caustic fusion.

Perhaps the contaminants most discussed in recent years among procedures of caustic chemicals have been hypochlorite and/or chlorate in caustic evaporation services. Increased corrosion rates on nickel evaporator tubes have been attributed to increased sodium chlorate ($NaClO_3$) levels in the caustic (Ref 209). The chlorate levels studied were high (300 to 700 ppm), yet laboratory tests showed corrosion rates significantly lower than actual experience. Certainly, velocity and abrasion are principal factors in increasing actual service rates. Most of the studies focused on chlorate levels. Recent

laboratory work showed significant modification to corrosion behavior resulting from hypochlorite additions as low as 1 to 2 ppm (Ref 210). Further studies are required before definitive recommendations can be made. It is recognized that chlorate and hypochlorite have a negative effect on nickel and nickel alloys in caustic service (Ref 207, 211, 212).

Monel 400 and Inconel 600, although excellent in caustic service, have higher corrosion rates than the Nickel 200 and 201 metals. Inconel 600 has shown a slight sensitivity to SCC above 190 °C (375 °F). However, it replaces nickel for direct fire production of anhydrous NaOH with sulfur-containing fuels. Monel 400 has a generally high corrosion rate at concentrations above 75% and temperatures above atmospheric boiling. Additional information on nickel and nickel alloys in various alkaline services is available in Ref 196.

Other Metals. A few other metals have useful resistance to NaOH, although use is generally limited to very special circumstances, frequently involving dual service. Silver has good resistance and at one time was used in evaporating to anhydrous NaOH. Zirconium and titanium are very good in moderate concentrations and temperatures (Tables 34, 37, 39, and 41). Zirconium is considered useful to 73% concentrations at temperatures to 140 °C (280 °F). Titanium, when attacked, absorbs hydrogen liberated in the corrosion process, limiting service to temperatures of about 100 °C (210 °F) and to concentrations generally below 50%. Iron-base nickel-chromium alloys (including 20Cb-3) show appreciable resistance that generally surpasses that of the austenitic stainless steels. Copper and some copper-base alloys (aluminum-bronze and copper-nickel) show useful resistance (Table 38). Higher nickel in the copper-nickel alloys indicates better resistance; alloy 70-30 (CDA 71500) has been used where copper contamination can be tolerated.

Certain metals should not be used with caustic because of excessive corrosion rates. These include aluminum, magnesium, zinc, tin, chromium, and zinc-containing brasses or bronzes.

Nonmetals. Many nonmetallic materials have excellent resistance to NaOH within their normal temperature ranges. Temperature limits are often much more restrictive than for resistant metals. Among the resistant nonmetals are types of organic linings and elastomers, some thermoplastics, and some reinforced plastics.

Linings were mentioned earlier as a means of using the economics of steel construction while achieving the corrosion resistance and product protection provided by organic, elastomeric, and even metallic linings. Many steel tanks in caustic service are lined not so much for corrosion protection as for minimizing iron contamination. It is recognized that as caustic concentrations increase, the recommended temperature limit also increases for most linings. The lower the concentration of the caustic, the more readily it permeates and attacks the linings. The common linings for these applications are spray-applied neoprene latex and phenolic-modified epoxy.

The neoprene latex material has found extensive application in caustic service for more than 30 years. Applied at thicknesses of 0.3 mm (12 mils) for tank cars and 0.5 mm (20 mils) for storage tanks, it is recommended for continuous service up to 115 °C (240 °F) for concentrations between 50 and 73%. It has been used at lower concentrations, but this application is questionable at high temperatures.

The modified epoxy-phenolic linings have also been used for many years. Typically applied at thicknesses of 0.25 to 0.38 mm (10 to 15 mils), these linings are often used for multiservice applications because they have a wider range of chemical resistance. They have been recommended for caustic applications up to 73% at 130 °C (270 °F); low-concentration high-temperature service is more effective, depending on the individual formulation.

Spray-applied amine-epoxy linings have been successfully used in equipment and railcars handling solid caustic beads. Probably the most severe exposure results from hot-water washing of residues.

Several types of elastomeric sheet linings possess excellent caustic resistance. For economic reasons, their use is generally limited to small tanks or equipment. Recommended materials include neoprene, chlorosulfonated polyethylene, EPDM rubber, and certain formulations of natural rubber. They are usually used for applications up to 50% caustic, with temperatures limited by individual elastomer type. Neoprene is recommended to as high as 110 °C (230 °F), and chlorosulfonated polyethylene to as high as 120 °C (250 °F). Abrasive services are also effectively served by the elastomeric linings.

Fabricated rubber parts (seals, o-rings, diaphragms) are also made of these elastomers and are useful in caustic service. The perfluoroelastomers are very resistant, but fluoroelastomers should not be used in strong or hot solutions.

A large number of thermoplastics have excellent resistance to caustic solutions up to their normal temperature limits. Included are PVC, chlorinated polyvinyl chloride (CPVC), polyethylene, PP, and the fluorocarbons (FEP, TFE, and PFA). Polyvinylidene fluoride is limited to 70% concentrations and temperatures of 120 °C (250 °F). Stress-cracking problems have been noted in some high-density polyethylenes; generally, cross-linked polyethylene has performed better.

Thermoplastic materials are used in a wide variety of caustic-handling applications, including valves, pipe, small vessels, pumps, gaskets, and lined pipe. The use of lined pipe (PP is common) is significant because it offers a plastic application with a high level of safety.

Fiberglass-reinforced plastics are used in various caustic applications, especially in piping and equipment. Often, the lower-concentration applications are more aggressive to fiberglass-reinforced plastic. Because glass is known to be attacked in caustic service, effective designs usually incorporate a special interior surface treatment. Synthetic surfacing veils (polyester and acrylic are common ones) should be specified for caustic applications. The selection and protection of a highly resistant inner surface, often called the corrosion barrier, is critical. Applications in high-concentration high-temperature service are usually not suited to fiberglass-reinforced plastic.

Epoxy resins generally have better resistance to caustic and are useful up to 95 °C (200 °F). Vinyl-esters follow, with potential application up to 80 °C (175 °F). Polyesters are generally comparable to the vinyl-esters; some are slightly better (bisphenol-fumarate), and some worse (isothalics and blends). The notable exception is chlorinated (chlorendic anhydride) polyester, which should not be used in NaOH. Any potential fiberglass-reinforced plastic applications for caustic service should be carefully reviewed with resin suppliers and manufacturers.

Glass and ceramics have very limited application in NaOH, especially if high temperatures and concentrations are involved. Borosilicate glass is especially sensitive to caustic attack in hot solutions (95 °C, or 200 °F) as low as 5% concentration. Alkali-resistant glass on steel may be used to pH 14 at 65 °C (150 °F) or pH 13 at 80 °C (175 °F).

Potassium Hydroxide

Potassium hydroxide is also known as caustic potash. It has a higher boiling point than NaOH at equal concentrations. Consequently, it is rarely evaporated above a 90% strength. It is very similar to NaOH in corrosion behavior as well as safety requirements.

Materials. Corrosion and degradation of metals and nonmetals is the same in KOH as in NaOH. Indications are that KOH is slightly more aggressive, but this generally relates to its higher boiling point and the increased likelihood of higher-temperature exposure. Table 45 shows the corrosion rates of some metals in KOH. These data do not indicate any higher rates, with the possible exception of titanium. Still, all of the rates are very low. It has been reported that nickel alloys are less sensitive to stress cracking in KOH and than in NaOH (Ref 196).

Table 45 Corrosion of metals and alloys in KOH solutions

Material	Corrosion rate			
	13% KOH[(a)]		**50% KOH[(b)]**	
	mm/yr	**mils/yr**	**mm/yr**	**mils/yr**
Titanium	0.023	0.9	0.01	0.4
Zirconium	0.005	0.2	0.0015	0.06
Nickel	nil		0.00008	0.003
Monel	nil		0.00005	0.002
Inconel	nil		nil	
Low-carbon steel	0.013	0.5[(c)]	0.0013	0.05

Source: Ref 62

(a) 207-day test at 30 °C (85 °F); 13% KCl added to solution.

(b) 207-day test at 25 °C (80 °F).

(c) Slight attack under spacer.

Most literature for such products as plastics and linings indicates the same levels of resistance for KOH and NaOH. One exception is that fiberglass-reinforced plastic shows a generally lower resistance for KOH, regardless of the resin type.

Soda Ash

Sodium carbonate is an alkaline salt. It is commonly called soda ash. This chemical was extensively used in alkaline processes to supply sodium oxide (Na_2O) equivalence. Over the years, some uses have been replaced with caustic. At one time, Na_2CO_3 was primarily synthetically produced using an ammonia-soda (Solvay) process. Current production is largely of the natural ash, which is mined and refined.

When in solution, Na_2CO_3 creates less alkalinity than the hydroxides (Fig. 84). A 0.1% solution creates a pH of 11; a fully saturated solution is 35%, which has a pH of 12.5. The related bicarbonates (sodium bicarbonate, $NaHCO_3$) are less alkaline, but they will convert to carbonates at high temperatures and increase the pH of the solution. The safety requirements for Na_2CO_3 can be considered less demanding because of its lower alkalinity.

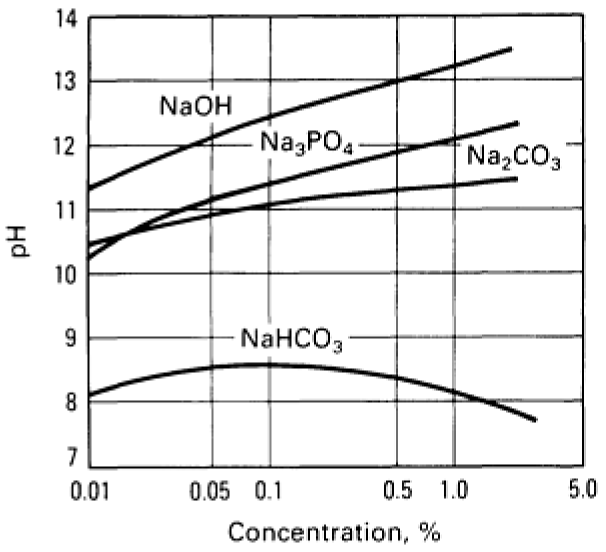

Fig. 84 Concentration versus pH of various alkaline solutions

Metals. Soda ash solutions can be handled easily in anything that is suitable for caustic. Similar to other alkaline solutions, the presence of carbonate ions (CO_3^{2-}) usually provides an inhibiting effect on metals. Carbon steel has good resistance and is used extensively in Na_2CO_3 solutions. There is a smaller possibility of alkaline stress cracking, and steel is routinely used up to boiling temperatures.

When nil corrosion rates are deemed necessary, the stainless steels and nickel alloys perform very effectively. Stainless steel has an SCC range similar to that in caustic, but at considerably elevated temperatures. Aluminum is attacked depending on concentration and temperature, but can be inhibited with silicates in dilute solutions. Similarly, zinc and zinc brasses are attacked, but also show beneficial results from various inhibitors.

Nonmetals. Because of the relative resistance of iron and steel, there is less need to consider nonmetals. Most linings perform well. Thin-film linings provide reasonable contamination protection when required. Most plastics have good resistance to Na_2CO_3; the same reactions that were present with caustic still occur, but to a much lesser degree. Although weaker solutions of NaOH or KOH are more aggressive at high temperatures, this is not the case with Na_2CO_3 solutions, because they are so much less alkaline.

Other Alkalies

Many of the corrosion rates of materials in alkaline service are attributed to the pH of the solution. Figure 84 compares these values with concentration for some industrial alkalies.

Essentially, all of the hydroxides behave similarly and can be handled in materials recommended previously for comparable concentrations and temperatures of caustic. The alkaline salts relate to Na_2CO_3 and can be treated similarly with few exceptions; salts would include borates, silicates, and phosphates. Sulfides are also considered alkaline salts, but are generally more corrosive to metals. Reactions with nonmetallic materials are similar to the other alkaline salts. Careful checking is warranted when selecting a lining for alkali service because performance variations with temperature and concentration can be significant.

Hypochlorites

These alkaline oxidizing salts are among the most corrosive salts. Sodium hypochlorite is produced as a liquid by chlorinating 20% NaOH. Resulting soda bleach solutions contain about 15% NaOCl with some residual NaOH to aid stability. These industrial-strength bleaches are diluted to concentrations of about 5% for household use. To enhance stability further, the NaOH used should not contain heavy metals, and the NaOCl should be stored in dark or polyethylene bottles at temperatures below 30 °C (85 °F). Sodium hypochlorite does not exist as a stable solid.

The solid hypochlorites include lithium, calcium, strontium, and barium, although the only major applications are for calcium hypochlorite ($Ca(OCl)_2$). The product is made by various processes, usually resulting in a dihydrate salt, $Ca(OCl)_2 \cdot 2H_2O$, containing 65% available chlorine. Solid $Ca(OCl)_2$ will decompose rapidly at high temperatures (175 °C, or 350 °F), releasing chlorine. It also reacts vigorously with many oxidizable organic compounds. Calcium hypochlorite solutions are encountered during production and in other chemical processes for bleaching, sanitizing, or deodorizing. The solid product is often dissolved in water to form dilute solutions used for bleaching operations and water purification.

Hypochlorite solutions are found in industrial applications, such as bleaching in the pulp and paper industry, odor control, and waste treatment/disposal. Solutions are often produced when neutralizing vent gas and other waste streams. Hypochlorite solutions are subject to decomposition, which is influenced by concentration, ionic strength, pH, temperature, light, and impurities. Trace metal contamination of cobalt, nickel, and copper catalyzes decomposition; iron and manganese provide the same effect, but to a lesser degree. The resulting decomposition reaction creates an aggressive environment. This is why many metals and plastics do not provide adequate resistance to hypochlorite solutions.

Sodium Hypochlorite

Metals. The hypochlorite ion (OCl^-) is similar to wet chlorine gas in its effects on materials. Not many metals show good resistance even at low temperatures and concentrations. Because hypochlorite solutions are unstable at neutral and lower pHs, they normally contain excess alkali, which modifies the aggressiveness somewhat. Corrosion rates of HOCl (OCl^- ion present at low pH) are compared with those found in batch manufacture of NaOCl in alkaline solution in Table 46.

Table 46 Corrosion of metals in HOCl and NaOCl

Material	Corrosion rate			
	17% HOCl[(a)]		**16% NaOCl[(b)]**

(b) Repeated exposures to batch manufacture of NaOCl, starting with 18-20% NaOH chlorinated to 16% NaOCl. Test duration: 170 days. Temperature: 20 °C (70 °F).

(c) Severe attack under spacer.

Titanium is the only metal that provides consistently good performance in NaOCl. Although special titanium alloys are available, the commercial grade 2 is usually suitable for a full range of concentrations and temperatures. Although titanium has been known to suffer crevice corrosion in hot wet chlorine, it apparently has not shown the same susceptibility in hypochlorite solutions. A wide variety of titanium products are used, including piping, pumps, valves, heat exchangers, fans, and vessels.

Tantalum is also very resistant to hypochlorite, but its use is limited because of its relatively high cost. Nickel-base iron-chromium-molybdenum alloys, wrought and cast (Hastelloy C, Chlorimet 3, and so on), show good resistance in various solutions. The high iron-chromium-nickel alloys, such as 20Cb-3, and silicon cast irons have also been used, especially as pump materials, in the less aggressive environments. Many of these materials have shown unpredictable performance in seemingly similar applications.

Sodium hypochlorite is usually maintained at low temperatures to prevent decomposition. The effect to higher temperature, even in the dilute solutions, is reflected by corrosion rates (Table 47). The presence of heavy-metal ions, especially in the case of higher solution concentrations, often causes instability with decomposition. This potential may rule against metals that might otherwise be acceptable, because the occurrence of decomposition often triggers a corrosion reaction.

Table 47 Corrosion of metals and alloys in NaOCl solutions at elevated temperatures

(a) 72-day test in 1.5-4% NaOCl with 12-15% NaCl and 1% NaOH (Ref 62).

(b) NaOCl solution (pH 9) with 500 ppm active chlorine and 1.2% NaCl (Ref 213)

The relative rankings in a more recent study (Table 47, exposure 2) offer an interesting insight for what may be new metals for hypochlorite service. Some of the newer super stainless steel materials indicate useful resistance in certain NaOCl solutions (Ref 207). Successful performance of a high-alloy duplex stainless (Ferralium 255) in a NaOCl scrubber was recently reported (Ref 214). When the stainless steels are attacked in NaOCl, the mode is usually pitting and/or crevice corrosion.

Nickel and some nickel alloys can be protected by alkaline inhibitors, such as Na_2SiO_3 and Na_3PO_4. The corrosion rates are significantly reduced, and the mode of corrosion becomes more uniform (Table 48). However, nickel finds few successful applications in NaOCl service, contrary to its dominance in NaOH.

Table 48 Effect of inhibitors on corrosion in NaOCl

16-h beaker test at 40 °C (105 °F); no agitation

Source: Ref 215

Aluminum and aluminum alloys are also inhibited by silicates. Hypochlorites usually promptly destroy their protective oxide film and cause rapid attack.

Copper is normally attacked by localized pitting, with corrosion rates exceeding 0.5 mm/yr (20 mils/yr).

Nonmetals. The instability of NaOCl has a significant impact on the resistance of nonmetals. Generally, those materials that are resistant to wet chlorine gas are resistant to hypochlorite at any normal concentration and temperature. Unlike the metals, there are many plastics, rubber and elastomers, glass, and ceramics that fall into this category. Because NaOCl is normally maintained at low or moderate temperatures, most resistant nonmetals are serviceable to their usual temperature limit.

A notable exception is occasionally found when service is at or near the NaOCl decomposition temperature (60 °C, or 140 °F). Some nonmetals are severely affected by the decomposition reaction, which is initiated by temperature or catalyzed by heavy-metal ions.

Coated or lined steel is common in NaOCl service, and a wide variety of resins are used. The fluorocarbon resins are essentially unaffected. Polyvinyl chloride and CPVC also show excellent resistance; steel vessels lined with unplasticized PVC sheet were used for making soda bleach for 20 years. Loose PVC liners have been used to extend the service lives of deteriorated lined tanks. Polyvinylidene chloride has provided service in some specialized bleaching solutions. Polypropylene is also used extensively in lined piping and pumps, although there have been reported incidents of stress cracking.

Many of the thermoplastics are used as solid products. In addition to many of those identified as lining materials, polyethylene (cross-linked and high-density) provides useful service as tanks and small vessels. The variations in formulation of thermoplastics should reinforce the requirement to compare specific products in any proposed solution if there is any question regarding resistance.

A number of fiberglass-reinforced plastics resist NaOCl at normal temperatures and concentrations. Many resins provide useful service. Generically, these would include bisphenol and chlorendic-type polyesters, vinyl-esters, and, to a limited extent, epoxy. It would seem that the use of fiberglass-reinforced plastic will be growing; applications include piping, equipment, tanks, pumps, and many special fabrications.

A number of factors control the usefulness of fiberglass-reinforced plastic in hypochlorite solutions (Ref 216). Foremost are factors that affect the stability of the solution and the degree of chlorination or, conversely, the level of excess alkalinity. It has already been indicated that temperature, pH, and concentration contribute to decomposition. Because heavy metals also trigger decomposition, any potential source of metal ions should be evaluated. This should include thixotropic additives, fillers, ultraviolet inhibitors, metallic contaminations, and curing systems.

The most common fiberglass-reinforced plastic curing system uses methyl ethyl ketone-peroxide (MEKP) with a cobalt-containing promoter--an obvious source of cobalt ions. The resin manufacturers provide mixed recommendations regarding alternative curing systems, some indicating that increased fabrication difficulty more than offsets the benefit of eliminating the cobalt. The quality of fabrication is a most important factor in successful applications of fiberglass-reinforced plastic and should not be compromised. Most resin suppliers recommend synthetic veils. Synthetic materials should certainly be used for strongly alkaline solutions. Postcuring is also recommended and provides a more resistant fabrication. Full curing of all secondary joints is most important. Finally, thixotropic agents should not be added to resin systems, especially when used in surfaces exposed to hypochlorite.

Glass-flake reinforced spray linings are also used in hypochlorite services. The problems encountered indicate that these applications should be limited to low-temperature services or applied where the environment is not overly aggressive to the substrate.

Elastomeric lining is common in a wide variety of hypochlorite applications--a result of typically low temperatures. Probably the most frequently used lining material is chlorobutyl, because of its good resistance coupled with moderate cost. Other sheet lining materials with good resistance include EPDM and chlorosulfonated polyethylene. Natural rubber also finds some useful low-temperature applications. Other elastomeric applications might use the fluoroelastomers, which are good in any hypochlorite service, or neoprene, which has limited range.

Glass is unaffected by hypochlorite within a moderate range of alkalinity and temperature. Glass-tubed heat exchangers have been used to cool soda bleach during manufacture. Vitrified clay pipe and other ceramic materials show excellent resistance to hypochlorite. Under certain conditions, concrete is resistant and has been used for manufacturing and storage tanks.

Calcium Hypochlorite

Although produced as a solid, the reactions of $Ca(OCl)_2$ in solution are very similar to those of NaOCl. In general, the recommended temperature levels for $Ca(OCl)_2$ are slightly higher, probably owing to the higher decomposition temperature. Like NaOCl, the calcium product is unstable at lower pH, but it can be concentrated to a higher degree. The corrosion rates for some metals are shown in Table 49.

Table 49 Corrosion of metals and alloys in $Ca(OCl)_2$

204-day test in 18-20% $Ca(OCl)_2$ at 20-24 °C (70-75 °F)

Material	Corrosion rate		
	mm/yr	**mils/yr**	**Pitting**
Titanium	nil		none
Zirconium	0.025	1[a]	none
Hastelloy C	<0.0025	<0.1	none
Chlorimet 3	0.025	1	none

(a) Severe attack under spacer

Plastics and elastomerics can usually be used in $Ca(OCl)_2$ to slightly higher concentrations and temperatures than in NaOCl. Virtually the same applications are served by these materials in both products.

The solid $Ca(OCl)_2$ product is typically packed in polyethylene or polyethylene-lined containers. Epoxy-phenolic lining performs effectively for trucks and railcars. It is critical to keep the product dry and away from organic fluids. Aluminum is sometimes used in handling solid $Ca(OCl)_2$ because any corrosion residue does not discolor the product.

Corrosion by Ammonia

A.S. Krisher, ASK Associates

Anhydrous ammonia, a major commercial chemical, is used in the manufacture of fertilizers, HNO_3, acrylonitrile, and other products. Except for a sensitivity to SCC, carbon steel is fully acceptable in NH_3 service. Stress-corrosion cracking of carbon steel NH_3 storage vessels was first observed in the early 1950s. In most cases, the developing cracks have been detected by inspection before leakage or rupture. However, there have been a few catastrophic failures. For example, in France in 1968, a tanker ruptured, killing 5 people. A second case was in South Africa, where a large tank failed in 1973 with 22 fatalities.

Ammonia is stored under three conditions. It can be stored by cooling it to a low enough temperature, (-34 °C, or -29 °F) to maintain it in the liquid state at atmospheric pressure. This method is frequently described as cryogenic storage. A second approach is to contain the ammonia under sufficient pressure (about 2070 kPa, or 300 psig) to maintain the ammonia in the liquid phase at ambient temperature. Cylindrical pressure vessels are often used for fairly small quantities. Spherical pressure vessels are used for larger quantities. The third condition involves some degree of refrigeration combined with pressurization. This is termed semirefrigerated storage.

Most cases of SCC have occurred in ambient-temperature pressurized storage vessels, for the most part in spheres. A few problems have been observed in semirefrigrated storage. There have been no documented cases of SCC in cryogenic storage vessels. When SCC does occur, cracks are primary transgranular and progress at a relatively slow rate compared to other SCC phenomena.

Laboratory Studies

One investigation using statically loaded tuning fork type specimens and tensile bars showed that NH_3 SCC is accelerated by cold work, welding, applied stresses, and the use of higher-strength steels. It was found that air contamination promotes SCC and that water in amounts greater than 0.1% inhibits cracking (Ref 217).

Other experiments using slow strain rate tests and a low-alloy steel also found that air contamination promoted SCC and that water at a level greater than 0.09% was an effective inhibitor. Electrochemical studies showed that the SCC involves an anodic chemical process (Ref 218, 219).

Field tests were conducted using specimens stressed by residual stresses from welding (Ref 220). Results indicated that high-strength steels fail more rapidly than low-carbon steel and that hard welds (welds that are harder than the base material) tend to accelerate cracking. Thermal stress relieving was also found to be effective in preventing SCC.

Another investigation using low-alloy steels and slow strain rate test methods produced SCC at temperatures as low as 0 °C (32 °F). Again, air contamination and low water content promoted SCC (Ref 221).

Results of an industry-sponsored technical investigation that used both slow strain rate tests and fracture mechanics type specimens are documented in Ref 222. It was found that oxygen levels greater than 5 ppm are required for SCC. Levels as low as 1 ppm caused cracking if carbon dioxide was also present and water was absent. This work also suggested that hydrazine ($NH_2 \cdot NH_2$), ammonium carbonate [$(NH_4)_2CO_3$], and ammonium bicarbonate (NH_4HCO_3) might be inhibitors. The fracture mechanics test methods were not successful, possibly because of the slow rate of cracking.

Other tests using low-alloy steel and the slow strain rate test confirmed again that oxygen as a contaminant is damaging, with indications that levels as low a 0.01 ppm might be sufficient to cause the cracking, at least in low-alloy steel (Fig. 85). Nitrogen also appeared to be a cracking accelerator in combination with oxygen. The lower limit of the required water content to inhibit cracking was found to be about 0.08 wt% (Fig. 86). This work showed $NH_2 \cdot NH_2$ to be an effective inhibitor at 0.025 wt% for a contamination level of 200 ppm O_2.

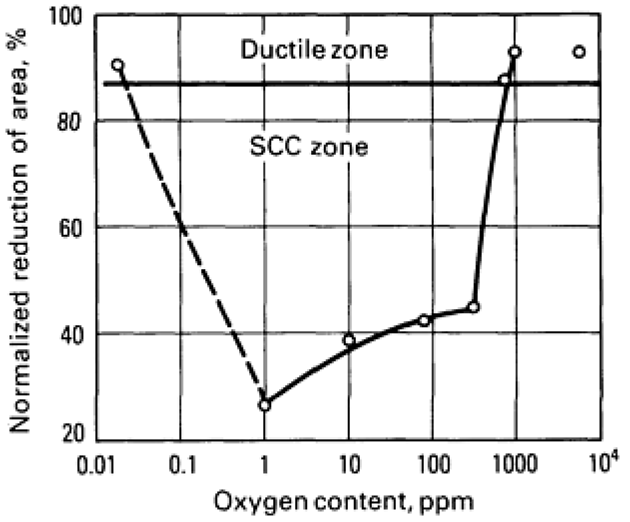

Fig. 85 Effect of oxygen content on apparent ductility observed in slow strain rate tests of low-alloy steel in liquid NH_3. Source: Ref 223

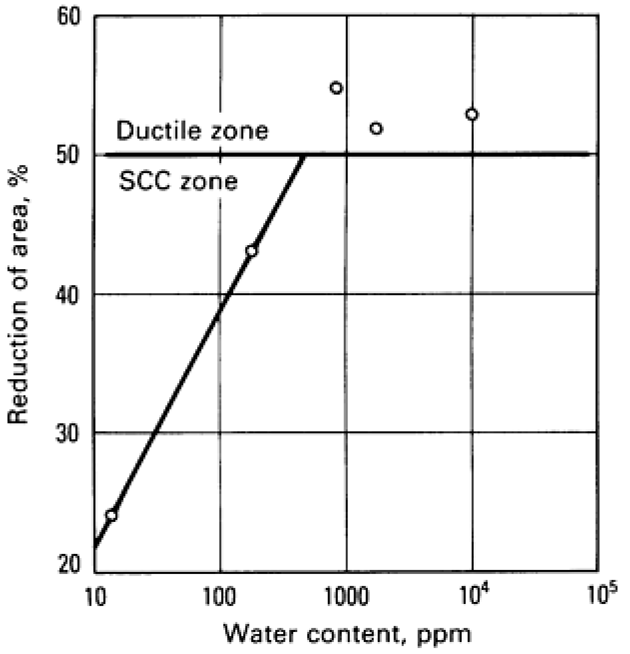

Fig. 86 Effect of water content on apparent ductility observed in slow strain rate tests of low-alloy steel in liquid NH_3. Oxygen content was 200 ppm, added as air. Source: Ref 223

This body of laboratory work (seven studies over a period of 19 years by six different investigators using three different methods in four different countries) is impressive in its consistency. All of the studies showed that the primary causes of the cracking are high stresses and air contamination. Nitrogen and carbon dioxide were suggested by separate investigators as promoting SCC. Cracking is accelerated by the use of high-strength steels, the presence of hard welds, and air contamination. The cracking mechanism can be inhibited by water above about 0.1%. Thermal stress relief, if done properly, reduces stress below the critical level.

Field Experiences

Some reports suggest that water is not always an effective inhibitor, especially when water is added after SCC is detected. The significance of these reports is clouded by a lack of evidence that adequate control systems were used to ensure that a sufficient level of water was maintained. The research studies discussed previously do not address the effectiveness of water addition in slowing the growth of pre-existing cracks.

There is also a problem area with the vapor phase of NH_3 tanks. Water is considerably less volatile than NH_3, resulting in a lower water content in the vapor phase than in the liquid. If NH_3 vapor condenses on the wall of the vessel, the water content will probably be inadequate for inhibition, and SCC in the vapor phase is possible.

There are also reports of recracking of vessels that cracked, were repaired, and then were stress relieved. It is extremely difficult to repair vessels that have suffered SCC. There are many cracks in the equipment, including some of submicroscopic, size. It is extremely difficult to prevent these cracks from propagating later. Stress relief of a vessel that has suffered SCC is also very likely to be unsuccessful. The very small cracks are contaminated to some degree. When this metal is subjected to the stress-relief thermal cycle, such phenomena a nitriding and carburizing may occur and promote further cracking.

Practical Operating Guidance

It is apparent that SCC of carbon and low-alloy steel NH_3 storage vessels can be a problem if proper procedures in design, fabrication, operation, inspection, and maintenance are neglected. If the degree of such neglect is large enough, catastrophic failure is possible. However, it is also apparent that application of proper procedures will ensure satisfactory long-term storage. Reference 224 discusses such practices. General recommendations for design, fabrication, operation, and inspection and maintenance practices are presented below.

Design and Fabrication. Normal design methods used for vessels to contain hazardous fluids should be followed, including all requirements of governing codes and agencies. Design should also be reviewed using fracture mechanics concepts to assess the risk of brittle fracture. Fabrication should be carefully inspected by a properly qualified engineering representing the end user.

A low-strength (specified tensile strength not exceeding 483 MPa, or 70 ksi) grade of carbon steel should be used. The hardness of welds should be specified to be 255 HB maximum, and the weld hardness should be checked in the field.

Postweld heat treatment (stress relief) at 595 °C (1100 °F) minimum should be specified for all pressure vessels. The lower temperature/longer time alternatives for such treatment allowed in some codes are less effective in reducing residual stress levels.

Operating practices should minimize air contamination. Water content should be maintained at 0.2% minimum if water is not objectionable to the user of the NH_3. Water (and, if feasible, oxygen) content should be checked by routine sampling and analysis.

Inspection and Maintenance. All tanks in NH_3 storage service should be carefully inspected on a routine basis. A new tank should be carefully inspected by the wet fluorescent magnetic-particle method after 1 to 2 years service. If no cracks are found, a somewhat longer inspection interval may be appropriate. If cracks are found, their severity should be assessed and appropriate actions taken. These actions may involve simply recording location and size of cracks, grinding out the cracked areas, or grinding out and rewelding the cracked areas. Figure 87 shows guidelines regarding modifications of inspection frequency as a function of oxygen and water content.

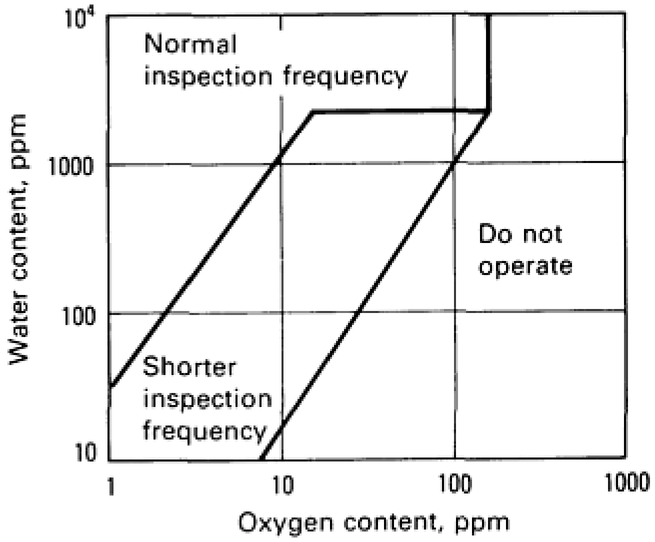

Fig. 87 Guidelines for changes in inspection frequency when oxygen or water content is outside preferred range. Source: Ref 224

Any existing tank that has not been so inspected and has been in service longer than 2 years should be inspected at the first opportunity. Stress relief after repairs is not recommended. As noted previously, it is unlikely to be beneficial and may be harmful.

Corrosion in the Pulp and Paper Industry

Chairman: Andrew Garner, Pulp and Paper Research Institute of Canada

Introduction

IN THE PAST DECADE, the understanding of corrosion phenomena in the pulp and paper industry has progressed from one based largely on practical experience to the point at which an appreciation of the corrosion mechanism is considered an essential first step to solving a problem. Recent cracking problems with kraft continuous digesters provide a good case in point. In the early 1960s, when the continuous digester process was first adopted, the industry had limited familiarity with caustic cracking. The occasional report of a cracked batch digester was considered to be an isolated incident, and its significance to the new continuous technology was not appreciated. This is evident from the fact that beginning in the mid-1960s, many continuous digesters were built with nonstress-relieved upper cooking zones. It is now known that these vessels have caustic levels and temperatures so close to the caustic cracking range that full stress relief is essential. Recognition of this was possible only because considerable investigation and research provided a mechanistic understanding of the problem and proposed solutions.

A parallel progression of events can be traced for paper machine corrosion phenomena. Process changes over the past three decades, including system closure and new brightening practices, have created a series of problems resulting in the failure of existing materials of construction. Components with high failure rates include bronze fourdrinier wires, CA-15 cast stainless steel suction press rolls, cast iron vacuum pump impellers, and type 304 stainless steel process piping. For most of these components, there has been a sustained effort to understand the failure mechanism, and in some of the later cases, a detailed understanding has been achieved.

For example it is now understood that pitting of type 304 stainless steel occurs when the pit site is sufficiently acidified by anions such as chloride or even sulfate; that pitting can be accelerated by thiosulfate, which is thought to deliver sulfur to the pit; and that pitting an be inhibited by bisulfite, which buffers the pit pH. The relative proportions of these anions determine whether or not pitting occurs. Therefore, the corrosiveness of white water can be predicted and controlled by process changes. The current understanding of these and many other corrosion problems in the pulp and paper industry are covered in this article.

Paper Machine Corrosion

Donald A. Wensley, MacMillan Bloedel Research

Corrosion problems in paper machines are generally most severe in the wet end and in ancillary equipment handling white water (Fig. 1). Metal surfaces in the wet end are exposed to the white water environment by immersion, splashing, vapor mist, and the formation of crevices beneath pulp pads or other deposits. White water environments cause rapid corrosion of bare carbon steel, appreciable corrosion of copper alloys and cast irons, and can even cause localized corrosion of stainless steels. Most wetted paper machine surfaces are constructed from austenitic stainless steels; types 304L or 316L are the predominant choices. The critical components in a paper machine wet end are discussed below.

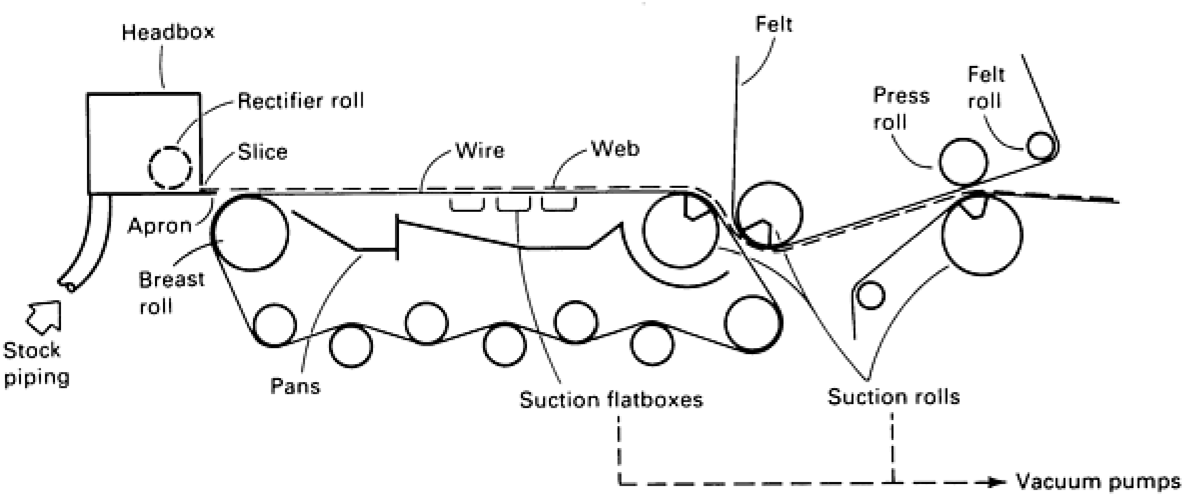

Fig. 1 Schematic diagram of the wet end of a fourdrinier paper machine

Paper Machine Components

Stock Piping. Paper machine stock piping is typically thin-gage (schedule 10) type 304L or 316L austenitic stainless steel. Corrosion is generally not a problem in stock lines if the correct stainless grades and weld filler metals have been chosen for the white water environment and if surfaces are kept clean. Surfaces that have become roughened or have weld projections that have not been removed provide sites for stock hang-up. Pitting or microbiological attack is likely to occur under deposits. Fatigue cracking problems in stock piping are associated with poor welding practice.

Headboxes. The headbox (Fig. 2) has the critical function of transferring flow formerly contained in a round pipe to a flat flow of uniform consistence across the width of the paper machine. Clean, smooth surfaces inside the headbox are essential. Aside from the corrosion aspect, the release of pulp pads resulting from stock hang-up may cause product quality problems or even sheet breakage. Pickling, passivation, and buffing with abrasives are commonly used to provide a smooth surface finish. Electropolishing improves the finish for surface of 0.4 μm (15 μin.) and above.

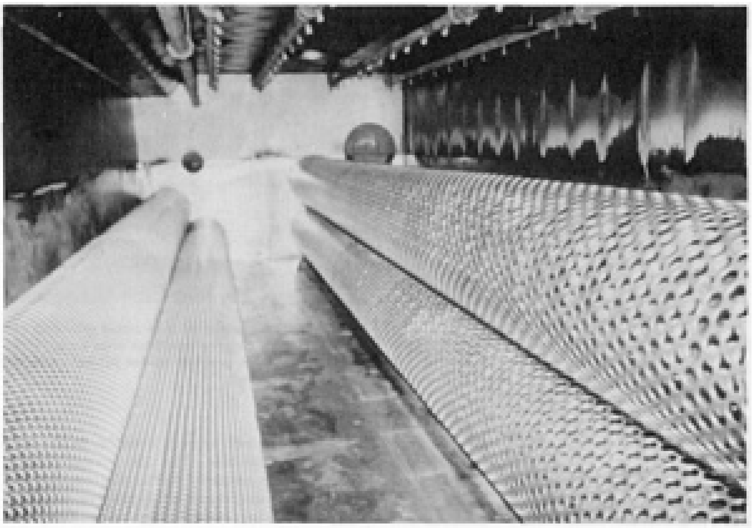

Fig. 2 View inside a paper machine headbox showing rectifier rolls and overhead shower nozzles. Material of construction is type 304L stainless steel.

It is especially important to implement proper cleaning techniques during fabrication. Stainless steels are naturally passive in most papermaking environments; however, the presence of embedded iron, iron oxides, heat tint, weld spatter, slag, and other surface contaminants impairs the corrosion resistance of the underlying metal. The misuse of carbon steel wire brushes for weld cleanup may cause serious pitting problems because iron particles will become embedded in the stainless steel surface. Iron contamination is best removed by passivating with a nitric acid solution, which dissolves the iron and leaves the stainless steel intact. Pickling solutions, which typically contain fluoride in addition to nitric acid, are much more aggressive. Pickling solutions also attack the stainless steel in addition to removing iron and weld heat tint; therefore, pickling should be done only as a final cleanup step on equipment for which excellent surface finish is not required.

Paper machine headboxes are often constructed from highly corrosion-resistant alloys as additional insurance against the possibility of corrosion roughening of internal surfaces. The existence of crevices inside the headbox, the presence of an air-liquid interface, the potential for internal mechanical damage (from rectifier rolls), and even possibility of stray current damage make the headbox environment more severe than that inside stock piping. A headbox can be constructed from type 317L stainless steel if type 316L stainless steel is used for other components. Overmatched fillers (fillers with higher alloying contents, particularly molybdenum contents, than base metal) have been used to provide additional corrosion resistance for weldments. Some headboxes have even been constructed of UNS N10276, a nickel-base alloy that is usually used in much more severe corrosion applications. The reasoning behind this material selection is that immunity to corrosion means freedom from maintenance.

Headbox apron and slice lips are very prone to pitting corrosion attack (Fig. 3). Pits initiate on surfaces outside of the liquid flow and then tend to grow in size, eventually reaching the edge of the lip. Corrosion extending to lip edges has a detrimental effect on sheet formation. The use of specialty stainless steels, such as UNS S31254 (254SMO), which contains 6% Mo, has been successful in combatting pitting of apron and slice lips.

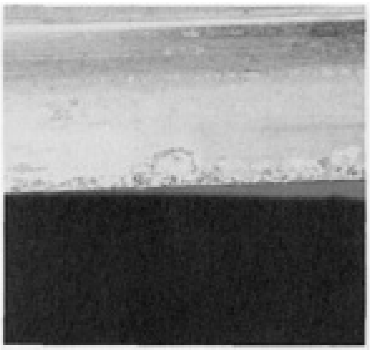

Fig. 3 Severe pitting corrosion of a type 316L stainless steel slice lip

Paper Machine Wire. The wire is so named because a phosphor bronze wire mesh was originally used as the moving screen onto which the dilute suspension was distributed from the headbox. Bronze wire life was limited by corrosion attack. Corrosion inhibitor additions were found to be beneficial. Wires coated with tin, nickel, or plastic also gave superior service. Synthetic plastic mesh fabrics are now commonly use for paper machine wires. Although this eliminates the wire corrosion problem, the use of plastic wires appears to have contributed to the increased corrosion of bronze couch rolls. This is attributed to the removal of an effective source of cathodic protection (that is, the metal wires anodically sacrificed themselves and protected the rolls).

Wet End Structures. White water draining through the wire is caught in stainless steel collecting trays and pans. Corrosion is likely to occur wherever pulp deposits can accumulate on metal surfaces. Structural members are generally protected with stainless steel cladding. Where this cladding is incomplete or has been removed, white water can gain access to the underlying structural steel. The white water pits or chests beneath the wet end of a paper machine can be of concrete or tile-lined construction.

Vacuum Pumps. Liquid ring vacuum pumps typically have ductile cast iron rotors (Fig. 4) and gray cast iron casings. From a corrosion standpoint, it is desirable to use fresh seal water. Paper machine white water is considered unsuitable for seal water use because of its high temperature and low pH. Even freshwater may be corrosive if the flow rate is so low that the temperature increases inside the pump or if the freshwater becomes contaminated by excessive white water carryover. A discharge seal water temperature of 50 °C (122 °F) and/or a pH less than 4.5 can cause accelerated cast iron corrosion. High discharge seal water conductivity (in excess of 200 μmho) may indicate excessive white water carryover. Accelerated impeller corrosion can occur at rotor tip speeds above 27 m/s (80 ft/s). The presence of sand or grit in the water will also shorten liquid ring vacuum pump life because of erosion.

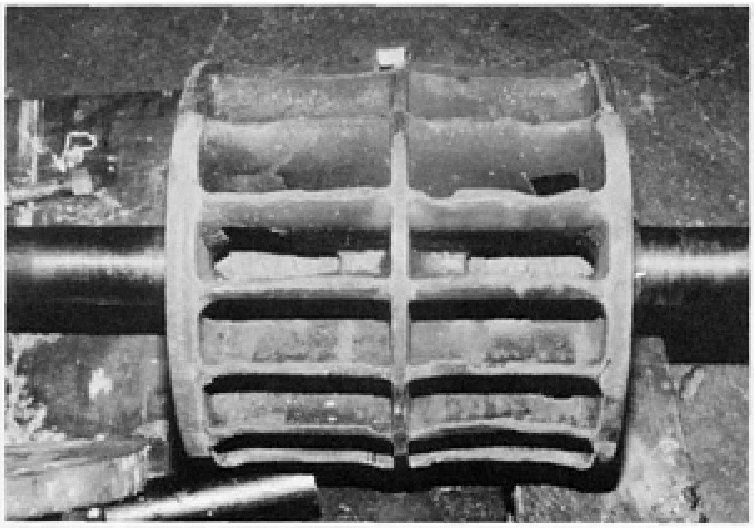

Fig. 4 Corroded ductile iron rotor of a liquid ring vacuum pump

As cast irons corrode in seal water or white water a residue of graphite is left behind (Fig. 5). Pearlitic ductile iron forms a more protective graphic surface layer than ferritic ductile iron because the three-dimensional carbonaceous residue left behind from pearlite dissolution acts as a binder for the graphite (Fig. 6). Rapid liquid ring vacuum pump corrosion can be expected if environmental, velocity, or erosion conditions are such that the protective graphite film is removed. In cases of severe corrosion, liquid ring vacuum pumps have been built with stainless-lined bodies and stainless steel rotors.

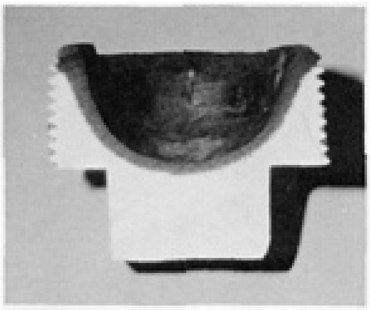

Fig. 5 Cross section of a corroded gray cast iron pipe plug removed from white water service clearly showing the graphite residue left behind as the iron matrix dissolved

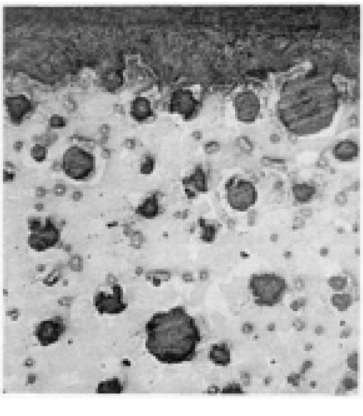

Fig. 6 Micrograph of a cross section of a pearlitic ductile iron coupon exposed for 1872 h in vacuum pump

discharge seal water

Suction Rolls. The corrosion-related failures of suction roll shells represent the most serious materials and corrosion problem in modern paper machines. A variety of alloys are used for suction roll shells, including bronzes and various grades of stainless steel (martensitic, austenitic, duplex, precipitation hardening). Failure are due to corrosion thinning, pitting, corrosion fatigue, and stress-corrosion cracking (SCC). More detailed information can be found in the section "Suction Roll Corrosion" in this article.

Roll Journals. Paper machine roll journals are subject to corrosion fatigue cracking (Fig. 7). Cracking develops at changes in section size--most often where journals meet roll heads. Depending on the location of the roll, the environment causing corrosion fatigue may be the humid paper machine atmosphere or may involve splashing of white water and/or the formation of damp pads of pulp on the journals. Felt roll journals may also be exposed to felt cleaning chemicals, some of which are acidic. Journals are constructed from a variety of materials, including medium-or high-carbon steels, low-alloy steels such as AISI 4140 and AISI 4340, cast irons, and various grades of stainless steel. No material is immune to corrosion fatigue; indeed, there is no fatigue limit below which indefinitely long operation could be guaranteed.

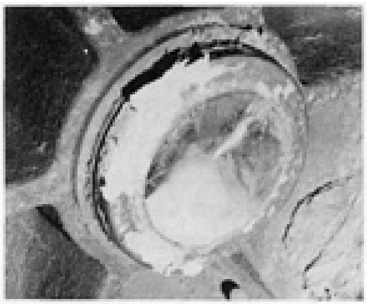

Fig. 7 View of the fracture surface of a felt roll journal that failed by corrosion fatigue. Material of construction is AISI 4140 low-alloy steel quenched and tempered to 300 HB.

Improved corrosion fatigue performance can be realized by protecting journals from the environment, by redesigning to increase their diameter and to remove step changes in section size, by polishing to remove surface flaws, and by selecting a material with superior corrosion fatigue resistance. Wet end roll heads and journals often have stainless steel shields to protect them from exposure to white water. Coatings, including paint and thermally applied metal spray, have also been used to protect journals. The disadvantage of such physical barriers is that they may inspection of surfaces for cracking. Duplex stainless steels and precipitation-hardening steels (such as 17-4PH, condition H1100) appear to offer much better corrosion fatigue resistance than the more conventional journal materials. Integral roll heads and journals made from ductile cast iron also appear to offer superior service if there is a generous radius between the head and journal.

White Water

The wet end of a paper machine produces a uniform paper web from an aqueous suspension of pulp fibers. Stock comes to the paper machine at about 3% consistency and is further diluted to about 0.5 to 1.0% at the fan pump before the headbox. Most of the white water is removed by drainage through the paper machine wire. The white waters from different sources along the wet end are kept separate and the rich white waters (containing more fibers) are recycled for incoming stock dilution. Lean white waters can be used elsewhere on the machine as shower water or as makeup water.

Closure of papermaking systems involves the recycle of white water, either directly or after treatment. The degree of closure can be expressed as the amount of water consumed per air-dried ton (adt) of paper produced. Closed mills may discharge less than 1000 gal/adt per day. An open mill, on the other hand, may discharge over 10,000 gal/adt. Closure results in an increase in the concentration of dissolved inorganic and organic solids, a decrease in pH, and an increase in temperature.

Closure is considered detrimental from a corrosion standpoint; however, there is no clear relationship between increasing closure and paper machine corrosion. Although accelerated corrosion may be expected for construction materials that

undergo general corrosion attack (carbon steels, cast irons, copper alloys), no effect on stainless steel corrosion may be noticed until a critical concentration of aggressive ions and/or temperature is attained. Increasing closure may only serve to decrease the margin of safety for corrosion-free service with a given stainless steel. Beyond a certain degree of closure, spontaneous pitting of the less corrosion-resistant stainless steels (types 304 and 321) may occur. Greater degrees of closure can be tolerated in those mills in which white waters were not particularly corrosive to begin with because the corrosivity of a given white water ultimately depends on its composition.

Composition. Paper machine white waters can vary widely in composition from mill to mill, within a given mill, or even from day to day on a given paper machine. The corrosivity of white water depends primarily on the pH, temperature, and the concentrations of aggressive inorganic anions, such as chloride and thiosulfate. The concentrations of dissolved inorganic compounds found in white waters will depend on whether the wood was seaborne, the type of pulping process used, whether bleaching or brightening was carried out, and the types of chemicals used in the wet end of the machine. The chemicals used include such additives as fillers, sizes, retention aids, defoamers, slimicides, and dyes. Mechanical pulps are often brightened with sodium hydrosulfite, a chemical that decomposes rapidly in the pulp stream to form other sulfur-containing ions that persist in the white water. An average white water composition--typical of a West Coast newsprint mill using a furnish of semibleached kraft and hydrosulfite-brightened thermomechanical pulp and groundwood--is:

Temperature	**118 °F (48 °C)**
pH (initial)	4.6
pH (on standing)	3.0
Sodium chloride (NaCl)	311 ppm
Sodium sulfate	855 ppm
Sodium thiosulfate	34 ppm
Sodium sulfite	75 ppm
Conductivity	1749 μmho

Temperature. It is widely understood that increased temperature is detrimental from a corrosion standpoint. In general, most chemical reaction rates (including corrosion reactions) double for each 10-°C (18-°F) increase in temperature. This is likely the case for general corrosion of carbon steel, cast iron, and copper alloys; however, to initiate pitting corrosion of stainless steels, it is necessary to exceed a certain critical temperature. This critical temperature will be lower at higher chloride concentrations. Closure will contribute to an increase in white water temperature; however, increased temperatures may offer considerable energy savings. High temperatures also help to improve drainage in the wet end of a paper machine, thus permitting an increase in machine speed.

pH. Although there are both acid and alkaline papermaking processes, most papermaking uses the acid process. Typical white water pHs are in the range 4 to 6. The pH is controlled on the acid side by alum additions and/or souring with sulfur dioxide, sulfite, or sulfuric acid.

Below about pH 4, the general corrosion rates of many alloys are accelerated. Hydrogen ions become so plentiful that their reduction replaces the reduction of dissolved oxygen molecules as the predominant cathodic half reaction in the corrosion process. Corrosion processes are no longer diffusion rate limited. Decreased pH also lowers the stability of passive films on stainless steels; this makes the steel more susceptible to pitting initiation and increases the probability that a pit, once initiated, will continue to grow.

The pH of a white water may decrease upon standing; pH may decrease by 0.5 to 2.0 units within approximately 1 day of sampling. The reasons for this decrease are not clear, but it is known that the continued oxidation of dissolved hydrosulfite and bisulfite generates free hydrogen ions. One would expect that white waters kept in storage (for example, during shutdowns) may become more corrosive. It has been observed that the instantaneous corrosion rate of carbon steel (a measure of white water corrosivity) often correlates well with the magnitude of the pH decrease subsequently measured in white water samples. The white waters showing greater pH decreases are those that originally gave higher carbon steel corrosion rates.

Chlorides. Coastal mills that rely on the transportation of logs in seawater may have chloride concentrations ten times higher than those found in inland mills. Chloride ions are very stable in white waters and will tend to build up in

concentration as closure proceeds. Chlorides can cause pitting and crevice corrosion of austenitic stainless steels. Chlorides are also agents for the SCC of stainless steels, but usually at temperatures above 60 °C (140 °F). Stress-corrosion cracking is therefore not a serious problem in most white waters. Chlorides accelerate the general corrosion of carbon steels; however, they do not appear to produce significant acceleration of the corrosion of copper-base alloys.

Sulfates. Sulfate ions (SO_4^{2-}) appear in white water as a residual chemical from the kraft pulping process, from seawater, from alum or sulfuric acid additions, and from the oxidation of more reduced sulfur-containing ions, such as sulfite (SO_3^{2-} or HSO_3^-), thiosulfate ($S_2O_3^{2-}$), and hydrosulfite ($S_2O_4^{2-}$). Sulfate is the thermodynamically stable form of sulfur in white waters.

Sulfate is not an aggressive anion; indeed, it can act as an inhibitor for chloride-related pitting if it is present in (molar) excess over chloride ions. On the other hand, sulfate ions make a significant contribution to white water conductivity and therefore indirectly tend to increase the rates of electrochemical corrosion reactions by facilitating charge transfer in the white water electrolyte. Sulfate ions also provide the food supply for sulfate-reducing bacteria, which in turn cause microbiological corrosion of paper machine equipment. Further, in white waters containing $S_2O_3^{2-}$, an excess of SO_4^{2-} ion is required for thiosulfate pitting to become established.

Thiosulfates. Anaerobic decomposition of warm hydrosulfite solutions produces both thiosulfate and bisulfite ions. Additions of hydrosulfite in excess of that required to meet target paper brightness levels serve only to introduce even more thiosulfate into the white water system. Indeed, it appears that the excess hydrosulfite is very rapidly, and stoichiometrically, converted to thiosulfate. The kinetics of oxidation to sulfate are sufficiently slow that appreciable thiosulfate concentrations can build up.

Thiosulfate concentrations in white water can be reduced by ensuring that the concentration in the original source is as low as possible. Storage of hydrosulfite solutions at 2 to 9 °C (36 to 48 °F) and/or the addition of an alkaline stabilizer to maintain a pH of 10 or more will minimize thiosulfate formation. Thiosulfate ions have been found to be particularly aggressive pitting agents for stainless steels (see the discussion "Thiosulfate Pitting" in this section). Pitting can occur at much lower concentrations (for example, 10 ppm $Na_2S_2O_3$) than that required for chloride pitting (>200 ppm NaCl). Thiosulfates also increase general corrosion rates of copper-base alloys.

Sulfites. Sulfite additions are often made to control the pH of pulp stock. Bisulfite (the stable form of sulfite in white water) is also produced during the decomposition of hydrosulfite brightening solutions. Sulfite is not considered to be aggressive; in fact, sulfites are often used as oxygen-scavenging corrosion inhibitors in other aqueous systems, such as boiler feedwater. Sulfites are readily oxidized to sulfate in the presence of dissolved oxygen. Sulfites may have inhibitive properties in paper machine white water. On the other hand, SO_2 evolution can occur under conditions of high sulfite concentration and low pH, leading to severe atmospheric corrosion problems.

Conductivity. White water conductivity depends on the concentrations of all dissolved ionic species, both inorganic and organic. For carbon steel, cast iron, and copper-base alloys, higher conductivity is an indication of higher corrosivity. This is not the case for stainless steels as long as they are passive and are not undergoing localized corrosion attack.

The corrosivity of carbon steel due to paper machine white water has been monitored by taking instantaneous linear polarization corrosion rate measurements together with simultaneous white water samples for analysis. Linear regression of the carbon steel corrosion rate with individual white water properties reveals that conductivity provides the best regression coefficient, r^2:

Property	r^2
Conductivity	84
ΔpH (on standing)	74
Na_2SO_4	72
NaCl	66
pH (on standing)	64
pH (initial)	18
Temperature	2

Corrosion Mechanisms

Compared with other pulp and paper mill process streams, paper machine white waters are not particularly aggressive. The conventional austenitic stainless steels used for the construction of wetted paper machine components are nonetheless subject to various forms of corrosion attack. The three major corrosion problems affecting stainless steels in paper machine white water systems are:

- Chloride pitting and crevice corrosion
- Thiosulfate pitting
- Microbiological attack

In recent years, there have been reports of rapid attack of type 304 stainless steel equipment in mills where this alloy had served well for decades. The recent unsuitability of type 304 stainless steel can be attributed to closure, hydrosulfite brightening, or both.

Chloride Pitting and Crevice Corrosion. Stainless steels rely on the stable formation of a passive surface film for immunity to corrosion in paper machine white waters. Oxidizing conditions must prevail for the passive film to form and be maintained. Dissolved oxygen from the air is sufficient to maintain stable passivity. Stainless steels can also withstand slightly reducing conditions in white waters without suffering serious attack.

There is a certain safe range of oxidizing conditions within which the stainless steel corrosion potential can vary (these oxidizing conditions can be measured electrochemically as a range of oxidizing potentials). In the presence of aggressive anions such as chlorides, however, this safe potential range is narrowed. If a certain critical corrosion potential (called the breakdown potential) is exceeded, chloride ions can attack the stainless steel surface. The attack manifests itself as pits because passive film breakdown occurs only in isolated locations, such as weak spots in the film due to defects in the underlying metal. Pitting attack is favored by the following conditions:

- Higher chloride concentration
- Higher temperature
- Highly oxidizing conditions
- Low pH
- Stagnant or low-velocity conditions
- Lower molybdenum content in the stainless steel

A new chloride pit tends to repassivate unless the favorable conditions for initiation are maintained until the pit has become established. The metal within the pit becomes anodic with respect to the surrounding metal outside, which becomes cathodic because of ready access to dissolved oxygen for the reduction half of the net corrosion reaction. Anodic dissolution and subsequent hydrolysis of metal ions inside the pit result in the generation of free hydrogen ions, which in turn promote the diffusion of additional anions into the pit to maintain charge neutrality. Because chloride anions are much more mobile than sulfate anions, chlorides preferentially migrate into the pit. Eventually, the solution inside a growing pit may come to resemble a solution of hydrochloric acid more than paper machine white water, and pit growth may continue almost independently of external conditions.

Crevice corrosion initiates beneath deposits or in other areas shielded from direct contact with the white water environment (Fig. 8). Crevice corrosion initiates more readily than pitting attack, which it closely resembles, because the

conditions for an oxygen concentration cell already exist. The metal surface inside a crevice has difficulty maintaining passivity because of reduced access to dissolved oxygen; on the other hand, the surrounding metals has ready access to dissolved oxygen. Passive film breakdown within the crevice is thus facilitated by the natural tendency of the crevice to become anodic and the surrounding metal to become cathodic. Once crevice corrosion is initiated, its growth mechanisms is the same as that for pitting corrosion.

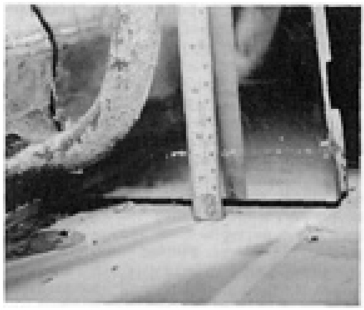

Fig. 8 Crevice corrosion of a type 316L checking plate located adjacent to a headbox apron. Corrosion developed under pulp pads that formed despite the highly polished surface.

The primary corrosion concern with white water system closure is that the critical chloride concentration and/or temperature for stainless steel breakdown will be exceeded. Under such conditions, pitting corrosion may occur spontaneously. This is a particular concern with type 304L stainless steel. Stainless steels are chosen for service in chloride pitting environments on the basis of molybdenum content. Because higher molybdenum alloys are also more expensive, it is common to select the alloy with the minimum molybdenum content required for resistance to pitting. A hierarchy of austenitic alloys, representing increasing resistance to chloride pitting and crevice corrosion, can be listed in increasing order or minimum molybdenum content:

Alloy	**Molybdenum, %**
Type 304L	0
Type 316L	2
SIS 2353	2.5
Type 317L	3
UNS N08904	4
UNS S31254	6
UNS N10276	15

Although type 316L stainless steel has thus far appeared to be resistant under conditions of high closure, it is often produced to have a molybdenum content barely above the minimum of 2% (rather than on the high end of the specified 2 to 3% range). A greater margin of safety for chloride pitting resistance can be ensured by instituting a supplementary requirement that the molybdenum content be no less than 2.5% or by purchasing according to Swedish specification SIS 2353.

Thiosulfate Pitting. Thiosulfate is an aggressive pitting agent, especially for stainless steels that do not contain molybdenum. Thiosulfate pitting, unlike chloride pitting, occurs below, rather than above, a certain critical potential--the thiosulfate reduction potential. Reduction of thiosulfate in the presence of hydrogen ions produces and adsorbed sulfur monolayer on the metal surface. The adsorbed sulfur activates the anodic dissolution of the metal and hinders repassivation. Excess hydrogen ions must be present for acidification of the pit; further, there must also be a larger amount of inert ions (sulfate and chloride) that can be transported into the pit to meet charge transfer requirements. The worst case for thiosulfate pitting occurs within the molar concentration ratio:

$$\frac{Na_2SO_4 + 1/2NaCl}{Na_2S_2O_3} = 10 \text{ to } 20$$

Above the range represented by the ratio, there is insufficient thiosulfate to reach the pit nucleus. Below this range, there is too much thiosulfate reduction, which prevents acidification of the pit.

Thiosulfate corrosion particularly affects those grades of stainless steels that do not contain molybdenum. Once formed, pits are very stable and are not subject to spontaneous repassivation. Scratches encourage the initiation of pits. Few, large pits tend to form rather than many, small pits, as in chloride pitting. Sensitized type 304 stainless steel (weld heat-affected zones, HAZs) is particularly susceptible to thiosulfate pitting. Type 316L stainless steel is the minimum grade that should be used for white water service where high thiosulfate levels may exist. It is recommended that thiosulfate levels be controlled below 5 and 10 ppm for equipment made of type 304 and 316 stainless steel, respectively.

Microbiological Corrosion. Paper machine white waters contain nutrients that can sustain bacterial growth. Microbiological growth thrives in near-neutral pH environments. White water temperatures are also usually within the favorable range of 40 to 50 °C (105 to 120 °F). Although higher temperatures may prevent the growth of some forms of bacteria, increased temperatures can increase the metabolism of those bacteria that can adapt to heat. The result is the formation of slimes.

Stock and white water flow systems are designed to minimize slime accumulations. Surfaces are polished and weld projections removed to prevent hang-ups. Wherever slime deposits can build up, however, microbiological corrosion can occur. Once a deposit has grown to a sufficient thickness to exclude oxygen, a colony of sulfate-reducing bacteria (*Desulfovibrio desulfuricans*) can become established. Enzymes produced by these anaerobic bacteria catalyze the reduction of sulfates to form free sulfide ions. Chemically reducing conditions quickly develop, resulting in the depassivation of the stainless steel surface beneath the deposit. Active corrosion in the form of pitting then proceeds.

Corrosion due to *Desulfovibrio desulfuricans* is manisfested by the presence of large, shallow pits covered with a black crust (Fig. 9). Perforations through stainless steel equipment are usually small because the entry of oxygen at a leak will stop the activity of sulfate-reducing bacteria (Fig. 10).

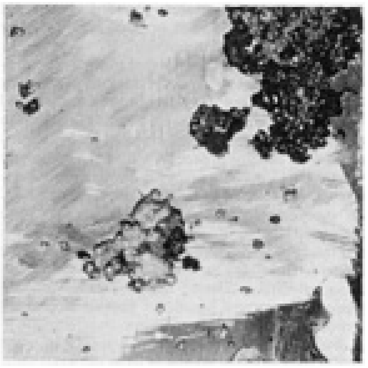

Fig. 9 Section of type 304L stainless steel plate removed from a tapered header used to deliver stock to a headbox showing severe microbiological corrosion

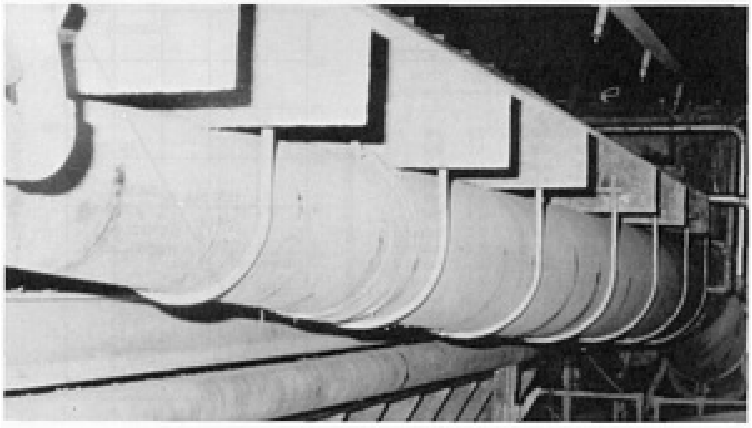

Fig. 10 External view of the type 304L stainless steel tapered header in Fig. 9, showing leakage occurring at small perforations

Corrosion Control in Pulp Bleach Plants

Andrew Garner, Pulp and Paper Research Institute of Canada

Pulp mill bleach plants have traditionally used austenitic stainless steels because of their combination of good corrosion resistance and weldability. Type 317L (18Cr-14Ni-3.5Mo) has been the typical bleach plant alloy for oxidizing acid chloride environments. However, bleach plants have become more corrosive over the past 20 years as mills have closed wash water systems and reduced effluent volumes. In modern closed bleach plants, type 317L is no longer adequate for long-term service (Ref 1), and many mills have turned to higher-alloy stainless steels, nickel-base alloys, and titanium for better corrosion resistance. Metals are chosen over nonmetals for moving equipment, such as washers. Metals are stronger, tougher, have better fatigue properties, and, if they have sufficient corrosion resistance, require virtually no maintenance. However, the more corrosion-resistant alloys are more costly, and the challenge is to choose an alloy with just enough resistance to avoid corrosion problems.

A wide selection of alloys is available for bleach plant applications. The list includes three families of stainless steels (austenitic, ferritic, and duplex), whose differing merits are outlined in Table 1. Table 2 list most of the commercially available candidate alloys and their chemical compositions. Table 3 outlines the influence of each alloy component on bleach plant corrosion resistance.

Table 1 Characteristics of three families of stainless steels for bleach plant service

Family	Examples	Characteristics	Comments
Austenitics	316L 317L 904L 254SMO AL-6XN	Tough, ductile, readily welded without loss of corrosion resistance; corrosion resistance related to alloy content	Bleach plant steels traditionally chosen from this group
	Nitronic 50	As above, with better pitting resistance than type 317L	Manganese-substituted austenitic, may be better value than type 317L; not common at present
Ferritics			
Low-interstitial type	29-4-2 29-4	Not as tough as austenitics, particularly after welding thicker sections. Special precautions needed for welding to avoid N_2 pickup. Corrosion resistance, related to alloy content, can be very good.	Higher alloys have remarkable corrosion resistance. Thin-section (<3 mm, or 0.120 in.) may find applications as corrugated deck or tubing; not common at present. (C + N) $\leq$ 0.025%
Ti- or Ti + Nb stabilized type	29-4C NYBY MONIT SEA-CURE	0.02% C max versions	Less expensive 0.02% C version of low-interstitial ferritics, for thin-section weldments ($\leq$1.14 mm, or 0.045 in.)
Duplex	2205 Ferralium	Tough, ductile, should be weldable without significant loss in corrosion resistance	Combines toughness and corrosion resistance of austenitics and ferritics. Can be made highly resistant to SCC

Table 3 Effect of alloy components on the corrosion resistance of stainless steels in bleach plant applications

Element	Effect	Comments
Beneficial alloy additions		
Chromium	Enhances resistance to initiation of pitting and crevice corrosion	Steel must have more than 11% Cr to exhibit stainless property
Nickel	Enhances resistance to propagation of pitting and crevice corrosion	Higher levels of nickel enable partly corroded component to remain functional; little or no nickel in ferritic grades
Molybdenum	Enhances resistance to initiation and propagation of pitting and crevice corrosion	Over three times more effective than chromium against pitting and crevice attack, but has solubility limit of about 7% in stainless steels
Nitrogen	Enhances pitting resistance, particularly in combination with molybdenum	Used in austenitic and duplex grades only; increases strength of the steel
Detrimental residual elements		
Carbon	More than 0.03% can cause sensitization, making heat-affected zones of welds less corrosion resistant.	Oxidized out of steel during refining, down to limit set by simultaneous, costly, chromium oxidation
Phosphorus	Can cause hot cracking, that is, cracks formed in weld metal upon cooling. Hot cracks are sites for crevice corrosion, which looks like pitting attack.	Can only be controlled by use of low-phosphorus charge materials. Less than 0.015% P is respectable.
Sulfur	As with phosphorus, can cause hot cracking	Can be controlled to very low levels (<0.005% S) by good steel-making practice. Less than 0.015% S is respectable. Less than 0.005% S is excellent.

Note: Silicon, manganese, and copper are added for steelmaking reasons or sulfuric acid resistance (copper).

Austenitic stainless steels, including the AISI 300 series and enriched variations of these steels, are tough and easy to weld. Their corrosion resistance ranges from fair to excellent, depending on the alloy content (Table 1).

Ferritic stainless steels in the 400 series are not used in bleach plants, because of their poor corrosion resistance, particularly after welding. However, there is a new generation of extralow carbon and nitrogen (low interstitial) grades that retain postweld corrosion resistance. As with austenitic stainless steels, the corrosion resistance of these ferritic stainless steels ranges from fair to excellent, depending on alloy content. However, steels such as 29-4 have not been used in the bleach plant, because of problems with embrittling precipitation in thicker sections (3 mm, or 0.12 in., and over) and because of the special precautions required to avoid nitrogen contamination during welding.

In contrast to the ferritic grades, the properties of austenitic and duplex stainless steels are enhanced by nitrogen. As a result, duplex stainless steels such as 2205 and Ferralium 255 have recently been developed with improved corrosion resistance.

Laboratory Assessment of Candidate Alloys

The relative corrosion resistance of stainless steels and nickel-base alloys can be assessed with the ferric chloride ($FeCl_3$) test, which was recently shown to be an appropriate assessment of bleach plant performance (Ref. 1). The relative resistance to pitting corrosion of a range of commercial stainless steels is shown in Fig. 11. A critical temperature has been measured for each alloy below which no pitting will occur in $FeCl_3$ (Ref 2, 3). The higher the cited pitting temperature, the more resistant the steel is to pitting. Steels such as type 316L and 317L, for example, have comparatively poor pitting resistance. The 904L-type alloys with about 4.5% Mo provide somewhat better pitting resistance, and the 6% Mo steels, such as 254SMO, are remarkably resistant. Based on these results, one might predict that the duplex steel. Ferralium 255, and the manganese-substituted austenitic, Nitronic 50, should outperform type 317L in the bleach plant.

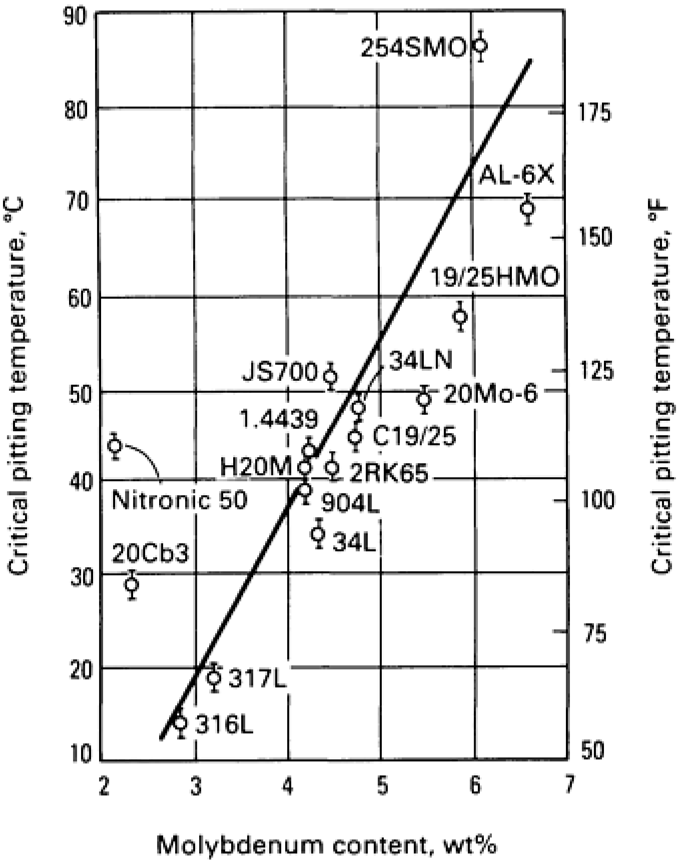

Fig. 11 Effect of molybdenum content on the $FeCl_3$ critical pitting temperature of commercial stainless steels. The more resistant steels have higher critical pitting temperatures

Generally, similar conclusions can be drawn from crevice corrosion tests in $FeCl_3$ (Ref 4, 5). Such data are presented in Fig. 12 and 13. The critical temperatures for crevice corrosion are lower than those for pitting, indicating that crevice corrosion is more readily initiated. If equipment is not designed to avoid crevice corrosion, then this will be the mode of failure. An example of this form of attack is shown in Fig. 14, which shows a type 317L corrugated deck from a C-stage washer that failed because of crevice corrosion.

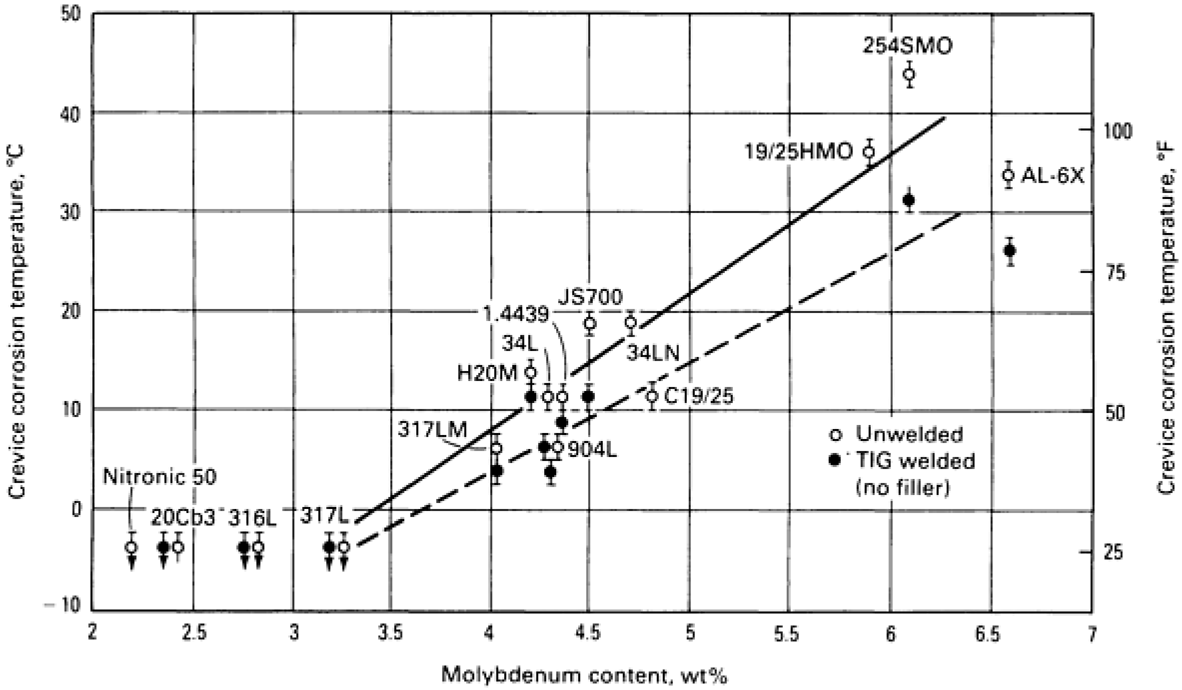

Fig. 12 Effect of molybdenum content on the crevice corrosion temperature of commercial stainless steels. The more resistant steels have higher crevice corrosion temperatures in the $FeCl_3$ test.

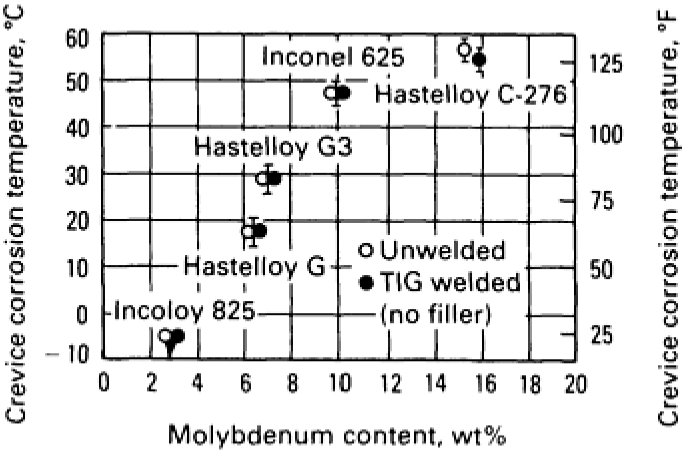

Fig. 13 Effect of molybdenum content on the crevice corrosion temperature of nickel-base alloys. Note the superior performance of Inconel alloy 625 and Hastelloy alloy C-276. Compare with Fig. 12.

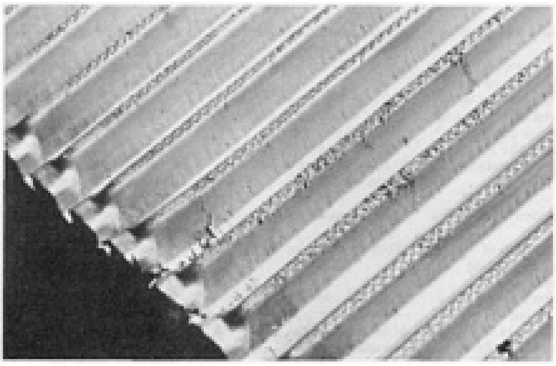

Fig. 14 Failure of corrugated type 317L washer-deck commonly associated with crevice corrosion

Field Testing of Candidate Alloys

Field testing of candidate alloys has been performed by a number of researchers (Ref 1, 6, 7, 8, 9). An early study measured pitting attack on a range of welded alloys in comparatively benign Nordic bleach plants (Ref 6). Pitting and crevice attack were later tested in more closed (more corrosive) Canadian bleach plants. This program focused on a few representative alloys, examined the selection of welding electrodes, and compared gaseous and liquid exposure in C- and D-stage washers (Ref 1). Figure 15 shows the corrosion products covering stainless steel test coupons that were exposed to a D-stage washer environment.

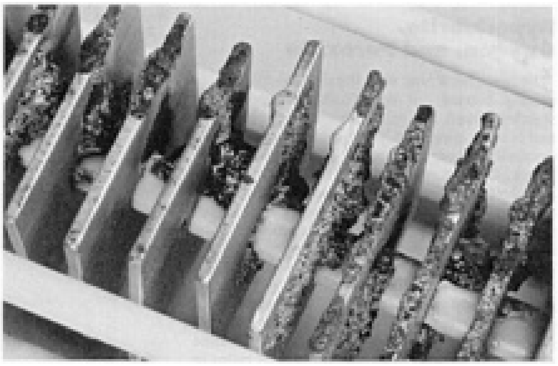

Fig. 15 Stainless steel coupons of type 316L, 317L, and 904L on a rack exposed below the incoming stock of a D-stage washer. Profuse ferrous oxide corrosion products cover the coupons.

Two other exposure programs of note were carried out by the Technical Association of the Pulp and Paper Industry (TAPPI) Corrosion and Materials Engineering Committee in U.S. and Canadian mills. Unwelded alloys were tested in the first program (Ref 7), while the second program tested welded alloys (Ref 8, 9). The alloys tested included almost all available choices for bleach plant application. However, alloy development has been such an active field in recent years, other promising steel, such as Ferralium 255, AL-6XN, and 29-4C, have been commercialized since the comprehensive TAPPI exposure programs.

Data from all these test rack programs can be interpreted as follows:

- The premium bleach plant alloy of the future: It will probably be chosen from 254SMO, Hastelloy alloy G-3, Sanicro 28, or 20Mo-6; VDM Cronifer 19/25 HMO, AL-6XN, and 29-4C (thin section) were not tested, but they should also be competitive
- Attractive alloys close to the type 317L cost level: Nitronic 50 and 1.4439 (317LMN) are promising

alternatives to type 317L. Ferralium 255 was not tested but should also be competitive

- Alloys with less competitive price of performance: Titanium, Hastelloy alloy C-276, Inconel alloy 625, and 29-4-2 all performed exceptionally well, but are expensive; 904L and related alloys appear to perform slightly below the level required for a premium alloy

Bleach Plant Environments

Residual oxidants, such as chlorine (Cl_2) and chlorine dioxide (ClO_2), are the primary cause of corrosion in the bleach plant. The corrosive influence of Cl_2 has been demonstrated with coupon testing at higher Cl_2 levels (Fig. 16) (Ref 10); other work has indirectly identified 25 ppm Cl_2 or ClO_2 as the level above which corrosion reactions are driven by residual oxidants (Ref 11). It seems probable that the 25 ppm of Cl_2 determined by iodine titration is close to zero actual Cl_2, because the titration is also sensitive to traces of oxidizing organics present in C-stage filtrates.

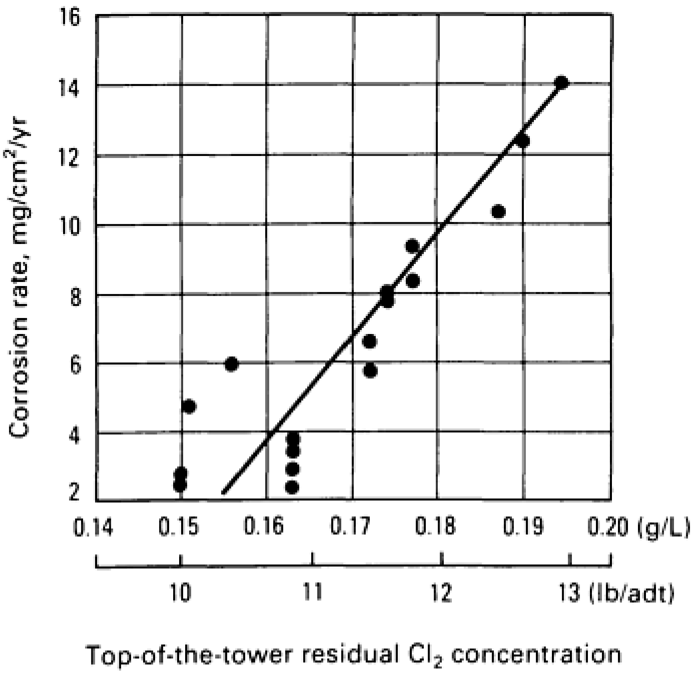

Fig. 16 Effect of residual chlorine on the corrosion rate of test coupons in the C-stage washer

Any steps that can be taken to lower residual oxidants to below 25 ppm will lower corrosion rates. Options include automatic chlorine control; chlorine dioxide sensor/controls, SO_2 antichlor, and NaOH additions (ClO_2 is not very corrosive at pH 7, and NaOH additions to a pH 4 filtrate will transform ClO_2 to ClO_2^- after a few hours).

Recycling of filtrates can compound corrosion problems. For example, residual ClO_2 can be recycled with a D2-stage filtrate to the D1-stage washer showers; therefore, an increase from 50 to 150 ppm ClO_2 has been measured in a D1-stage filtrate when D2-stage SO_2 additions were cut off during high ClO_2 usage. Recycling of D1- or D2-stage filtrate to the C-stage washer should be avoided completely, because the more acidic C-stage filtrate (pH 2) regenerates ClO_2 from chlorite ions, thus rendering the shower water highly corrosive to stainless steels. Many C-stage washers were lost because of this practice when recycling was first carried out.

Effect of Temperature, Chlorides, and pH

Temperatures and chloride ion concentrations are raised after bleach plant closure (Ref 1). The influence of these two changes on corrosion, although significant, is usually far overshadowed by the corrosive effect of residual oxidants. Typical environmental conditions for bleach plant washers are given in Table 4.

Table 4 Typical environmental conditions for bleach plant washers

Environment	Chlorination	Chlorine dioxide	Hypochlorite
Oxidant	30 ppm	30 ppm	30 ppm
	Cl_2	ClO_2	NaOCl
pH	2	4	9
Temperature, °C (°F)	45 (115)	65 (150)	40 (105)
Chloride ion (Cl^-), ppm	1500	1000	2000
Electrochemical potentials, mV_{SCE}			
Redox potential	1000	500	. . .
Washer potential	750	500	. . .

Recycling can lower pH in all acidic washing stages. Lower pH will create a corrosion problem only during the last stage of bleach plant closure, namely when C-stage filtrate is used for C-stage tower dilution. With this practice, lower pH can give the pulp the viscosity protection required for the consequent higher-temperature chlorination. However, when pH decreases to 1.5 or 1.2 as compared to the normal pH 2, stainless steel corrosion rates increase dramatically. It is probable that a critical lower limit pH exists for any given stainless below which corrosion rates are high, but such limits have not yet been identified with any degree of certainty. What can be assumed is that more highly alloyed materials should have lower limiting pHs and that nickel and molybdenum should be the most influential alloying elements.

Vapor-Phase Corrosion

The corrosion of nonwetted components, such as shower pipes and metal vats above the stock level, is a major problem in C-stage washers. This attack is caused by excess chlorination, in which gaseous chlorine from the filtrate makes small droplets of condensation highly corrosive. Chlorination stage gas-phase attack is probably the most aggressive in all the bleach plant. Methods of avoiding this problem include improving chlorine control; using titanium or nonmetallic-coated shower pipes; and, for stainless steel vats, cladding with 6% Mo stainless or nickel-base alloys to just below the liquid level or lining the whole vat with nonmetallic coating (good design and workmanship is essential).

The vapor space above D-stage washers is not very corrosive unless SO_2 is used in excess, is poorly controlled, or is badly mixed. When both SO_2 and ClO_2 are present in the vapor space, any condensation will contain hydrochloric acid (HCl) and sulfuric acid (H_2SO_4), mixtures of which are very corrosive to stainless steel.

D-Stage Washer Corrosion

Sodium hydroxide or SO_2 additions are made to bleached pulp before the pulp machine in order to improve drainage and to limit brightness reversion. Such additions are often made before the D2 washer so that the washer may also be protected from residual-related corrosion. In some cases, SO_2 additions are made before the D1-stage washer for corrosion protection, and in Nordic countries, SO_2 is even added before some C-stage washers. Sulfur dioxide additions are an effective (if costly) way of limiting corrosion; they work because SO_2 reacts irreversibly with the residual oxidant to form nonoxidizing reaction products, for example, with ClO_2 (Ref 1):

$$2ClO_2 + 5SO_2 + 6H_2O \rightarrow 2HCl + 5H_2SO_4$$

The amount of acid formed by this reaction has a negligible effect on washer corrosion, and sufficient SO_2 should be used to maintain a trace of residual SO_2 at all times. Sulfur dioxide control can be automatic or manual; in the latter case, a target maximum pH of 3 is often used for additions before the D2-stage washer.

If SO_2 additions are discontinued--for example, because of SO_2 shortages--rust nodules or "barnacles" may appear within a few weeks on the washer (Fig. 15). Residual ClO_2 (present because SO_2 was discontinued) has caused the iron oxide [FeO(OH)] corrosion deposits to form (Ref 1). The deposits are insoluble above pH 3.5, and their presence exacerbates the corrosion problem, because additional under-deposit formation occurs. Deposits can be avoided by increasing the pH to above 5.5 (target pH 7) with NaOH and by holding residual ClO_2 to less than 25 ppm.

When a D-stage washer drum has been in operation for a number of years it is not advisable to change to C-stage service if there is any evidence of rust deposit. The deposits may plug corrosion pits, and in C-stage washing at pH 2, the deposits will be dissolved quickly, causing the washer to leak.

Hypochlorite, Oxygen, and Peroxide

Because bleaching with these three oxidants is usually carried out under alkaline conditions, stainless steels are much less subject to pitting the crevice corrosion. Hypochlorite washers are commonly made of type 316L to resist crevice attack. Oxygen reactors are often made of high-nickel stainless steels such as 20Cb3 to guard against chloride SCC, which can occur at higher temperatures in pressure vessels. Some lower alloys have been used in this latter application, apparently without problems, although type 304 stainless steel has failed by chloride SCC. However, chloride pitting corrosion can also occur in oxygen reactors, and alloys containing higher molybdenum levels may be necessary. Alkaline peroxide is used to brighten mechanical pulps in newsprint production without any corrosion consequences. Peroxide has also been used in place of ClO_2 in chemical-pulp bleach plants and appears to present no more corrosion problems than ClO_2.

Corrosion of Welds

Stainless steel washers fail occasionally because of weld-related corrosion. The principal causes of weld-related corrosion are detailed in Table 5 and outlined in Ref 12.

Table 5 Principal causes of corrosion of austenitic stainless steel weldments

Attack site and mode	Reason for attack	When is it a problem?	How to avoid
Weld metal			
Pitting	Welding with no filler	All molybdenum-containing austenitics[(a)]	Use appropriate filler.
	Welding with underalloyed filler	3 to 6% Mo austenitics[(a)]	Use appropriate filler, for example, IN112.
Crevice corrosion	Microfissures in weld metal create sites for crevice corrosion (looks like pitting)	In ferrite-free stainless steel weld metal, for example, fillers commonly recommended for 904L[(a)]	Use IN112 electrode for 3 to 6% Mo austenitics.
	Lack of penetration	In one-side or stitched butt-weld joints	Ensure full penetration, and do not use stitchwelds on process side.
	Entrapped welding flux	Shielded metal arc welded joints	Use electrode with good flux detachment.
Heat-affected zone	Precipitation of carbides during welding	When steel has over 0.03% C	Use steel with 0.03% C max.
Fusion line	Unmixed zone formed at fusion line	With high-alloy steels close to their corrosion limits	Use lower heat input on final pass.
	Precipitation of carbides at fusion line (knife-line attack)	In niobium- or titanium-stabilized steels	A very rare problem. Niobium- and titanium-stabilized steels not common

(a) Particularly after high heat input welding

Welding without filler metal creates a preferential attack site on austenitic stainless steel and should be avoided in washer construction. It is important not to select a filler metal that gives a deposit that is less corrosion resistant than the base metal. For type 316L, the American Welding Society standard filler is adequate (Ref 13). However, for type 317L and the more highly alloyed materials, recent field and laboratory tests have shown that a filler metal with a composition similar to that of the base metal can have much lower pitting resistance (Ref 1, 14).

The optimal weld metal for all 4.5 to 6% Mo austenitic stainless steels is Inconel alloy 112 or an equivalent (for example, Inconel alloy 625 or Avesta alloy P12). Inconel alloy 112 is a good choice because:

- It is metallurgically compatible with all austenitic stainless steels
- As-welded Inconel alloy 112 is highly resistant to pitting and crevice corrosion
- There is no significant galvanic effect between Inconel alloy 112 and austenitic stainless steels in bleach plant liquors
- If microfissures or hot cracks occur in the weld metal, they will not be preferentially attacked by crevice corrosion. This is a particular problem for most ferrite-free stainless steel fillers

Microfissuring or hot cracking is a phenomenon associated with thermal stresses during welding. These stresses usually cause small cracks to form in the weld metal or HAZ of a stainless steel or nickel-base alloy weldment. Higher nickel content alloys, which have a greater coefficient of thermal expansion, are more susceptible to hot cracking. Cracking is more likely to occur because of higher phosphorus (>0.015% P) and sulfur (>0.015% S) in the alloy or contamination of the weld area. It is most commonly seen in the HAZ in the previous pass of a multiple-pass weld. Hot cracking rarely has a detrimental effect on the mechanical properties or structural integrity of a fabrication. However, it can be very detrimental to the corrosion properties of a weldment. Microfissures form crevice corrosion sites that are readily attacked.

Recent laboratory tests have shown that other fillers can be used for 904L, such as Sanicro 27.31.4L CuR, Smitweld NiCro 31/27, and Thermanit 30/40 E. These fillers would be appropriate for microfissure-free shop construction. However, contaminated weldments are best repaired with Inconel alloy 112 or an equivalent filler.

Another common problem with stainless steel weldments--sensitization in the HAZ--is avoided in bleach plants by the use of low-carbon steels (0.03% C max for austenitics). Similarly, fusion-line attack (sometimes called knife-line attack) due to precipitation of carbides at the fusion line in niobium- and titanium-stabilized austenitic steels is rarely seen, because these steels have been made obsolescent by new steelmaking technology.

However, attack at the fusion line is possible when overalloyed fillers such as Inconel alloy 112 are used with high heat input welding. Such welding can create zones consisting of melted base metal that is not mixed with weld filler--called unmixed zones--at the fusion line. Cases of unmixed zone corrosion have occasionally been observed in the bleach plant. In practice, this can be minimized by the use of lower heat input on the final weld passes.

Electrochemical Protection

The discussion thus far has centered on the selection of material or the control of the environment to minimize corrosion. A third approach has recently become available with the development of electrochemical protection for bleach plant washers (Ref 10, 15, 16).

General Description. The life of a stainless steel washer can be greatly extended if the washer is cathodically polarized from the oxidizing potentials imposed by residual oxidants such as chlorine (Fig. 17) to a more negative, passive potential by the use of a rectifier and a platinized anode mounted in the washer vat (Fig. 18). Electrical contact to the washer is made through a rotating mercury contactor; the washer potential is measured with a reference electrode and is automatically controlled with a feedback-controlled rectifier to a potential set point or window that minimizes corrosive attack.

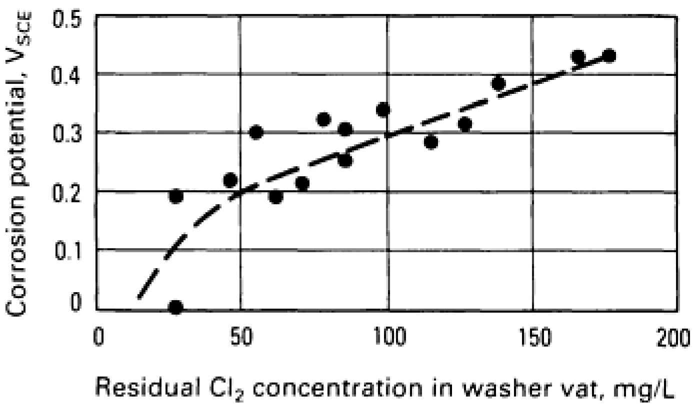

Fig. 17 Effect of residual Cl_2 concentration in the washer vat on the free-corrosion potential of a type 317L stainless steel bleach plant washer. Source: Ref 15

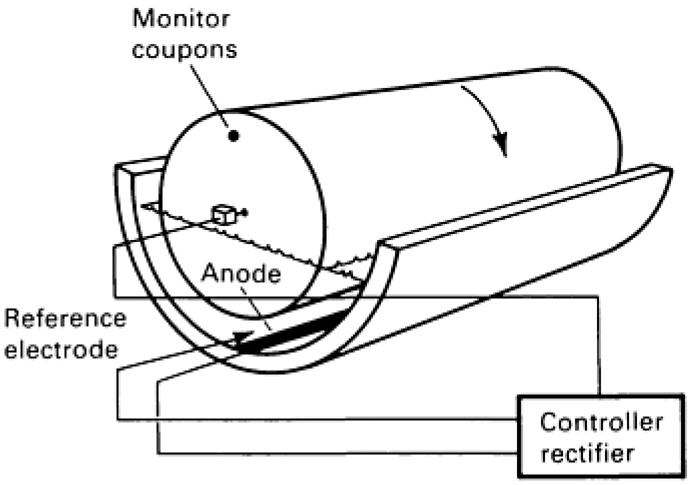

Fig. 18 Components of a washer electrochemical protection system

Principle of Protection. A detailed description of the principle of electrochemical protection is provided in Ref 15. However, the essential feature of the technique is the use of the electron as an antichlor for corrosion protection. Electrons are fed from the rectifier to the washer in the form of electric current. At the washer surface, they react with chlorine (Ref 2):

$$Cl_2 + 2e^- \rightarrow 2Cl^-$$

Therefore, like SO_2, electrons react with the corrosive oxidant (chlorine) to form relatively harmless chloride ions. For corrosion protection, the electron has a clear advantage over SO_2: It can be delivered to the cathodic reaction site. For this reason, comparatively few electrons are needed. The required current is low, and running costs are negligible.

Because of the comparatively low cost of electrochemical protection and the ease of retrofitting to existing washers, commercialization of the technique has found wide acceptance. The first successful operation of one of these systems was in Nova Scotia, Canada, in 1978. By the end of 1986, there were about 90 installations worldwide.

Monitoring Technique. The corrosion rate of each protected washer is monitored with coupons, using a technique designed for comparison of protected and unprotected coupons (Ref 17). A mounting bolt is welded to the end face of the rotating washer as shown in Fig. 18, and two coupons, together with segmented crevicing disks, are mounted so that one is in electrical contact with the washer and the other is isolated, with all other mounting details being identical (Fig. 19).

The degree of protection is assessed by comparing the corrosion of protected and unprotected coupons after a 60-day exposure period (Fig. 20).

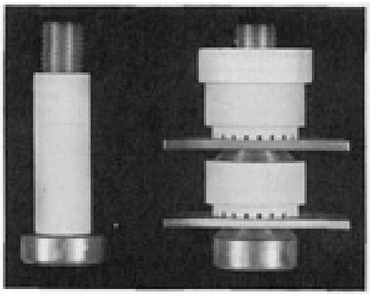

Fig. 19 Crevice corrosion monitor assembly

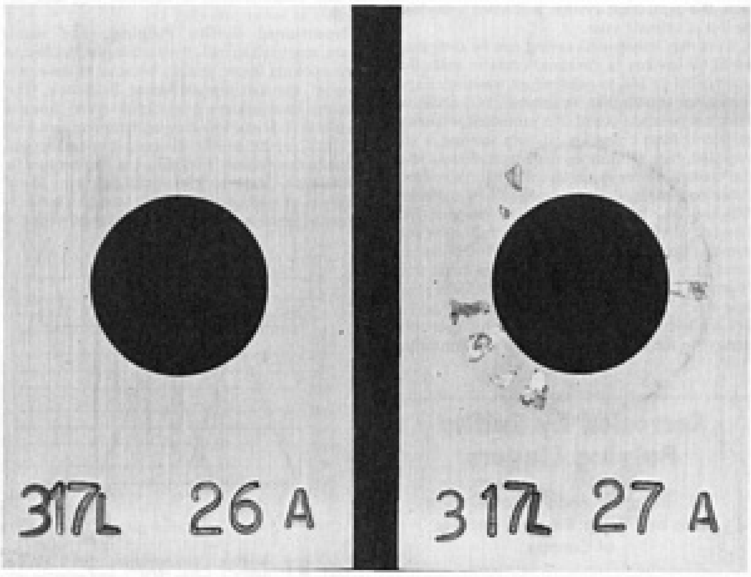

Fig. 20 Type 317L stainless steel monitor coupons after a 60-day exposure attached to a C-stage washer. The coupon on the left was in electrical contact with the washer and was therefore protected. The coupon on the right was isolated and unprotected. Substantial crevice corrosion occurred on the right-hand coupon at 7 of the 20 possible crevicing sites.

Results to Date. Both weight loss and depth of attack measurements have been made on coupons to assess the comparative severity of pitting or crevice corrosion (Ref 10). The ratio of unprotected and protected coupon weight loss is used as a measure of protection. Table 6 lists protection ratios measured for washers that have been protected for up to 5 years (6 washers types/212 test coupons). These results show that protection lowers corrosion rates. On the average, unprotected coupons lose six times more weight than protected coupons.

Table 6 Type 317L test coupon data from the first six electrochemical protection systems

Washer	Protection period, years	Average protection ratio[(a)]
C-stage	5.4	4.9
D2-stage	4.0	2.6
D2-stage	3.3	12.3
D1-stage	2.9	8.2
D2-stage	2.9	1.9
D1-stage	1.8	6.2
General average	**6.0**	

(a) Unprotected ÷ protected type 317L coupon weight loss (larger ratios indicate better performance).

Improved performance with protection can be compared with improved performance after alloy upgrading in the absence of protection. The results of an extensive bleach plant exposure program, which involved 880 coupons, 40 test racks, 10 mills, and no electrochemical protection (Ref 1), were reexamined to obtain the average weight loss ratios (using type 317L as a base case) for alloys 904L and 254SMO. These data are given in Table 7; greater ratios indicate better performance. Type 317L coupons lose 5.5 times as much weight as 254SMO coupons. Therefore, the improved performance achieved by the electrochemical protection of type 317L appears to be very close to that gained by upgrading type 317L to unprotected 254SMO.

Table 7 Test rack weight loss data for unprotected steels

Steel	**Average weight loss ratio[(a)]**
Type 317L	1
904L	2.5
254SMO	5.5

(a) This ratio is obtained, for example, by determining the average weight loss for type 317L coupons ÷ average weight loss for 904L coupons (larger ratios indicate better performance).

Economics. The installation and operating costs of electrochemical protection systems are small compared to the resulting cost savings. Capital cost savings are such that if the life of a washer is extended from 5 to 10 years by protection, the protection system will have a payback period of about 1 year.

Even this substantial saving can be overshadowed by savings in chemical costs in mills that add NaOH or SO_2 to pulp before washing. Experience has shown that, in general, SO_2 additions need not be made ahead of a protected washer to protect it from corrosion. If pulp souring is still required, then this can be done immediately after the washer, where much less SO_2 will be needed. Additional savings can be realized by eliminating SO_2 use in a closed bleach plant, because SO_2 free recycled filtrate used for tower dilution consumes much less unreacted ClO_2. Protection systems have been installed on washers made from types 316L, 317L, and 904L, and 254SMO stainless steels. A protected 254SMO washer probably represents the state-of-the-art for corrosion control in the most severe washer environments.

Corrosion by Sulfite Pulping Liquors

C.B. Thompson and Andrew Garner, Pulp and Paper Research Institute of Canada

Sulfite pulping, one of the oldest methods of chemical pulping, dates back to the 1860s. For many years, sulfite pulping was the primary chemical method for making paper, although since the 1950s it has been overtaken in importance by the

kraft process to such an extent that the sulfite industry was perceived by many as dying out. In recent years, however, a growing appreciation of the versatility of the sulfite process and the appearance of combined sulfite and mechanical pulping methods (semichemical or chemi-mechanical) have combined to ensure the future of sulfite pulping. These changes in the industry are thoroughly documented in Ref 18).

This section will discuss the various methods of sulfite pulping, the principal corrosion mechanisms occurring in sulfite environments, and the major corrosion problem areas found in sulfite mills. Information on corrosion in the disk refiners used in the later stages of semichemical and chemi-mechanical pulping can be found in the section "Corrosion of Mechanical Pulping Equipment" in this article.

Sulfite Pulping

Sulfite Chemistry. Sulfite pulping liquors are prepared by dissolving SO_2 in a solution of calcium, sodium, magnesium, or ammonium hydroxide. The pH of the resultant cooking liquor depends on the base and the amount of SO_2 dissolved, and it can range from 1 to above 13. The exact value is chosen according to the particular mill process and the desired pulp characteristics. Fresh sulfite liquor is essentially a mixture of sulfite and bisulfite ions in an aqueous solution of SO_2. The ratios of these three components can vary widely, according to the liquor pH. The relative concentrations of bisulfite and sulfite ions a different pH levels are shown in Fig. 21; bisulfite dominates at pH values less than 6, while sulfite ions dominate at pH values above 7. The concentration of aqueous SO_2 also increases at lower pHs (Ref 19).

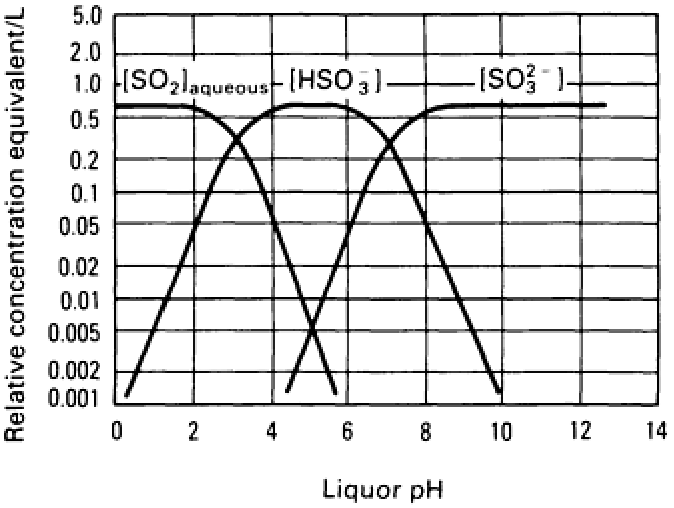

Fig. 21 Relative concentrations of bisulfite (HSO_3^-), sulfite (SO_3^{2-}), and aqueous sulfur dioxide (SO_2) as a function of liquor pH at 130 °C (265 °F). Aqueous sulfur dioxide and bisulfite dominate at acidic pHs, sulfite dominates at alkaline pHs. Source: Ref 19

Traditional Sulfite Pulping. For many years, most sulfite mills used a calcium hydroxide base cooking liquor, mainly because of the economy of the calcium carbonate feedstock. The calcium-base process is restricted to very low pH (typically 1.5) and low cooking temperatures (140 to 150 °C, or 295 to 300 °F) because of scaling and solubility problems. Furthermore, the process is difficult to adapt to high-yield pulping. These reasons, as well as increasingly stringent antipollution legislation, have led to the expanded use of soluble sodium, magnesium, and ammonium bases in recent years.

A typical sulfite operation is shown in Fig. 22. Sulfur (either in powder or liquid form) is burned to produce SO_2. The gas is cooled rapidly to minimize the formation of sulfur trioxide (SO_3) and then passed into absorption towers, where it is

dissolved in the hydroxide base to form the raw pulping liquor. Pulping is carried out in either batch or continuous digesters; when the cook is complete the chips are released into a blow tank. The chips are then taken for washing, screening, and bleaching as required. The spent cooking liquor (red liquor) can be evaporated and burned in a furnace for steam generation and/or recovery of cooking chemicals, or it can be further treated to obtain chemical by-products. A typical operation might also include equipment for SO_2 recovery from the cook and an acid accumulator.

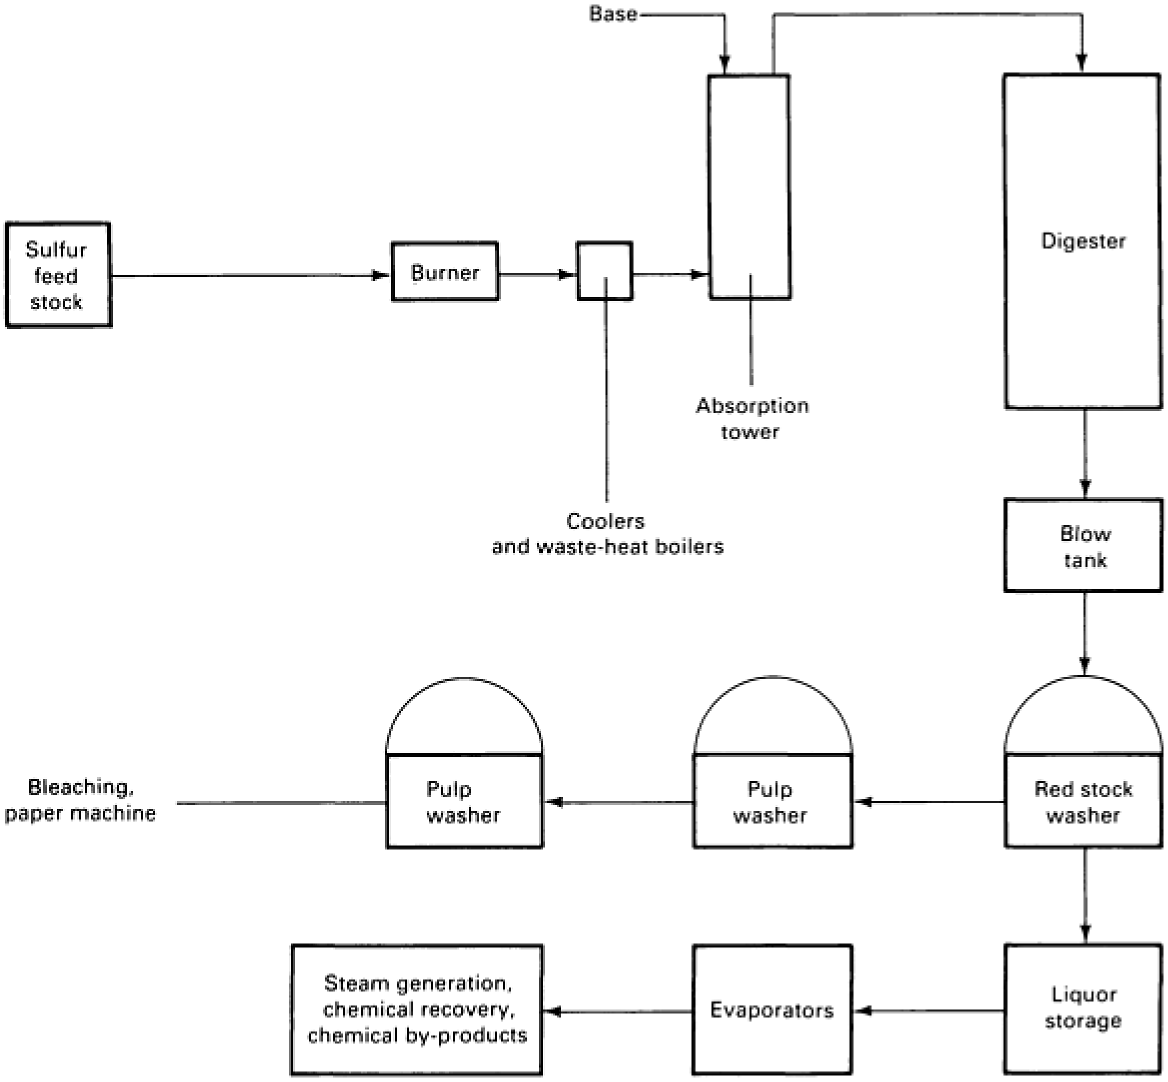

Fig. 22 Typical layout for a traditional low-yield sulfite mill operation

Recent developments in sulfite mills have centered around the need to decrease pollution, to increase pulping efficiency (that is, increase the proportion of usable fiber obtained per cook), and to adapt to market demands for specific grades of pulp. These requirements have resulted in a variety of processes, such as high-yield sulfite pulping and chemi-thermomechanical pulping, in which sulfite chemical treatment of the chips is combined with additional treatment of the fiber in a disk refiner. The interrelationship of these process with pure chemical pulping and pure mechanical pulping is shown in Fig. 23. An important practical point to note is that high-yield and very high-yield sulfite pulping require the use of a digester, but chemi-mechanical and chemi-thermomechanical pulping use smaller impregnation vessels or steaming tubes for pretreatment of the chips.

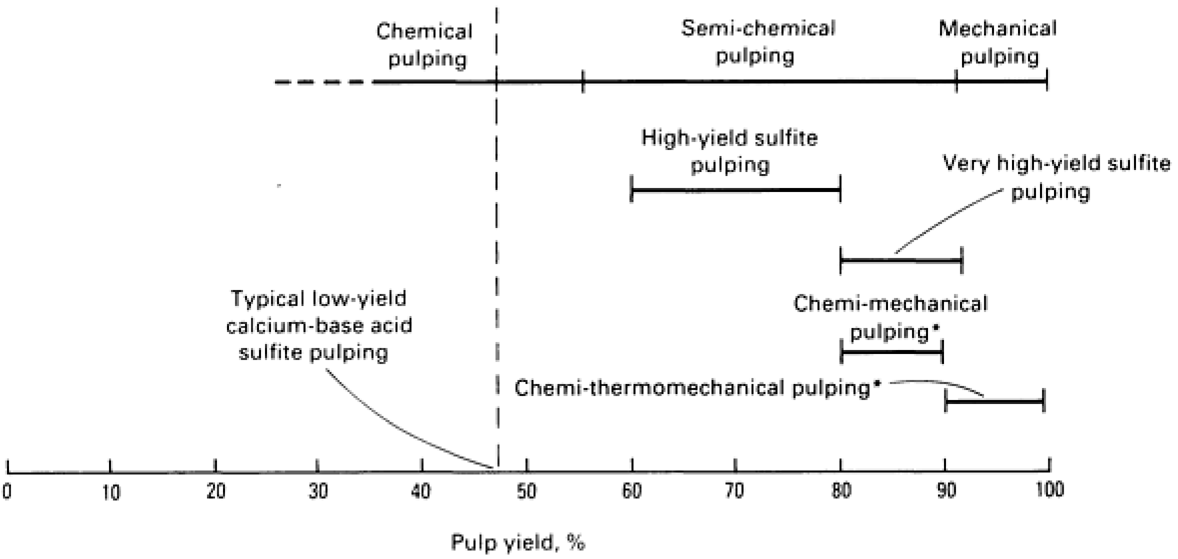

Fig. 23 Interrelationship between chemical, semichemical, and mechanical pulping processes. The processes marked with an asterisk use impregnation vessels or steaming tubes rather than digesters. Source: Ref 18

Corrosion Mechanisms in Sulfite Liquors

Stainless steels are used for most process equipment in the sulfite mill. As in any industrial plant, the steels in sulfite mills can experience many different types of corrosion. The most serious ones are usually connected in some way to the presence or absence of SO_2. Chloride-induced localized corrosion and SCC may also be problems, particularly in coastal mills.

The presence of SO_2 in sulfite liquors can affect corrosion of stainless steels in three ways. It can:

- Maintain passivity against acidic cooking liquors
- Form H_2SO_4 by decomposition of the liquor
- Form H_2SO_4 by oxidation to SO_3

These effects are discussed in more detail below.

Maintaining Passivity. Sulfur dioxide in solution helps to maintain the passivity of stainless steels such as types 316L and 317L that are commonly used in sulfite mills (Ref 20, 21). Therefore, a potential corrosion problem exists in any situation in which the concentration of dissolved SO_2 becomes very low. This may happen, for example, in vacuum evaporators or in batch digesters during a cook. However, practical experience has shown that this type of corrosion is usually not of concern with batch digesters. Unless conditions are especially severe (that is, high temperature, low pH, high chlorides), austenitic stainless steels containing more than 2.7% Mo can withstand short periods without any dissolved SO_2 present. Opening the digesters to the atmosphere between cooks also helps to maintain passivity.

Sulfuric Acid Formation by Liquor Decomposition. Acid bisulfite liquors can spontaneously decompose to form H_2SO_4 (Ref 22):

$$3SO_2 + 2H_2O \rightarrow 2H_2SO_4 + S$$
$$3NaHSO_3 \rightarrow NaHSO_4 + Na_2SO_4 + S + H_2O$$

The decomposition reactions are accelerated by increasing temperature, the presence of thiosulfate, and low liquor pH (<4). Thiosulfate forms spontaneously in acid bisulfite and sulfite liquors and is therefore always present to some extent. The presence of trace concentrations of cobalt, molybdenum, and selenium can also catalyze the decomposition reactions, even in cases in which the liquor pH is greater than 4. Liquor decomposition is dangerous for corrosion due to the formation of H_2SO_4, but it is also very serious for pulp production because it can result in a charred cook. Consequently, thiosulfate levels are regularly monitored in acid bisulfite and bisulfite mills. However, despite these precautions, liquor decomposition can still occur in isolated areas, such as under pulp deposits or in stagnant areas of a digester (Ref 23). Liquor degradation due to thiosulfate is usually of more concern in mills producing bleached pulp (that is, long cooking times) than in the case of short-cook high-yield mills.

Sulfuric Acid Formation by Oxidation. Free SO_2 is formed at acid pHs and raised temperatures because of the dissociation of bisulfite ions in the liquor:

$$HSO_3^- \rightleftarrows SO_2 + OH^-$$

$$H^+ + HSO_3^- \rightleftarrows H_2O + SO_2$$

Therefore, any vapor space above sulfite liquors may contain gaseous SO_2. If oxygen is present in the system, corrosion can then occur from the direct formation of H_2SO_4 on the exposed steel surfaces. This occurs by the oxidation of SO_2 to SO_3, followed by the condensation of H_2SO_4, particularly on cooler parts of process equipment (Ref 24):

$$2SO_2 + O_2 \rightarrow 2SO_3$$

$$SO_3 + H_2O \rightarrow H_2SO_4$$

Corrosion Problem Areas

A general guide to corrosion in sulfite mills is provided in Ref 23. In addition, the formation of SO_3 in sulfite pulping operations has been thoroughly documented in Ref 25.

Liquor Preparation. In the majority of cases, sulfur is burned to obtain SO_2. The gas is then cooled before being passed into absorption towers, where it is dissolved in the chosen base. Sulfur feedstocks may be either liquid or powder. In the case of powder sulfur, precautions must be taken to prevent weathering of the pile in order to minimize the ***in-situ*** formation of thiosulfate and H_2SO_4. Similarly, moisture must be avoided in liquid sulfur storage tanks to reduce the possibility of H_2SO_4 attack at the watering.

The most serious potential corrosion problem in the liquor preparation area is the formation of SO_3. This can occur by inefficient sulfur burning or by the entry of air into the burner-SO_2 absorption system. Precautions include cooling the SO_2 rapidly after its formation and ensuring that all metallic parts in contact with SO_2 in the absorber tower are continuously sprayed by the absorbing solution. In addition, the amount of iron in contact with the SO_2 gas is minimized because the metal catalyzes formation of the trioxide.

Digesters. Both batch and continuous digesters are used in sulfite mills. Continuous digesters are generally preferred for neutral sulfite semichemical and chemi-mechanical pulping applications. In North America, batch digesters for acid sulfite pulping are normally made of carbon steel plate lined with acid-resistant carbon brick. Metallic fittings within the digester are made from a minimum of type 316L stainless steel with a molybdenum content of 2.7% or greater. Corrosion is not usually a problem, although the bricks degrade and must be replaced after 6 to 10 years. Some batch digesters are stainless steel lined; this practice is common in Scandinavia. Localized corrosion and SCC have been found in these digesters, often associated with high (>1000 ppm) chloride levels in the liquor at coastal mills. As a result, these digesters are usually constructed of type 317L stainless steel (Ref 26). More highly alloyed stainless steels, such as type 317LMN and 904L, and nickel-base alloys have also been used in particularly corrosive conditions.

Digesters for use in neutral, alkaline, and chemi-mechanical sulfite pulping can be made from a range of materials, including carbon steel and austenitic stainless steels. In one case, accelerated corrosion in the vapor phase of a type 317L stainless steel continuous high-yield bisulfite digester was recently a problem because of SO_3 formation (Ref 27).

Formation of SO_3 was minimized by raising the liquor pH from 4 to 6, by using a plug screw feeder to reduce the entry of oxygen with the chips, by feeding chips in below the liquor level, and by preheating the water in the adjacent blow tank to lower its dissolved oxygen content. At the same time, the vapor space of the digester was clad in 904L stainless steel to provide increased corrosion resistance.

Liquor Recovery Systems. Evaporations are commonly made from type 316L or 317L stainless steel, although type 304L or carbon steel has been used for the final effects in sodium-base systems. Pitting and crevice corrosion under scale deposits are the most commonly reported problems. Liquor decomposition to form H_2SO_4 may also occur. In general terms, magnesium- and calcium-base systems are considered to be most corrosive towards evaporators (Ref 26).

Recovery boilers have been largely constructed from carbon steel, although increasing use has been made of composite stainless steel-carbon steel water tubing to combat corrosion. Flame-and plasma-sprayed stainless steel have also been used for the same purpose. Sulfite mill recovery boiler exhaust gases contain significantly more sulfur dioxide than those from kraft recovery boilers; they may also contain greater amounts of SO_3, hydrogen sulfide (H_2S), or HCl (Ref 28). Type 316L and 317L stainless steels and fiber-reinforced plastics have been used for scrubber bodies and internals, but have sometimes been replaced by higher-alloyed stainless steels or nickel-base alloys because of severe pitting and crevice corrosion. Attack can be especially severe in the inlet quenching/chloride removal zone, where even titanium and nickel-base alloys have suffered extensive general dissolution. Special care must be taken in these areas to avoid scale buildup and the presence of wet-dry zones, where chloride concentration can occur.

Corrosion in the Recovery Boiler

Recovery boilers are used in the wood pulp industry to recover pulping chemicals and to raise steam by burning the organic residues present in spent pulping liquors. By far, most of the recovery boilers in North America burn kraft process liquor (black liquor). When evaporated to about 65% solids and immediately before firing in the boiler, a heavy black liquor contains 50% organic solids and approximately 6% total sulfur, mostly in the form of Na_2SO_4 and $Na_2S_2O_3$. Some coastal or closed cycle mills operate with high sodium chloride (NaCl) content (for example, 12% NaCl) black liquor.

One typical boiler configuration is shown in Fig. 24. It differs from an electric utility boiler in that the underlying firing zone is a bed of molten salt (the smelt bed) that operates under reducing conditions and is contained in a water-walled furnace bottom. In addition, the combustion zone is extraordinarily tall so that chemical reaction products can condense and run down the water wall before reaching the superheater.

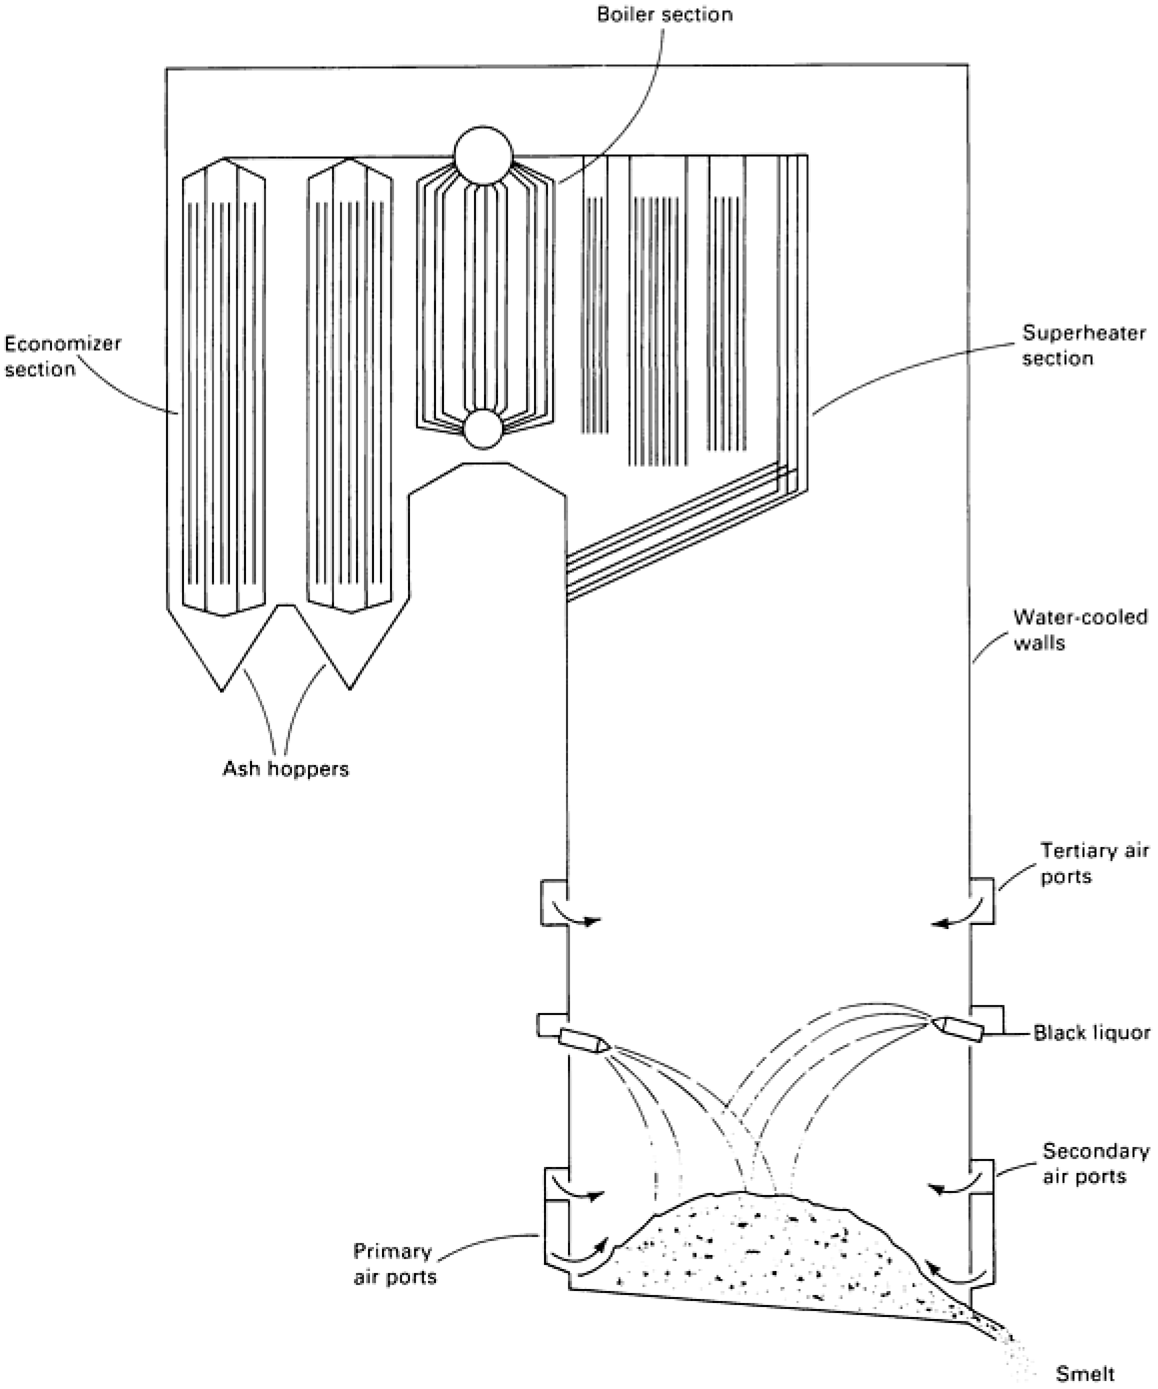

Fig. 24 Schematic of typical recovery boiler used in the wood pulp industry

In and above the smelt bed, chemical reactions take place that reduce sulfate to sulfide and form sodium carbonate (Na_2CO_3). The operating philosophy of the boiler places safety and a continuous supply of regenerated liquor (green liquor, made by dissolving smelt in water) ahead of steam supply and energy efficiency. Steam pressures are generally in the range 4135 to 10,340 kPa (600 to 1500 psi), and a typical boiler might generate 135,000 kg (300,000 lb) of steam per hour, burning 725 to 900 Mg/day (800 to 1000 tons/day) of solids.

Corrosion Mechanisms

There are numerous mechanisms of corrosion or chemical degradation of the recovery boiler. Whether or not corrosion can take place and the rate at which corrosion proceeds depend on the composition and metallurgical condition of the

material of construction, on the environment to which the materials are exposed (for example, liquid or gaseous phase, concentrations of chemicals), and on the temperature of the material and environment.

Composition of some alloys and coatings are listed in Table 8. The corrosion products formed on the surface of the metal depend on the metal composition and on environmental factors. These corrosion products often protect the underlying metal from exposure to the corrosive environment and therefore reduce or prevent further corrosion.

Table 8 Metal alloy and coating compositions for recovery boiler tubing

(c) Type 347H shall have a niobium plus tantalum content of not less than eight times the carbon content and not more than 1.0%.

The environmental characteristics determine whether or not corrosion may be expected. Metals can be exposed to corrosive chemicals in solid, liquid, or gaseous phase, with the latter two being most harmful.

The temperature of the metal in contact with the corrosion environment will determine the rate at which corrosion reactions will take place. Sometimes, a corrosion reaction proceeds slowly because of the temperature. Sometimes,

corrosion reactions take place only in a specific temperature range. Table 9 shows the typical locations where the different types of corrosion have been found in recovery boilers.

Table 9 Corrosion mechanisms and typical locations in recovery boilers

Mechanisms	Locations
Sulfidation reaction	Water wall tubes, studs, and air ports in furnace hearth zone. Both furnace-side and back-side surface of tubes
Molten hydroxides	Around primary air ports on back-side surface of tubes
Sulfidation-oxidation reaction	Lower superheater section, or further downstream, when liquor/smelt carryover is excessive
Sulfur trioxide adsorption to form liquid pyrosulfates	Superheater and boiler bank
Sodium chloride enrichment and deformation	Superheater and boiler bank
Sulfur trioxide adsorption to form liquid bisulfates	Economizer and back-end rows of boiler bank
Acid dew-point corrosion	Cold-side of economizer, direct contact evaporator, precipitator, ID fan, and all flue gas ducting connecting these sections

Metal wastage due to corrosion can occasionally be accelerated by and confused with erosion and overheating, although erosion and overheating fall outside the strict definition of corrosion. However, the combination of metal properties, composition of corrosive chemicals in contact with the metal, thermal cycling, and the temperature will determine the rate at which corrosion will take place.

Corrosion in the Furnace

Corrosion, in combination with erosion, can severely damage tube metal, pin studs, stack studs, flat studs, and protective coatings in the furnace hearth zone. The corrosion rate of carbon steel in recovery boilers rapidly increases above 315 °C (600 °F). Operating pressures above 6900 kPa (1000 psig) could result in external tube metal temperatures at or above this value.

Corrosion by Flue Gas in the Absence of Sulfur Compounds. When the bare metal surface of carbon steel is exposed to flue gases containing oxygen at elevated temperatures, corrosion may occur as follows:

$$3Fe + 2O_2 \rightarrow Fe_3O_4 \qquad \textbf{(Eq 1)}$$

$$4Fe + 3O_2 \rightarrow 2Fe_2O_3 \qquad \textbf{(Eq 2)}$$

$$2Fe + O_2 \rightarrow 2FeO \qquad \textbf{(Eq 3)}$$

The corrosion products formed, magnetite (Fe_3O_4), ferric oxide or hematite (Fe_2O_3), or ferrous oxide (FeO), depend on oxygen concentrations and temperatures. Of these products, only Fe_3O_4 is formed as a dense surface layer that prevents further attack of the underlying metal. The other iron oxides, Fe_2O_3 and FeO (formed at temperatures above 565 °C, or 1050 °F), do not form a dense protective layer, and corrosion proceeds in the underlying metal at the same rate.

When the steel is alloyed with such metals as chromium, nickel, or molybdenum, the formation of Fe_3O_4 will prevail; in such cases, only minor amounts of Fe_2O_3 are formed, and no FeO is formed. These alloys are, therefore, more corrosion resistant. At higher alloy contents, other metal oxides will also be formed that protect against further oxygen attack. The corrosion resistance of higher-alloyed steels is primarily due to the formation of a protective layer of chromium oxide (Cr_2O_3).

Corrosion by the Flue Gas in the Presence of Sulfur Compounds. In the presence of sulfur-bearing compounds, such as in kraft recovery boilers, the dominating corrosion reaction of carbon steel is (sulfidation reaction):

$$Fe + S \rightarrow FeS \qquad \textbf{(Eq 4)}$$

Iron sulfide is formed as a porous layer on the metal surface and does not protect the underlying metal. Because of the chemical structure of iron sulfide, the underlying iron can migrate through the sulfide layer and react with flue gas. Thus, corrosion will proceed, and iron sulfide will continue to build up on the outer surface. At high sulfur concentrations, an outer layer of iron disulfide (FeS_2) can also be formed:

$$Fe + 2S \rightarrow FeS_2 \qquad \textbf{(Eq 5)}$$

Elemental sulfur can be formed as a result of the following reactions in the boilers:

$$Na_2S + 2CO_2 \rightarrow Na_2CO_3 + CO + S \qquad \textbf{(Eq 6)}$$

$$2Na_2S + 3SO_2 \rightarrow 2Na_2SO_3 + 3S \qquad \textbf{(Eq 7)}$$

$$2H_2S + O_2 \rightarrow 2H_2O + 2S \qquad \textbf{(Eq 8)}$$

$$Fe + S \rightarrow FeS \qquad \textbf{(Eq 9)}$$

Of these sulfur-producing reactions, the reaction of sodium sulfide (Na_2S) with carbon dioxide ($2CO_2$) as shown in Eq 21 appears to predominate. Some of this elemental sulfur then reacts with iron to form iron sulfides.

Laboratory experiments have shown that iron monosulfide (FeS) will be formed at low reaction rates when oxygen is not present. The corrosion rate increases considerably when oxygen is also present, especially at temperatures above 150 °C (300 °F). At a hydrogen sulfide to oxygen ratio of approximately 1 (in the gas phase), the formation of FeS (Eq 23) is at a maximum rate. When the oxygen concentration is increased further, the corrosion reaction will increasingly lead to the formation of Fe_3O_4 (Eq 1) and FeS_2 (Eq 5), which develop protective layers against continuing corrosion of underlying metal.

Oxygen and gaseous sulfur concentrations can vary widely in time and place in the recovery boiler furnace, and little is known about actual concentration profiles and gradients. They are dependent on such variables as the sodium and sulfur content in the black liquor, bed temperature, bed size, primary air flow, and primary air pressure.

Water wall tubes in the furnace hearth zone are usually covered with a layer of solidified smelt. This solid smelt layer decreases the corrosion rate because the tube metal is not exposed directly to molten smelt or corrosive gases and because the tube surface temperatures are lowered due to the insulating properties of the solidified smelt. One method of corrosion protection in the furnace hearth zone is to increase the thickness of the smelt layer by attaching pin studs to the tubes. The studs cool the smelt and serve as anchors to hold the solidified smelt layer onto the tubes. Corrosion from the smelt itself is negligible at normal tube metal temperatures (below 345 °C, or 650 °F). Stud wastage will occur and require repair before wastage of the underlying tube metal occurs.

In nonwelded wall recovery units, furnace gases and smelt may penetrate to the outside or back-side surface of the tubes because of improper tube or stud alignment and/or flat (fin) stud wastage. This can lead to severe cold-side corrosion, as described in the following discussion "Corrosion by Molten Hydroxides" in this section.

When liquor or smelt is carried into the superheater section, where tube metal temperatures are often above 425 to 510 °C (800 to 950 °F), corrosion may take place as the direct result of the smelt deposits on the metal (see the discussion "Corrosion in the Superheater" in this section).

Some research work indicates that the solidified smelt layer is not always directly attached to the tube metal, but is separated from it by a thin layer of irregularly spaced porous material, probably dried black liquor. This provides a space between tube metal and smelt layer through which corrosive gases may attack the tube metal. The formation of this porous layer spacing will largely depend on operating variables.

Corrosion by Molten Hydroxides. Highly volatile hydroxides of sodium and/or potassium are released from the furnace bed and may diffuse to the cold side of the furnace tubes, especially close to the primary air ports. Because temperatures are much lower here, condensation/sublimation of the hydroxides may occur.

Liquid hydroxide causes corrosion of the tube metal. Sodium hydroxide has a melting point of 315 °C (600 °F) and may exist in the liquid state in high-pressure boilers. In combination with carbonates, sulfates, and potassium, deposit melting points have been found as low as 250 °C (480 °F). Laboratory experiments show even lower melting points (as low as 170 °C, or 340 °F), when substantial amounts of potassium hydroxide are also present. The condensation/sublimation deposits on lower-temperature metal surfaces are characterized by low sulfide content.

In practice, molten hydroxide corrosion does not appear to take place in boilers with operating pressures below 6000 kPa (870 psig), because of lower saturation temperatures. The potassium content, which greatly affects the deposit melting point, can vary from mill to mill, depending on wood species and the source of chemical make-up.

Molten hydroxides are much more corrosive toward stainless steel than carbon steel. There have been numerous reports of tube-side corrosion on the water walls of composite tube recovery boilers. Once cladding is wasted to expose underlying carbon steel, subsequent attack is much slower. This form of attack of stainless steel occurs at ports in the water walls, particularly the primary air ports.

Corrosion in the Superheater

Tube metal temperatures are highest in the superheater section. Superheated steam temperatures at the superheater outlet can be as high as 510 °C (950 °F). Outside tube metal temperatures make the superheater metals vulnerable to high rates of corrosion. At these temperatures, carbon steel is not corrosion resistant, even if the corrosive environment consists only of oxygen with no smelt or sulfur-bearing compounds present. Superheater tube materials in the high-temperature section consisting of structural steels, such as T-11 and T-22 (see Table 8 for compositions), and stainless steels have a higher corrosion resistance than carbon steel. Even these higher-alloy steels may also be vulnerable to corrosion.

Corrosion by Flue Gas Constituents. Under normal conditions, ash and/or black liquor carryover is deposited on the superheater tubes and dislodged by sootblower action. The porous structure of the ash deposits will allow bare tube metal to be exposed to the flue gases. The exposed surfaces are subject to corrosion by the flue gases, which contain the following:

Compound	Concentration
Oxygen (O_2)	0-5%
Hydrogen sulfide (H_2S)	0-50 ppm
Sulfur dioxide (SO_2)	0-500 ppm
Sulfur trioxide (SO_3)	0-50 ppm
Carbon monoxide (CO)	0-5%
Water vapor (H_2O)	30-35%
Carbon dioxide (CO_2)	10-15%
Nitrogen (N_2)	50-55%

Oxygen. Unprotected metals at high superheater temperatures will react with excess oxygen in the flue gas, as described in the discussion "Corrosion by Flue Gas in the Absence of Sulfur Compounds" in this section.

Hydrogen Sulfide. Hydrogen sulfide and other total reduced sulfur (TRS) compounds are generated in the furnace hearth zone and, with proper combustion, will be oxidized to SO_2 by the time the flue gas reaches the superheater section. It is possible that the TRS concentration leaving the combustion zone is in the range of 0 to 1000 ppm, while O_2 concentrations are normally 2 to 5%. In this case, the H_2S/O_2 ratio will be far below 1, which is the critical ratio for iron attack by dissociated H_2S. Hydrogen sulfide dissociates as follows:

$$2H_2S + O_2 \rightarrow 2H_2O + 2S \qquad \textbf{(Eq 10)}$$

$$Fe + S \rightarrow FeS \qquad \textbf{(Eq 11)}$$

When TRS generation in the furnace is excessive and air supply to the tertiary and/or secondary combustion zones is insufficient to oxidize TRS, then the H_2S/O_2 ratio may increase to its critical ratio of 1, and iron attack by sulfur will be at a maximum rate. Therefore, excessive TRS and the use of low excess air may lead to this type of superheater corrosion. However, generation of TRS in the furnace is minimized by proper air distribution. Maintenance of proper air distribution usually avoids this type of corrosion. Further, proper air distribution is essential for compliance with air emission standards.

Sulfur dioxide is formed in the combustion zone by the oxidation of sulfur bearing compounds. Sulfur dioxide causes negligible corrosion in the superheater.

Sulfur trioxide can be formed through the oxidation of SO_2 at high temperatures in the gas phase:

$$2SO_2 + O_2 \rightleftarrows 2SO_3 \qquad \textbf{(Eq 12)}$$

Equation 12 is an equilibrium reaction, and under normal furnace conditions, only a small amount of the SO_2 present will react to form SO_3.

Another mechanism for formation of SO_3 is the catalytic action of metal surfaces along with the flue gases flow. Oxides of iron and oxides of vanadium are known catalysts. Excessive firing of oil with a high vanadium content (fuel oil may contain up to 500 ppm V and 3% S) may lead to deposits of vanadium pentoxide (V_2O_5), which enhances the formation of SO_3.

Sulfur trioxide in the gas phase does not impose a corrosion problem. However, when it combines with water vapor and condenses, corrosive H_2SO_4 and/or sulfurous acid (H_2SO_3) are formed. This type of corrosion is known as dew-point corrosion and occurs when flue gases are cooled to the temperature at which condensation takes place (see the discussion "Corrossion in the Economizer" in this section). Another harmful effect of SO_3 is adsorption on Na_2SO_4 deposits in the superheater and boiler bank areas; this lowers the pH of these deposits and causes sticky ash formation.

Carbon Monoxide. Incomplete combustion leads to CO in the flue gas. Carbon monoxide alone does not cause corrosion, but it slightly increases the corrosion process by H_2S gases due to its reducing characteristics. Maintaining sufficient and proper air delivery, especially secondary/tertiary air, will minimize or eliminate the presence of CO in the flue gases.

Water Vapor. The reaction of iron metal with water vapor:

$$3Fe + 4H_2O \rightleftarrows Fe_3O_4 + 4H_2 \qquad \textbf{(Eq 13)}$$

is favored by thermodynamics to proceed to the right. The reaction rate, however, is slow, and corrosion inside or outside of the tubes is not usually due to this reaction.

Carbon dioxide alone seldom corrosion. In combination with Na_2S, however, it releases sulfur compounds from the smelt (Eq 21), leading to the corrosion reaction of sulfur with iron.

Nitrogen is inert and does not participate in any of the combustion or corrosion processes in recovery boilers.

Formation of Superheater Ash Deposits

Deposits will, normally be present on superheater tubes. The source, structure, and composition of these deposits can vary. Recent research has established that two basically different mechanisms cause the formation of superheater deposits:

- Carryover of black liquor particles
- Vaporization/condensation of sodium compounds

These two mechanisms act alone or in combination, depending on liquor composition, bed temperature, combustion air delivery system, and liquor spray pattern. The structure and composition of the deposits vary according to aging factors and the mechanism by which they were formed. The sodium to sulfur ratio in the flue gas is an important parameter of corrosion/deposition chemistry. This ratio is usually 1.4 or higher in kraft recovery flue gases.

Deposits From Black Liquor Carryover. Black liquor particles can be entrained in the combustion gases. The organic will be burned off, leaving predominantly Na_2CO_3, Na_2SO_4, Na_2S, and some NaOH. These deposits are found at lower elevations of the radiant superheater surfaces close to the furnace, especially at the leading side of the tubes. The carryover deposits may sinter and fuse, thus forming a hard, thick layer on the tube surface. This type of deposit formation may be found on units that are significantly overloaded.

Deposits From Vaporization/Condensation of Sodium Compounds. Vaporization of sodium and sodium compounds begins in the furnace bed. These compounds condense on the cooler sections of the superheater and the boiler bank tubes, forming a thin white deposit consisting mainly of sodium sulfate and some sodium carbonate. A minor amount of sodium chloride may also be present. Condensation of these compounds may occur on bare tubes or in the porous spaces between the previously laid down carryover deposits. This results in a mixture of carryover and condensation deposits.

Deposits formed by the vaporization/condensation process are likely to be found at higher, cooler elevations away from the furnace and especially on the trailing side of the tubes where flue gas velocities are lower. Also, at lower elevations closer to the furnace, some condensation products may be found on the trailing side, where they are shielded from the gas stream.

The type of process by which the deposits are laid down determines their chemical characteristics and composition. Carryover deposits will be richer in sodium carbonate. The pH of a saturated solution of this material is usually well above 7 (alkaline). Vaporization/condensation deposits usually do not contain much sodium carbonate, but consist mainly of sodium sulfate. The pH of a saturated solution is slightly below 7 (acid) or can be much lower because of SO_3 adsorption on the surface. A typical deposit analysis is shown in Table 10.

Table 10 Typical tube deposit analysis

Deposit	Superheater tube leading side; carryover	Boiler bank tube trailing side; vaporization/condensation
Na_2CO_3, %	37.6	0
Na_2SO_4, %	60.5	97.6
Other, %	1.9	2.4
pH saturated solution	12.0	4.4

Deposit Enrichment With Chlorides. The two mechanisms of deposit formation--liquor carryover and vaporization/condensation--occur independently and may lead to a mixture of deposits. The porous spaces in the carryover deposits may be filled with deposits from condensation. These deposits are commonly found close to the tube metal where the temperature is lowest.

Sodium chloride (NaCl), potassium chloride (KCl), and potassium hydroxide (KOH) are among the most volatile chemicals present in the recovery furnace. They may also be found in high concentrations, together with deposits from condensation (Na_2SO_4), closest to the tube metal.

Research work indicates Cl/Na and K/(K + Na) ratios increase when progressing from the outside of the deposit layer to the inside toward the tube metal surface. The increased amount of chlorides and potassium in the deposits is of particular concern with closed chemical recovery systems (that is, those with bleach plant effluent recovery) and in mills processing seawater-borne logs. IN other mills, chloride levels in the liquor cycle can also be excessive. Sodium chloride concentrations up to 40 g/L in the white liquor have been reported (the corrosive influence of chlorides is explained in the discussion "Effects of Chloride Compounds" in this section). A comparison of kraft recovery superheater deposit compositions from different types of mills is given in Table 11.

Table 11 Examples of kraft recovery superheater deposit compositions

Deposit, %	Mill A[a]	Mill B[b]	Mill C[c]	Mill D[d]
NaCl	2.2	16.0	22.5	3.7
Cl/Na (molar)	4.9	25.5	26.8	4.4
K/(K + Na) (molar)	1.7	5.7	7.5	11.4

(a) Inland pulp mill with bleach plant (open cycle).

(b) Pulp mill with bleach plant (closed cycle).

(c) West Coast pulp mill using seawater-born logs.

(d) Pulp mill using hardwood chips

Corrosion Mechanisms in Superheater Ash Deposits

The adsorption of SO_3 on ash deposits and the resulting problem in pH impose a serious corrosion problem in that an acidic environment is created. This type of corrosion may occur especially in sulfuric liquor systems with high sulfidities, but may also be found in kraft liquor systems. It has been found that Na_2SO_4 and SO_3, in combination with water vapor, may form sodium pyrosulfate ($Na_2S_2O_7$) and sodium bisulfate ($NaHSO_4$) according to:

$$Na_2SO_4 + H_2O + SO_3 \rightarrow Na_2S_2O_7 + H_2O \quad \textbf{(Eq 14)}$$

$$Na_2S_2O_7 + H_2O \rightarrow 2NaHSO_4 \quad \textbf{(Eq 15)}$$

The adsorption of SO_3 and the reaction with Na_2SO_4 occur only in deposits depleted of Na_2CO_3. Sodium trioxide will be neutralized when carbonate is present, such as in the deposits from black liquor carryover (that is, on the superheater and boiler bank tubes closes to the furnace), according to:

$$Na_2CO_3 + SO_3 \rightarrow Na_2SO_4 + CO_2 \quad \textbf{(Eq 16)}$$

This reaction proceeds rapidly at temperatures above 400 °C (750 °F).

When carbonate is no longer present in the deposits and SO_3 is still present in the flue gas, $Na_2S_2O_7$ may be formed. At lower temperatures, $NaHSO_4$ may also be formed.

The corrosive attack from $Na_2S_2O_7$ is thought to occur only in the liquid state. The liquid state of pyrosulfate may occur in many areas of the recovery boiler because its melting point is about 400 °C (750 °F). Solid $Na_2S_2O_7$ is not particularly corrosive. In recovery systems with high potassium content, sodium and potassium pyrosulfates ($Na_2S_2O_7/K_2S_2O_7$ eutectic) may be liquid at temperatures as low as 280 °C (540 °F).

Sodium bisulfate is stable at temperatures below 280 °C (540 °F) and will therefore not be found in the higher-temperature sections in the superheater. However, $NaHSO_4$ can form on lower-temperature surfaces of the superheater, boiler bank, and economizer. Fouling and corrosion of these metal surfaces may result because of the presence of molten $NaHSO_4$. This corrosion mechanism may be found in kraft recovery boilers having low sodium to sulfur ratios and high SO_3 concentrations in the flue gas and in a narrow temperature range from approximately 185 to 280 °C (370 to 540 °F).

In kraft pulp mills having normal white liquor sulfidities (25 to 30%) and normal recovery furnace operation, the concentration of SO_3 in the flue gas will be low, and it all will likely be neutralized by Na_2CO_3. Some of the following conditions, however, may increase SO_2 and therefore SO_3 formation and lead to acidic deposits or sticky ash:

- High white liquor sulfidity and low sodium to sulfur ratio in the liquor
- Low char bed temperature
- Excessive or uncontrolled spent acid additions
- Excessive firing of oil with high sulfur and vanadium content (catalytic formation of SO_3)

- High potassium content in the liquor

Any one of these conditions or a combination may be conductive to the formation of acidic sulfates and may require special attention and correction.

Effects of Chloride Compounds. The role of chloride compounds in superheater corrosion is not clear. Little research has been done on these corrosion mechanisms, and it is thought that chloride compounds may either directly attack tube material or decrease the melting point of deposits, thus causing fluxing of normal protective metal oxides.

Sodium chloride vapor, when condensed in the tube surface deposits, may release HCl in accordance with the following reaction:

$$4NaCl + 2SO_2 + O_2 + 2H_2O \rightarrow 4HCl + 2Na_2SO_4 \qquad \textbf{(Eq 17)}$$

Subsequent reactions of HCl fumes with tube material (either metal or metal oxides) may involve the formation of volatile iron chlorides and/or metal oxychlorides.

From laboratory experiments, it is known that the deformation and melting points of a mixture of Na_2S, Na_2CO_3, and Na_2SO_4 can be greatly affected by the NaCl content. The lowest first deformation point of a mixture of Na_2S, Na_2CO_3, Na_2SO_4 and NaCl has been found below 595 °C (1100 °F). The deformation and melting points can be lowered by as much as 220 °C (400 °F) with NaCl concentrations above 10%. Potassium may decrease these melting points even further.

In closed cycle mills with bleach plant effluent recovery or in mills using seawater-borne logs, the chloride input to the recovery boiler can be high. Because of the condensation/vaporization mechanism, the NaCl content of superheater deposits has been shown to be above 15%, and deposit deformation and melting may occur around 595 °C (1100 °F). Erosion-corrosion of tube metal may occur when 70% or more of the total deposit is in the liquid phase, thus making the entire deposit flux.

In kraft pulp mills without bleach plant effluent recovery or seawater-borne logs, the deposit melting point is not significantly affected, and subsequent fluxing of deposits does not usually occur. However, some conditions may cause high chloride levels or other conditions conducive to deposit fluxing, such as:

- High chloride input to the system due to a high chloride content in the spent acid from ClO_2 generation
- Excessive or uncontrolled spent acid additions producing temporarily high inorganics input to the liquor
- Local hot spots in the superheater due to flue gas channeling or improper design features

These conditions should be avoided or minimized.

Effects of Miscellaneous Chemistry. Superheater metal wastage may also occur as a result of the reaction and/or decomposition of sodium-sulfur compounds at elevated temperatures. The Na_2S and $Na_2S_2O_3$ contents in smelt or ash deposits between the furnace hearth zone and the superheater will generally decrease from their concentrations in the smelt to deplete the superheater tube deposits unless excessive liquor/smelt carryover takes place. Usually, a small amount of Na_2S can be found in the deposits at the superheater bends.

In laboratory experiments, it has been shown that sodium-sulfur compounds may react or decompose at elevated temperatures, resulting in the formation of free sulfur. These experiments (at 370 °C, or 700 °F) indicated the following reactions:

$$Na_2SO_4 + Na_2S \rightarrow Na_2SO_3 + S + Na_2O^{*} \qquad \textbf{(Eq 18)}$$

$$Na_2S + O_2 \rightarrow Na_2S_2O_3 + Na_2O^*$$ **(Eq 19)**

$$Na_2S_2O_3 \rightarrow Na_2SO_3 + S$$ **(Eq 20)**

$$Na_2S + 2CO_2 \rightarrow Na_2CO_3 + CO + S$$ **(Eq 21)**

$$2Na_2S + 3SO_2 \rightarrow 2Na_2SO_3 + 3S$$ **(Eq 22)**

Equations 21, 22, and 18, 19, and 20 also occur in the furnace bed and around the water wall tubing where tube metal temperatures are much lower.

The formation of free sulfur at the superheater lower bends may result in metal attack:

$$Fe + S \rightarrow FeS$$ **(Eq 23)**

when bare tube metal is not protected.

Corrosion in the Boiler Generating Bank

Tube metal temperatures in the boiler bank area are lower than in the superheater. This makes boiler bank tubing less vulnerable to corrosion.

Certain conditions, however, may cause elevated temperatures in the boiler bank riser tubes. This may lead to accelerated corrosion. In localized areas, conditions that cause overheating include:

- Internal scale
- Flue gas channeling
- Mechanical blockage of water flow
- Low water level
- Improper water distribution/circulation

At moderately elevated temperatures, accelerated corrosion may result when the tube metal is subjected to a corrosive environment.

The corrosion mechanisms in the boiler bank are the same as for the superheater, that is, corrosion by flue gas constituents or by ash deposits. Lower temperatures in the boiler bank result in lower corrosion rates. In addition, there is less chance for the formation of chloride-containing deposits.

Corrosion at the Drum Tube Seats. Tube metal wastage may occur at the drum tube seats. Corrosion is due to the combined action of chemicals and water and may be accelerated in the high stress areas resulting from the tube rolling technique or vibration-induced stresses. The water present may be from tube seat leakage, water-washing remains, soot blowing, or absorption by deposits around the tube seat.

Erosion by Sootblower Steam / Water Mixtures. Boiler bank tubes, superheater tubes, and economizer tubes may be subject to steam/water mixture sootblower action, resulting in tube metal wastage. The damage usually appears as localized external wall thinning, and the affected area usually has a smooth, polished appearance. Proper sootblower spacing and care in piping design (which ensures that only dry steam is used for sootblowing) and proper maintenance of steam traps should be exercised. Leaking poppet valves cause steam to condense in the lance tube when the sootblower is idle. This water runs from the nozzle and may cause corrosion of wall tubes and casing. Leaking poppet valves and defective steam traps should be promptly repaired.

Corrosion in the Economizer. External corrosion of economizer tubes may occur when economizer flue gas exit temperatures and/or feedwater temperatures are low. The flue gas exit temperature and feedwater temperature entering the economizer determine the tube metal temperature. The tube metal temperature may drop below the acid dew point. The

dew-point temperature is highly affected by SO_3 concentrations in the flue gas. An increase in SO_3 in the flue gas elevates the dew-point temperature. Therefore, condensation is more likely to occur.

It is generally good practice to maintain the flue gas temperature at the economizer outlet at or above 160 °C (325 °F) and to maintain the feedwater temperature entering the economizer at or above 135 °C (275 °F) in order to prevent condensation. If condensation occurs, the product is dilute H_2SO_4:

$$SO_3 + H_2O \rightarrow H_2SO_4 \quad \textbf{(Eq 24)}$$

The H_2SO_4 attacks metals and protective iron oxide coatings:

$$Fe + H_2SO_4 \rightarrow FeSO_4 + H_2 \quad \textbf{(Eq 25)}$$

$$Fe + Fe_3O_4 + 4H_2SO_4 \rightarrow 4FeSO_4 + 4H_2O \quad \textbf{(Eq 26)}$$

Therefore, corrosion may take place, especially at localized areas where ambient air can leak through doors or holes in the casing. In this type of corrosion, the rate increases as the temperature decreases, not because the corrosion mechanism itself proceeds faster at lower temperatures, but because more of the corrosive H_2SO_4 is formed.

Economizers are particularly susceptible to this type of corrosion because operating gas temperatures are near the acid dew point and any ambient air leakage or other air infiltration, such as at vents, will tend to lower gas temperatures in localized areas. It should be noted that economizers are particularly susceptible to high leakage/infiltration due to high-draft conditions.

Acid dew-point corrosion can also occur in other downstream components of the system, such as electrostatic precipitators and flue gas scrubbers. Corrosion in the economizer can also be caused by the formation of molten bisulfates below 280 °C (540 °F), as explained in the discussion "Adsorption of SO_3" in this section.

Note cited in this section

* Sodium oxide (Na_2O) is very reactive and combines quickly with CO_2 or H_2O to form Na_2CO_3 or NaOH, respectively.

Suction Roll Corrosion

Max D. Moskal, Stone Container Corporation

Suction rolls are used to remove water from paper at the wet end of the paper machine. One way to accomplish this is by passing the paper web through a roll nip, one roll of which is the suction roll. The suction roll is drilled to an open area of about 20%, and a vacuum is applied to the inside of the roll. A typical cross section through a suction roll is shown in Fig. 25. A rubber cover is often used on the suction press roll or mating roll to give a desired nip pressure relationship. Many machine designs have been used in the wet end of paper machines throughout the years. A typical paper machine may use three or more suction rolls designated as couch, wringer, pickup, or press rolls (Fig. 26).

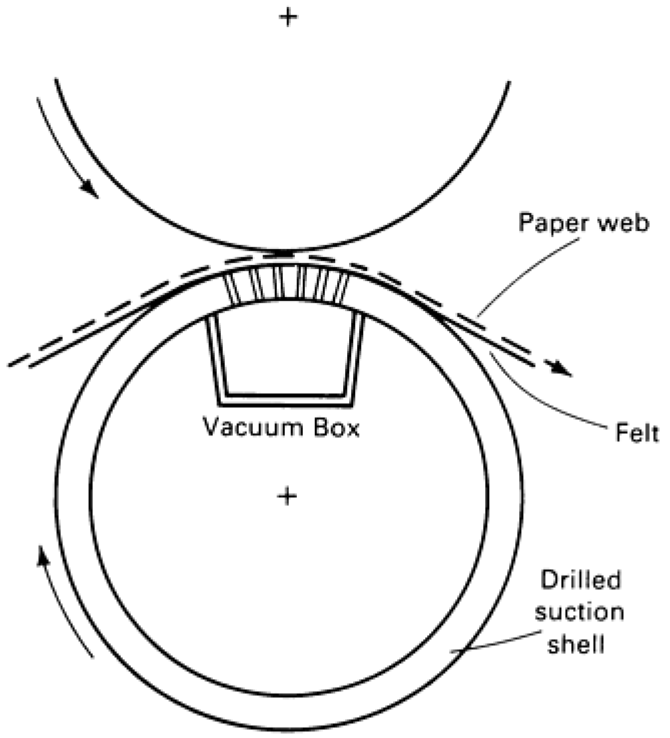

Fig. 25 Cross section of suction roll configuration

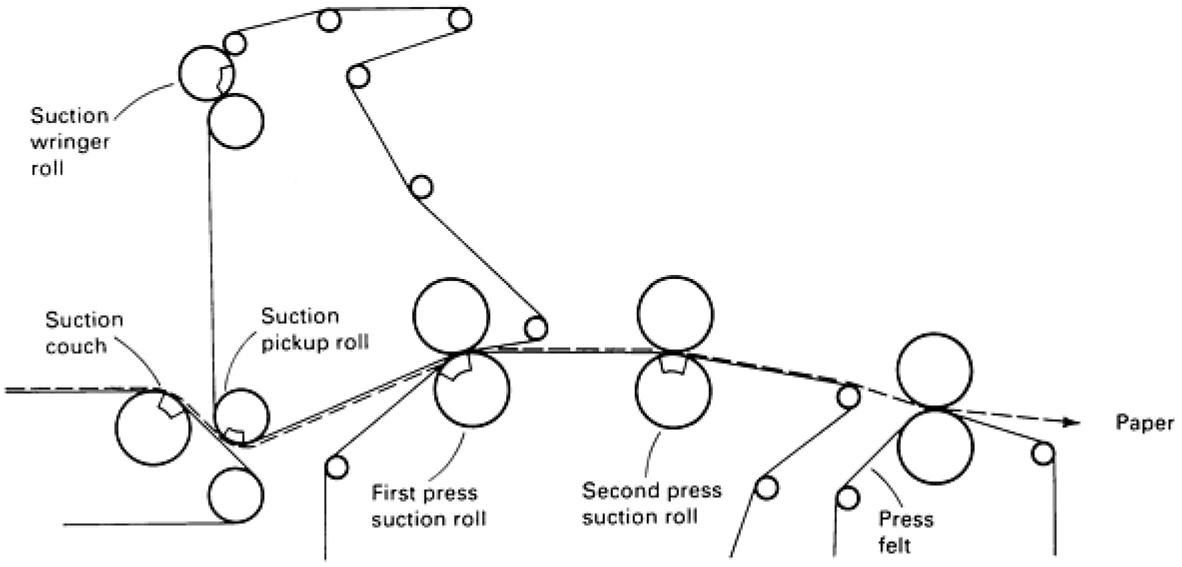

Fig. 26 Schematic diagram of wet end of paper machine showing types of suction rolls

The critical component in the suction roll is the drilled shell, which is subject to corrosion and fatigue cracking. During the past 30 years, changes have evolved in design and machine environment that have increased the cracking and corrosion tendency of the suction shell. For example, demands for increased machine production and speed have been resolved by increasing roll nip pressures. Wider machines have also been designed. These new designs have required heavier and stronger shells to meet the increased stress that is imposed. The corrosive environment in the paper machine wet end has also become more severe as water systems have been closed, water temperatures increased, and chemicals used to clean paper machine felts. Numerous changes have also occurred in a search for materials and designs that better resist shell corrosion and corrosion-assisted cracking.

This section describe the history of suction roll and materials development, the operating environment, corrosion fatigue of suction rolls, shell manufacturing methods, and corrective measures.

History of Suction Roll Alloys

Prior to about 1950, suction shells were cast from bronze having a composition of approximately 85% Cu, 5% Pb, 5% Zn, and 5% Sn. Bronze has many advantages, such as castability, machineability, corrosion resistance, and relatively low cost. However, bronze lacked the strength needed to resist the higher press loads that were introduced at that time, and it lacked the stiffness necessary to maintain shape and roundness on larger and wider paper machines. In 1964, it was noted that suction roll nip pressures had increased from the original levels of 26 kN/m (148 lb/in.) up to 79 kN/m (451 lb/in.) (Ref 29). Designs with nip pressures to 131 kN/m (750 lb/in.) were proposed in the 1960s and were actually achieved in the 1970s. Also, paper machine widths increased from typically 3.8 m (150 in.) in the 1950s to over 6.3 m (248 in.) in the 1970s, with maximum machine widths achieved in excess of 10 m (394 in.).

The first stainless steel materials to be widely used were forged type 410 martensitic alloy and centrifugally cast CF-3M and CF-8M austenitic alloys. The austenitic alloys were deemed especially desirable for low-stress, high-corrosion applications, such as the couch position. From 1955 to 1965, the influence of corrosion on fatigue was not widely recognized. In one case (Ref 29), shell designs were based on the fatigue strength of these alloys in air (Fig. 27).

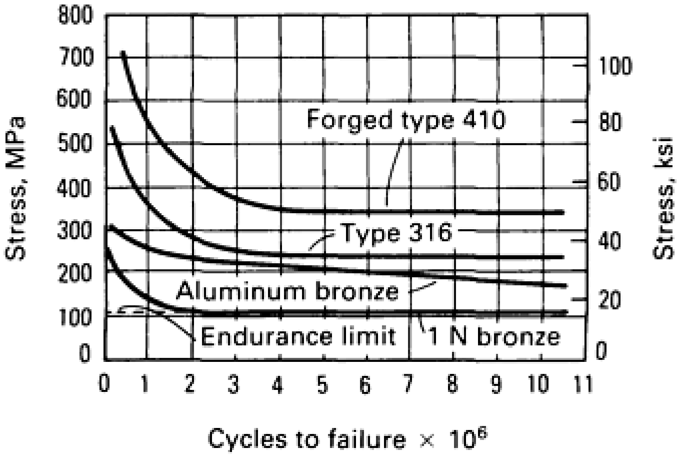

Fig. 27 Typical fatigue curves of suction shell alloys as tested in air. These data were used to establish early designs of suction rolls. Courtesy of the Technical Section, Canadian Pulp and Paper Association

In 1957, the first centrifugally cast CA-15 martensitic stainless steel shells were cast. Also during this early period, shells were cast from alloy A-63 stainless steel and aluminum bronze. Tables 12 and 13 list the nominal compositions of the alloys used for suction shells.

(a) Remainder of compositions is iron.

(b) Alloy has been discontinued for suction shells in North America.

(c) Details of composition not published, but similar to ASTM A-296, alloy CA-6NM (discontinued specification).

(d) Obsolete alloy.

(e) Contains nitrogen.

(f) Contains nitrogen and tungsten.

(g) Alloy A-682 has a composition similar to that of VK-A378, only reduced chromium and nickel.

Between 1969 and 1977, a host of new centrifugally cast stainless steel alloys was introduced for suction shells. These were DSS69, C169, alloy 70 (martensitic), and alloy A170, A171, A271, and A-75 (duplex/ferritic-austenitic). Also during this period, rolled and welded stainless steel shells were produced in Sweden from type 316 and 3RE60 stainless steels. Continuous-cast bronzes GC-CuSn5ZnPb and GC-CuA19,5Ni also emerged during this period.

In 1971, the reduced fatigue strength of bronzes and stainless steels in synthesized white water was reported (Ref 30). The importance of residual stresses on fatigue cracking was also more widely recognized at this time.

Between 1978 and 1986, additional new stainless alloys were introduced. These included centrifugally cast precipitation-hardening duplex alloys VK-A378 and KCR-A682 and duplex alloy A-86. In 1978, the argon-oxygen decarburization process was introduced in the United States for suction shells. This permitted more economical melting and casting of stainless alloys with a very low carbon content. Centrifugally cast CF-3M has since been produced instead of CF-8M. Several forged alloys were also introduced during this period: PM-4 1300 and PM-4-1300M (martensitic), PM-3-1811MN (austenitic), PM-3-1804M, and PM-2-2505 (duplex).

During the 1980s, emphasis has been placed on stainless steel development with greater corrosion and fatigue resistance and low residual stresses.

Paper Machine Environment

A detailed discussion of the paper machine corrosion environment is given in the section "Paper Machine Corrosion" in this article. However, considerations specific to suction roll corrosion will be covered in this discussion.

Suction rolls are subjected to a variety of corrosive environments. The severity of the environment depends primarily on the type of paper produced on the machine, the source of water, and the degree of closure of the mill. The corrosivity of the environment depends primarily on pH, temperature, dissolved solids content, chlorides, and the presence of sulfur compounds. The area around the suction rolls is subjected to splash from stock and white water, and deposits of paper fiber are present in crevices. Bacteriological growth can also occur, especially in areas that are difficult to treat with biocide chemicals (commonly used biocides are listed in the article "Corrosion Inhibitors in the Water Treatment Industry" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*). Suction rolls are also subject to corrosion from chemicals and waters used in showers around the rolls and from felt treatment chemicals.

Laboratory studies have shown that $Na_2S_2O_3$ in stock and white water systems results in severe pitting corrosion of the less resistant martensitic stainless steels, and thiosulfate is believed to be important in corrosion and cracking of suction roll shells. Sodium thiosulfate, residual sodium hydrosulfite ($NaHSO_2$), and the sulfide ion are also highly corrosive to bronze.

Biological corrosion has also been observed within the drilled holes of suction shells. The hole area is highly favorable to the growth of microbes because of the presence of dissolved organic materials, dissolved inorganic salts, and a favorable temperature range of 40 to 50 °C (105 to 120 °F). Anaerobic sulfate-reducing bacteria thrive in crevice locations and under salt and fiber deposits. Therefore, because of the concentration of ions and the localized pH reduction, the chemical environment beneath deposits can become far more aggressive than the bulk stock or white water chemistry. Additional information on biological corrosion can be found in the articles "Microbiologically Influenced Corrosion," and "Evaluating Microbiologically Influenced Corrosion" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

The showers and chemicals used on the paper machine also influence the environment around suction rolls. Showers are used to clean machine felts, to remove deposits from drilled holes in suction rolls, and to lubricate roll seal strips. A wide variety of shower cleaning chemicals are used for felts and rolls, including acids, aliphatic and aromatic solvents, or animal and vegetable oils. Lubricating and needle showers are often supplied with white water at temperature ranges of 40 to 50 °C (105 to 120 °F), this white water is more corrosive to the suction roll than freshwater. Attack from chemicals has also contributed to failure of elastomeric covers on suction rolls (Ref 31). Figure 28 shows damage to a CA-15 martensitic stainless steel suction shell from muriatic acid used for felt cleaning.

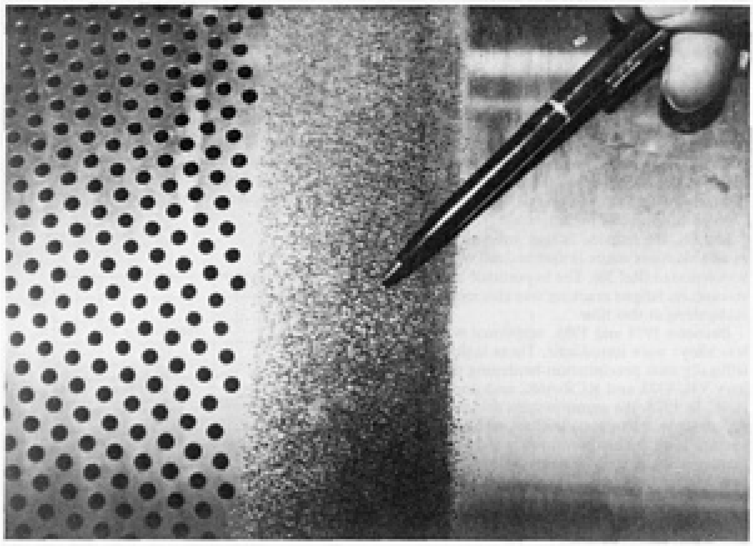

Fig. 28 Corrosion damage to a CA-15 stainless steel shell caused by muriatic acid felt cleaning

Off-line chemical cleaning has been used to remove deposits from drilled holes in suction rolls. There have been numerous cases of severe damage to both shells and rubber covers when corrosive cleaning chemicals were used (Ref 32).

Corrosion Fatigue Testing

In the 1960s, several investigators recognized the need to obtain corrosion fatigue data for suction shell materials using a synthesized paper machine white water environment. Corrosion fatigue testing of suction materials was first described by R. Thompson, who used a conventional R.R. More rotating-beam machine equipped with a corrosion chamber around the specimen (Ref 33). Liquid was continuously dropped onto the stressed portion of the specimen. Corrosion fatigue tests were conducted using a reverse bending plate with a single hole drilled in the stressed regions (Ref 34). Crack growth rate tests were employed to evaluate the corrosion fatigue characteristics of suction roll materials (Ref 35, 36). These investigators used compact-tension specimens subjected to cyclic loading in an electrohydraulic fatigue machine.

Corrosion fatigue test data have been published largely by shell producers and paper machine equipment manufacturers. A variety of test data have been shown for all of the alloys used for suction rolls. Because different test methods and a variety of environments have been used for tests, direct comparison of corrosion fatigue strength data is very difficult.

Rotating-bending fatigue test data for several alloys in white water at pH 3.5 and varying chloride and sulfate contents are shown in Fig. 29. Rotating-bending fatigue test data by a different investigator for alloys in a highly aggressive white water are shown in Fig. 30.

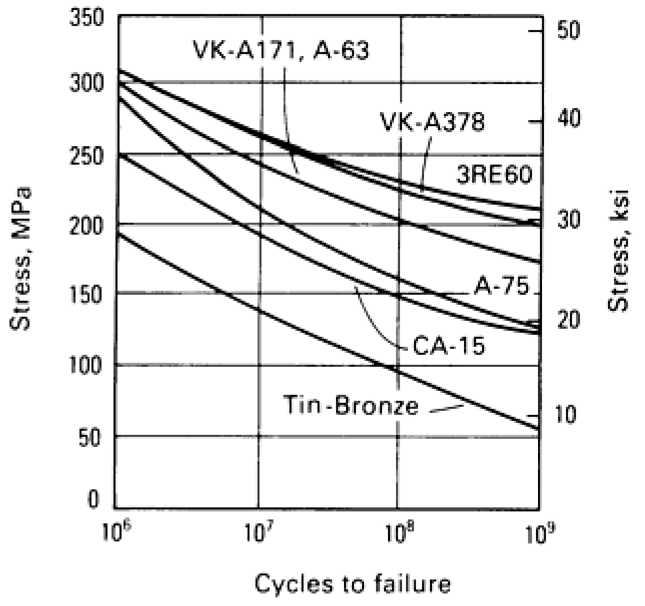

Fig. 29 Fatigue curves in white water based on the data of material suppliers. 1500- to 1750-rpm rotating-bending test, pH = 3.5, Cl^- = 20-400 ppm, SO_4^{2-} = 250-1000 ppm. Courtesy of Technical Association of the Pulp and Paper Industry

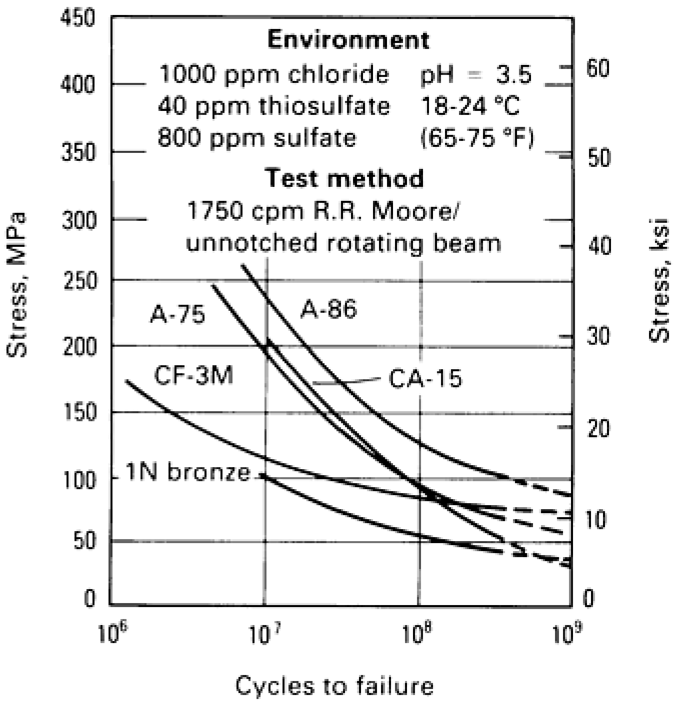

Fig. 30 Fatigue curves for suction shell alloys in an aggressive environment. Courtesy of Sandusky Foundry & Machine Company

In 1985, the TAPPI Corrosion and Materials Engineering Committee summarized survey results on the correlation among corrosion fatigue testing methods. The survey included data provided by ten investigators on the type of testing used, specimen configuration, test conditions, and environment (Ref 37). The TAPPI committee also published documents describing standard methods and test environments for suction shell alloys (Ref 38, 39).

Recent investigations in near-threshold fatigue crack growth testing have indicated that mean stresses could have a significant effect on the threshold for crack growth in duplex stainless steel alloys (Ref 36). These data correlate with the concept that high residual tensile stresses in suction rolls decrease fatigue life in service.

Roll Failures

Corrosion and cracking failures have been reported for couch, press, and felt wringer rolls. There has been no widespread problem with the lightly loaded suction pickup rolls. Failure by cracking is frequently unexpected, and is usually the most cause for concern. When cracks progress a significant distance around the shell, the suction roll begins to vibrate and must be immediately removed from the paper machine. Deterioration of shells by general corrosion and pitting is another important means of failure. Severe roughening of the outside diameter surface of bronze couch rolls is known to reduce the life of fourdrinier wires. An example of outside diameter surface corrosion in bronze is shown in Fig. 31. General corrosion in drilled holes results in hole enlargement, decreasing the land area between holes to a point at which corrosion fatigue cracking can occur (Fig. 32).

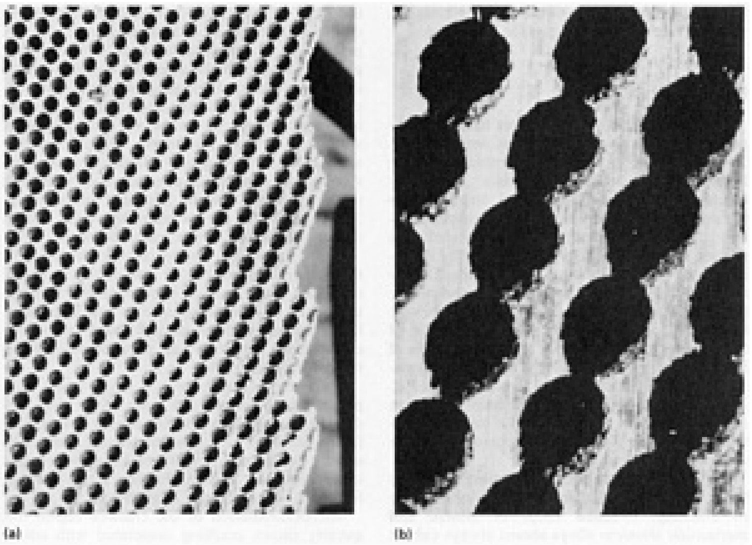

Fig. 32 General corrosion in drilled holes. (a) Inside surface of bronze shell adjacent to fracture. The hole enlargement varied periodically along the length of the shell and corresponded to shower nozzle spacing. (b) Close-up view of hole corrosion. Courtesy of MacMillan-Bloedel, Ltd.

Most suction rolls that are reported to have failed have been removed from service because of cracking. Cracked shells of bronze and martensitic stainless alloys almost always exhibit a visible condition of surface corrosion or pitting in the drilled holes. Higher-alloyed duplex and austenitic stainless steels seldom show visible corrosion, although fatigue failures in these alloys are known to be corrosion assisted.

Failure Experiences. Two separate surveys covering roll failures have been published since 1979 (Ref 32, 40). The surveys indicated that most failures occured in bronze and martensitic stainless steel shells. However, it was also noted that there are far more bronze and CA-15 shells in service as compared to other alloys. Cracking was also more prevalent in the higher-speed and more corrosive newsprint machines than in fine paper, pulp, or board machines.

Corrosion Fatigue Failures. Fatigue cracking is first observed in shells as single cracks in the land area between two drilled holes or as cracks that begin at a hole and have not yet progressed to a neighboring hole. Cracking then proceeds across the land regions connecting several holes, eventually joining and proceeding circumferentially around the shell (Fig. 33). Cracking usually manifests on the roll inside diameter surface near the mid-span, where operating stresses are

the highest. Martensitic stainless steels show many fatigue initiation sites through the cross section of the fractured surface (Fig. 34). Bronze and duplex stainless steels seldom show well-defined fatigue initiation sites.

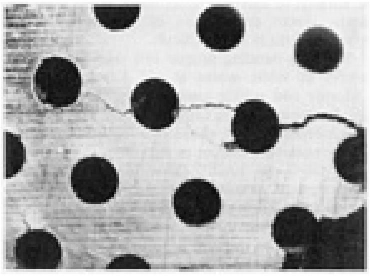

Fig. 33 Typical cracking between drilled holes on the outside surface in a stainless steel alloy shell. Courtesy of The Institute of Paper Chemistry

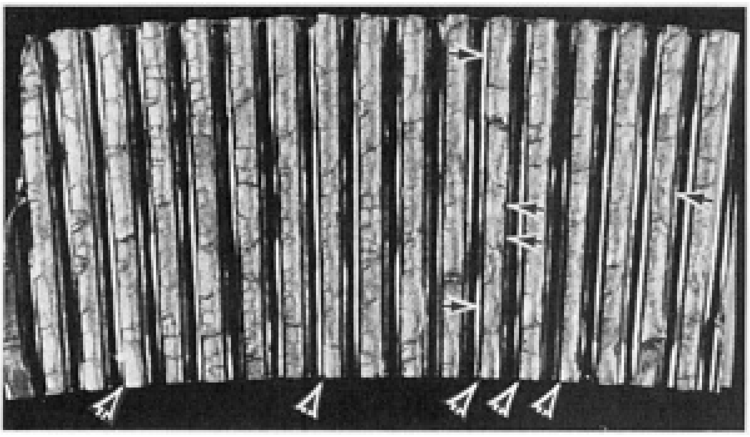

Fig. 34 Fracture surface of CA-15 stainless steel suction shell showing several fatigue nucleation sites (arrows). See also Fig. 35.

Longitudinal cracking is often observed near the mid-span of austenitic and duplex stainless steel shells, and this has been attributed to overloading or residual stresses from heat treatment. Longitudinal cracks eventually turn to the circumferential direction and proceed around the roll to ultimate failure.

Rolls may develop only a single crack that progresses to failure, but more often, they will develop tens or hundreds of cracks before final failure occurs. Bronze and martensitic steel shells usually exhibit many small cracks before a larger crack develops. Duplex stainless steels develop fewer cracks or a single large crack.

Microexamination of the cracked region frequently shows cracking associated with corrosion pitting (Fig. 35). Cracking has also been attributed to manufacturing defects, poor drilling quality (Fig. 36), excessive porosity (Fig. 37), welding repairs, and electrical discharge machining used to remove broken drill bits. Intergranular cracking has been observed in austenitic stainless steel that was sensitized during heat treatment and in bronze shells that were exposed to mercury and ammonium contamination.

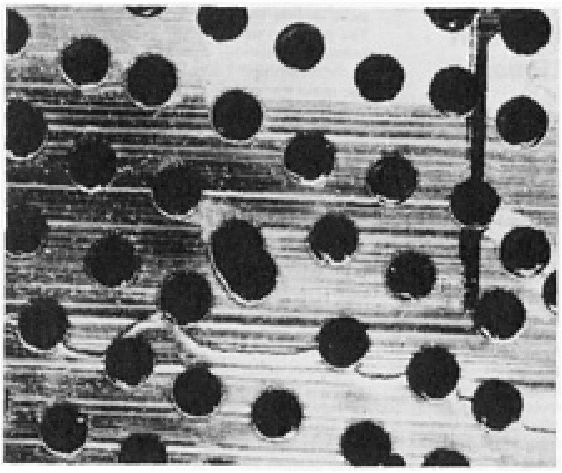

Fig. 36 Fatigue cracking of CA-15 stainless steel suction roll due to poor drilling quality

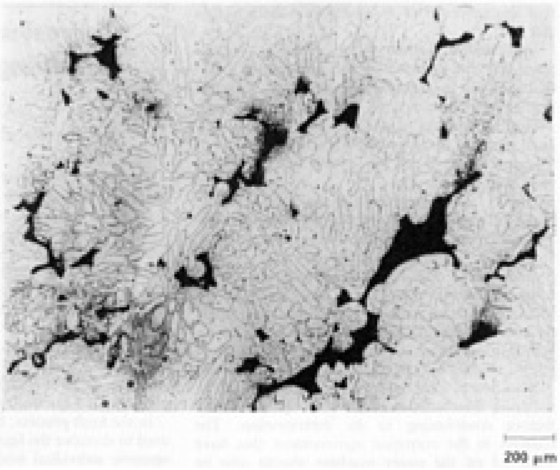

Fig. 37 Casting porosity in duplex stainless steel shell

Rubber Cover Failures. A recent Canadian survey showed that the cost of premature rubber cover failures on suction rolls was about as large as the cost of shell failures (Ref 40). In the survey, 38 mills were questioned about rubber cover

failures on suction and nonsuction rolls for the year 1983. A total of 70 cover failures were experienced in the 38 mills surveyed.

A significant cause of rubber cover failures is deterioration from chemicals used on the suction rolls, both on-line and off-line. Organic solvents have been found to be highly detrimental to rubber covers, especially when used in a continuous mode as opposed to batch treatment. High-pressure hydraulic cleaning can produce mechanical damage and detachment of rubber covers.

Shell Manufacturing Methods

Most suction roll shells are produced by the centrifugal casting method, followed by continuous-casting (bronze), rolled and welded (stainless steel), and forging processes (stainless steel). Each method of manufacturing claims certain advantages. After production of the rough shell, it may be heat treated (depending on the alloy), machined to near-final shell dimensions, and drilled. The shell is then finished on the inside diameter surface and head seats machined. The outside diameter surface is finished by turning, belt sanding, or grinding. A smooth outside surface finish is not required if the shell is to be subsequently rubber covered.

Castings. The process of centrifugal casting is the oldest and most versatile method of shell production. It is applicable for both bronze and stainless steel alloys. Metal is poured into a spinning mold that is horizontally positioned, and the spinning motion is continued until the metal shell has completely solidified. In this process, the last metal to freeze is at the inside diameter surface of the casting. Nonmetallic and intermetallic impurities concentrate on this inner surface, which is later machined away.

Continuous casting is a relatively new method of producing cast shells. It is applicable only to bronze alloys. In this method, the molten metal is poured through holes in a distributing vessel into a vertical collar-type mold. Metal flow, speed of extraction from the mold; and cooling are coordinated so that the casting process is continuous. An advantage of continuous casting is that the uniformity of metal properties through the wall can be readily controlled.

Weldments. Welded stainless steel shells have been produced in Sweden since the early 1970s. Most production has been limited to 3RE60 duplex stainless steel alloy, which is hot formed from plate into semicylinders. The semicylinders are subsequently welded longitudinally to form short cylinders, and several short cylinders are welded at the ends to form the suction shell.

Forgings. Forged suction shells are produced by first upsetting and punching a hollow cylinder from a solid cylinder, then enlarging and forging the shell on a pipe-forming mandrel. The process minimizes the porosity and segregation that may be found in castings, but can be subject to inclusions and other internal flaws.

Heat treatment of suction shells has proved to be a critical operation affecting the corrosion and the residual stress properties of shells. Current practice in heat treatment is limited to stainless, steel suction shell alloys. Although aluminum bronze is heat treatable, shells from this material are currently furnished in the as-cast condition.

Each stainless steel alloy requires a specific heat treatment to provide the best combination of corrosion resistance and low residual stresses. Slow cooling from the final heat treatment produces lower residual stresses, but (depending on the alloy) may produce undesirable intermetallic phases and a low corrosion fatigue resistance (Ref 41, 42). Austenitic alloys may be given a single-solution anneal treatment, but martensitic alloys are quenched and tempered. Duplex alloys may be subjected to a single-solution treatment or, in the case of copper-bearing duplex alloys, may be given one or two additional subcritical aging treatments.

Drilling. Suction shells are drilled using multiple-spindle machines. Couch rolls are frequently drilled with larger hole sizes of up to 6.3 mm (0.25 in.), but press roll drilling is typically 4.0 mm (0.16 in.). The drilling process is critical in that hole spacing must be maintained to within close dimensional tolerances.

Gun drilling was first developed in Europe for drilling stainless steels and is particularly applicable when drilling long, straight holes in thick-wall stainless steel shells. Twist drilling of these alloys sometimes results in converging of drilled holes at the inside diameter surface (Fig. 36). Gun drilling also has the advantage of producing a smooth surface finish within the drilled hole. This reduces the tendency toward the initiation of corrosion and deposit formation. Gun-drilled holes have been measured to have a surface finish of R_a = 0.5 μm (20 μin.) as compared to R_a = 5.0 μm (200 μin.) for

twist-drilled holes, where R_a is the arithmetic average roughness. A process of reaming after twist drilling has also been used to produce a good surface finish in the drilled holes.

Shell Quality. Several types of manufacturing defects have been attributed to the failure of suction shells, as discussed above. In an analysis of 52 suction roll failures, about 50% of the failures were attributed to defects in manufacture or design, 35% were due to improper material selection for the environment, and 15% could not be attributed to any cause (Ref 43).

Corrective Measures

Three factors influence suction shell resistance to corrosion fatigue; stress, corrosion environment, and the corrosion fatigue strength of the alloy. A favorable change in any of these factors will produce an increase in shell life.

Bronze shells are occasionally removed from service because of general or pitting corrosion. The factors that influence these failures are the corrosion environment and the resistance of the alloy to the environment.

Good judgment in roll design, material selection, and control of the paper machine environment all contribute to the long life of suction rolls. Good quality control during the manufacture of the shell and timely in-service cleaning and roll inspection also contribute to a favorable service life.

Operating Stresses. Both the applied stress and internal residual stresses inherent in the shell material contribute to the stress in operation of the suction roll. The responsibility for the level of applied stress rests chiefly with the roll designer who selects the limit of design stress for the material selected. Each shell material will have a limit of stress that will give long life in a particular environment. The magnitude of applied stress is a function of roll configuration and applied loads. Drilled hole patterns must also be favorably designed to reduce applied stress. The most important factor influencing the stress in the roll is shell thickness; of course, stress decreases as the shell thickness increases. A stress calculation procedure has been developed by TAPPI that can be used as a guide for determining stresses in suction rolls (Ref 44).

The residual stress that is inherent in the alloy and the heat treatment are also important factors contributing to roll life. Shell materials with known high residual stresses should be designed more conservatively or, preferably, not used at all. This is covered in the discussion "Material Selection" in this section.

Gun-drilled or reamed holes for improved surface finish will reduce corrosion and improve the cleanliness of drilled holes in service. Gun drilling or reaming is usually not performed on bronze shells, but would be helpful in the maintenance of the shell in service.

Corrosion Environment. The papermaker often has little control of some factors influencing the corrosion environment, yet there are many conditions that are within his control. For example, thiosulfate ion contamination and residual hydrosulfite ($NaHSO_2$) in newsprint paper machine white water can occur in $NaHSO_2$ brightening; practices for reducing this problem are addressed in Ref 40. Freshwater showers will provide more effective cleaning and reduce corrosive effects. Good maintenance of the roll is also an important factor in minimizing corrosion. Drilled holes must be kept clean of deposits by the use of needle showers and periodic off-machine cleaning. A careful program of biological control should be maintained. The papermaker should also avoid the use of cleaning chemicals (such as muriatic acid) that are known to be damaging to shell alloys and roll covers. The use of a corrosion inhibitor such as sodium mercaptobenzotriazole should be considered to reduce the corrosion of bronze rolls. The use of inhibitors for couch rolls is described in Ref 45. An example of severe pickup roll corrosion due to thiosulfate that was corrected with inhibitors is discussed in Ref 46.

Materials Selection. When a new or replacement roll is contemplated, the question of material selection is of primary importance. Past operating experience with existing suction rolls should be used as a guide in selecting the new shell material. Reference 47 describes conditions that contribute to roll failure and will aid in new shell materials selection.

Duplex stainless steel has the highest resistance to fatigue cracking, followed by martensitic stainless steel and bronze. Austenitic stainless steel has good corrosion resistance to most environments, but has relatively low fatigue resistance and moderate-to-high residual stresses (Ref 41, 42). Duplex stainless steels have the highest fatigue strength and generally have moderate-to-low residual stresses; bronze has low residual stress, as does CA-15 martensitic stainless steel.

Selection of a new alloy should involve an evaluation of the condition of the existing roll and the factors contributing to its deterioration. The changes in the corrosion environment that have occurred on the paper machine should also be evaluated. One is tempted to select an identical alloy if the previous material served for 15 or 20 years. However, it is more likely that changes in the machine environment have occurred at a recent time and that the life of a new roll of the same alloy would be substantially reduced. This factor accounts for the recent popularity of the stronger corrosion-resistant duplex stainless steel alloys.

Suction shell material cost is also a consideration. In North America and Europe, bronze is the lowest cost shell alloy, followed by martensitic stainless steel, austenitic stainless, and the duplex alloys. In Japan, bronze is seldom used because of availability and cost.

Manufacturing Quality. There is little published information relating to suction shell manufacturing quality. Shells should be inspected using liquid penetrant prior to drilling to detect such flaws as porosity, slag, and cracks. Skillful control of melting and casting procedures can minimize these defects. Weld repairs should be used with discretion, and only before shell heat treatment. Type 1N bronze should not be weld repaired, because of hot shortness, which develops in the alloy. Careful attention should be given to drilling and machining quality and dimensional control. Industrywide standards giving acceptance criteria for casting flaws and drilling quality have not yet been developed.

In-Service Inspection. Periodic inspection of the suction roll is a critical step that will help to extend its life and minimize unexpected shutdowns. Rolls should be removed from the machine, disassembled, and thoroughly cleaned and inspected at least annually. Inspection should include an evaluation of drilled hole cleanliness, fatigue cracking of the shell, and rubber cover deterioration or detachment. Water-washable liquid penetrant has been successfully used to detect cracks on the inside and outside surfaces. A careful visual examination should also be made for corrosion and cracks.

When cracking is observed during an annual inspection, immediate consideration must be given to replacement because of the long lead time required for shell manufacture. Consideration should also be given to inspecting the roll more often than once per year to observe the rate of crack growth. Thus, a careful record must be made whenever cracks are observed.

Corrosion by Kraft Pulping Liquors

R.A. Yeske, The Institute of Paper Chemistry

The kraft process is the predominant pulping process used in North America to extract fibers from wood for use in the manufacture of paper, tissue, and board. The term kraft is derived from the German word for strong, which reflects the high strength of paper products derived from kraft pulp. This high strength, together with effective methods of recovering pulping chemicals, explains the popularity of kraft pulping. In 1984, more than three-fourths of the pulp produced in the United States--approximately 39,000,000 metric tons, or 43,000,000 short tons--was manufactured by the kraft process (Ref 48).

In the kraft process, hot alkaline sulfide liquor is used to dissolve the lignin from wood chips and to separate individual wood fibers for use in paper-making (Ref 49). Wood chips are exposed to cooking liquor for several hours at elevated temperature and pressure in a process called digestion. Digestion may occur by repetitive batch processes in small batch digesters, or the process may occur continuously in larger continuous digesters. The contents of the digester are then discharged under pressure into a receiver called a blow tank. Finally, the fibers are separated from the spent liquor in a series of washing stages.

Pulping chemicals are recovered from the spent liquor in a series of process steps shown schematically in Fig. 38. First, the spent liquor (known as black liquor) extracted for the pulp is concentrated to 60% solids content in multiple-effect evaporators. A soapy by-product called tall oil is usually extracted from the liquor at some stage of the concentration process. The heavy black liquor is burned as fuel in a chemical recovery boiler. The steam produced by the combustion of the organic constituents of black liquor is used for process use and for power generation. The inorganic constituents in the spent liquor fall to the bottom of the recovery boiler, where they are extracted as a molten salt called smelt.

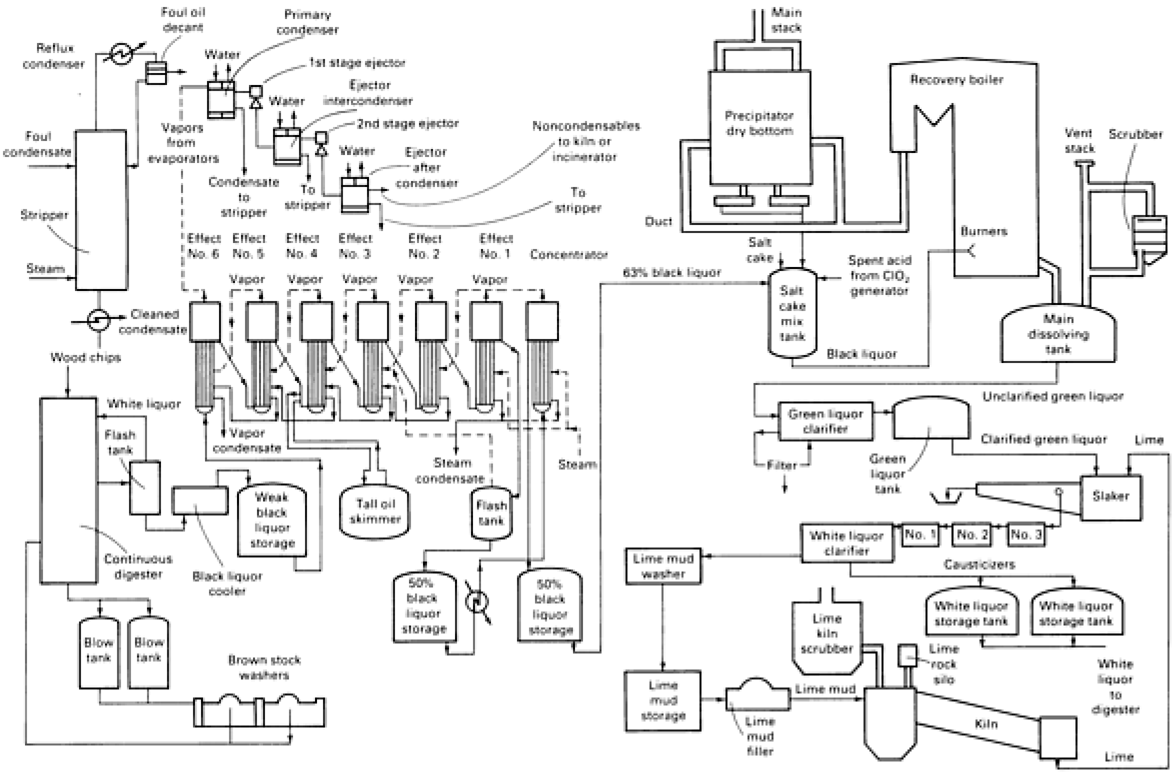

Fig. 38 Schematic representation of kraft pulping and chemical recovery

The smelt recovered from the boiler is converted into cooking liquor in a process known as recausticizing. The molten smelt, which consists primarily of Na_2CO_3 and Na_2S, is dissolved in water to make green liquor. The green liquor is first clarified to remove insoluble dregs and then causticized by exposure to slaked lime. In causticizing, Na_2CO_3 is converted to NaOH by the reaction:

$$Na_2CO_3 + Ca(OH)_2 \rightarrow 2NaOH + CaCO_3 \quad \textbf{(Eq 27)}$$

The $CaCO_3$ precipitate is removed from the liquor by clarification or filtration, leaving a white liquor with approximately 100 g/L of NaOH, 30 g/L of Na_2S, and lesser amounts of residual carbonates and sulfoxy compounds. The white liquor is stored for reuse as cooking liquor. Meanwhile, the $CaCO_3$ precipitate (lime mud) is washed and converted to lime in a lime-burning kiln. This lime is later slaked and reused in the causticizing processes.

Although some details vary from mill to mill, the process equipment used in kraft pulping is more or less the same throughout the industry. The principal items include pressure vessels for batch or continuous digestion, rotary drum pulp washers, multiple-effect liquor evaporators, storage tanks for various liquors, chemical recovery boilers, electrostatic precipitators, rotary lime kilns, slakers, green and white liquor clarifiers, and liquor storage tanks. Ancillary equipment includes pumps, valves, piping, heat exchangers, control instrumentation, and equipment for tall oil processing. To some extent, diffusion washers are replacing rotary drum washers and pressure filters are replacing clarifiers in the modern pulp mill.

Much of the equipment used in the kraft pulp mill is fabricated from plain carbon steel, although carbon steel has limited resistance to corrosion and cracking when exposed to kraft process liquors. In critical locations (such as evaporator tubes in high-temperature evaporator effects), stainless steel is routinely used because of rapid attack of plain carbon steel. In other locations, stainless steel can be used to avoid the inconvenience of periodic replacement of carbon steel equipment. In general, the high temperatures and alkalinity of kraft liquors prevent the use of polymeric materials of construction in pulp mill equipment. However, brick and tile linings, as well as sprayed-on concrete linings, are often found in recausticizing equipment, particularly where abrasion is a concern. Periodically, pulp mill equipment is acid cleaned by

recirculating inhibited acid--usually HCl--to remove carbonate deposits that build up on screens and heat-exchanger surfaces.

Corrosion in Pulp Mill Equipment

Batch digesters were initially thought to be immune to the severe corrosion affecting digesters used in the sulfite pulping process. In 1930, a catastrophic digester failure killed several workers and prompted the industry to measure the wall thickness of kraft digesters (Ref 50). The digesters were inspected, and several were retired because of corrosion-induced wastage of the vessel wall. Thereafter, the industry was vigilant in monitoring the thickness of batch digester walls and retiring vessels that had corroded beyond safe limits.

Corrosion damage appears in batch digesters in several forms, including uniform wastage, large gouges, pitting, and occasional cracking (Ref 51). In some cases, the gouges are clearly associated with erosion caused by steam impingement during direct steam heating of the digester, by recirculating liquors, or by impingement of high-velocity pulp slurries discharged at the end of a cook. Figure 39 shows an example of erosion-corrosion of a blow target plate used to break the momentum of the pulp mass discharged from the digester under pressure. Grooves are often found beneath blind nozzles and other areas where liquor-saturated pulp can lodge, allowing liquor to run down the walls between cooks. Corrosion is often more severe in the bottom cone area, where flow rates are higher during indirect heating and during blows. In some digesters, corrosion is most severe in the splash zone, where cooking liquor splashes on the hot sidewalls during digester charging. Welds are often sites of preferential attack in batch digesters, including accelerated corrosion and occasional episodes of SCC.

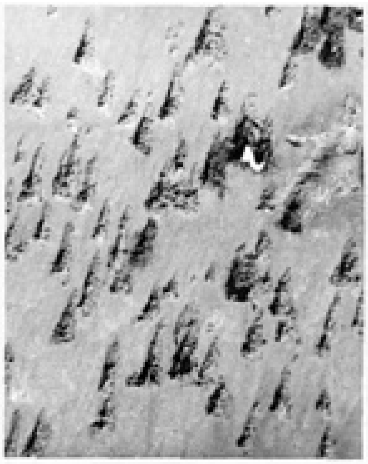

Fig. 39 Erosion-corrosion of a blow target plate by pulp discharged at high velocities from a batch digester

In the late 1940s, the industry became alarmed over an abrupt decrease in the service lives of batch digester vessels because of a corrosion-induced loss of wall thickness. At one mill with 20 digesters in operation, the service life of digesters installed after 1947 was only 3 to 5 years, while the lifetime for digesters installed before 1947 was 12 to 14 years (Ref 52). Several events apparently combined to increase the corrosion rate. The modern low-odor recovery boilers introduced about this time were more effective in retaining sulfur in the process, with resultant increases in the sulfidity of the cooking liquor. Batch digester production was increased by using more frequent batch cooks of greater severity (higher temperatures and more aggressive cooking liquors). Furthermore, semikilled steel was used to fabricate digesters, replacing the rimmed Bessemer steels used in earlier generations of digesters. Each of these factors played a role in the apparent increase in digester wall corrosion.

Considerable progress was made in understanding and controlling batch digester corrosion as a result of the intensive investigations completed in the early 1950s. The effect of liquor composition was thoroughly investigated through surveys and laboratory corrosion studies. General wastage was greatly accelerated by thiosulfates and low concentrations of polysulfides in the cooking liquor (Ref 53, 54) and by the introduction of air into the digester during charging (Ref 55). Linear regression equations were developed to relate the corrosion rate to concentrations of various minor and major constituents in white liquor (Ref 55, 56). Laboratory and field studies showed that most digester corrosion occurred at the start of the batch cook (Ref 57, 58), and corrosion rates were described in the arcane unit, mils per two-thousand cooks

(MTTC). Digester walls were found to be passivated during later stages of the cook and reactivated when raw liquor was introduced into the vessel for the next cook.

Particularly troublesome was a phenomenon called hot plate boiling, in which liquor that was charged into the vessel splashed off the chip pile onto sidewalls that were still hot from the previous cook (Ref 59). The evaporative concentration of dissolved chemicals and the damage to the passive film from the thermal shock combined to reactivate the surface of the vessel for further corrosion during the early stages of the next cook.

The influence of the composition and the microstructure of digester steel on susceptibility to corrosion remains controversial. One researcher noted that vessels that were deoxygenated with silicon corroded more rapidly during contact with cooking liquor than steels with lower silicon and higher oxygen levels (Ref 60). This observation explains the preferential attack of high silicon welds that is frequently noted. Several laboratory studies confirmed the effect of silicon on the corrosion rate of steel (Ref 61, 62, 63), while other studies dismissed the effect as insignificant (Ref 64). A similar controversy regarding the benefits of normalizing heat treatments also developed (Ref 55, 65). The issue of silicon content has never been fully resolved, but many digesters have been subsequently fabricated with special digester steel (for example, ASTM A285 Grade C, containing no more than 0.03 wt% Si) and low-silicon weld filler metal (for example, E6010) in final passes on structural welds.

Digester lifetimes were extended by a variety of measures involving mill operations, the use of linings, and the specification of low-silicon steels. Chip- and liquor-charging practices were modified to eliminate hot plate boiling. This was accomplished by introducing cooking liquor from the bottom of the digester, by using special liquor injection nozzles, and by simultaneous charging of chips and liquor. Graphite brick linings were once extensively used, but stainless weld overlays and thermal-sprayed coatings are now preferred.

The durability of stainless weld overlays has often been inadequate in spite of a TAPPI standard for acceptable overlay practice (Ref 66). Pitting, cracking, and interpass corrosion are the most common complaints. Excessive dilution of the filler metal and production of partially martensitic overlays have been implicated in the poor performance of overlays. The choices of filler metal composition, heat input, and travel speed affect the uniformity of the overlay and the dilution of the filler metal. The weld overlay composition recommended by TAPPI for batch digester protection is as follows (Ref 66):

Alloying element	Composition, wt%
Carbon	0.15 max
Manganese	2.50 max
Phosphorous	0.045 max
Sulfur	0.030 max
Silicon	1.00 max
Chromium	18.0 min
Nickel	8.0 min
Molybdenum, when desired	Cr:Mo $\geq$8:1

The schaeffler diagram predicts that overlays of the specified composition will be devoid of the ferrite required to prevent hot cracking. Furthermore, the high allowable carbon concentration may result in sensitizing of the overlay by the heat of subsequent weld passes. Consequently, mill operators often specify a higher-chromium equivalent and lower carbon in the as-deposited overlay.

Blow Target Plates. Erosion-corrosion of the target plate in blow tanks is a continuing maintenance problem, but some advantage can be obtained by using more highly alloyed material. For example, Hastelloy alloy C-276 has endured for 4 years in target plate service where 18-8 austenitic stainless steels were lasting for only a few months.

Piping and Ancillary Equipment. Carbon steel piping is subject to corrosion and erosion-corrosion in the kraft pulp mill, but is often chosen for economy. Elbows lines and other areas of high abrasion are particularly susceptible to attack. Type 304L stainless steel is effective in controlling corrosion damage in piping. Pump impellers, pump casings, and valves made from cast CF-8M are usually resistant to attack by kraft liquors.

Continuous Digesters. In contrast to the cyclic environments encountered in batch digesters, wetted surfaces in continuous digester experience the same environment for months at a time, although the exact environment depends on the elevation in the digester. Wood chips are added at the top of the vessel, and the pulp mass works its way downward while the chips are successively saturated with liquor, cooked, washed, cooled, and discharged from the bottom of the vessel. Cooking, extraction, and wash liquors are circulate through the pulp through a series of internal screens and downcomer pipes.

Although the rate of uniform wastage in continuous digesters is usually quite low--of the order of 0.13 to 0.25 mm/yr (5 to 10 mils/yr)--higher rates of attack have been observed locally. In particular, erosion-corrosion can be a problem where fresh cooking liquor impinges on steel surfaces near the top of the digester. Pitting of welds and preferential corrosion of weld filler metal have also been observed in continuous digesters, but this attack may be result of acid cleaning practices, rather than attack by cooking liquor.

A severe corrosion problem in continuous digesters literally burst upon the scene in 1980 with the catastrophic failure of a large continuous digester vessel during routine operation (Ref 67). The digester ruptured near the top of the vessel because of extensive SCC of shell girth welds. This cracking was restricted to the welds in the impregnation zone at the top of the digester. Caustic SCC was implicated because of the branched, intergranular appearance of the cracks and the presence of sodium hydroxide in the hot cooking liquor.

Subsequent inspections of similar digester revealed that more than half of the 140 continuous digesters operating in North America exhibited cracking in structural welds (Ref 68). Cracking has been found in girth and vertical shell welds, attachment welds inside the digester, and nozzle welds. Both longitudinal and transverse cracking have been observed, but the deepest cracking has been found in longitudinal cracks in the weld HAZ. Examples of cracking in actual digester welds are shown in Fig. 40.

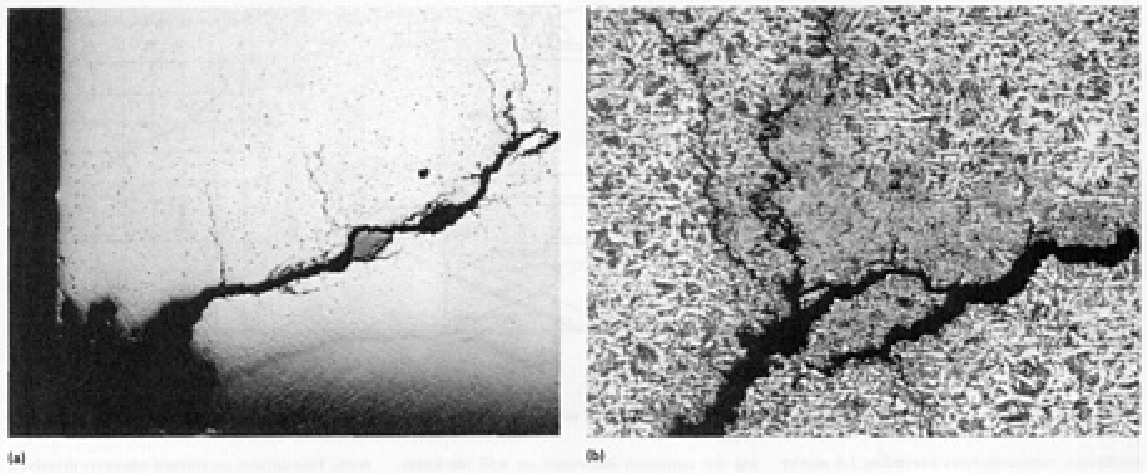

Fig. 40 Examples of digester weld cracking. (a) Macrograph showing cracking in a sample taken from a continuous digester weld. 10×. (b) Photomicrograph showing branched, intergranular nature of cracking in an actual continuous digester weld. 40×

Most of the cracking has been found in the impregnation zone, where the caustic concentration in the cooking liquor is highest. Furthermore, the residual stresses in impregnation zone welds were often not relieved by postweld heat treatment, because the shell is thinner in this zone and stress relief is not required under provisions of the ASME. Boiler and Pressure Vessel Code.

An extensive survey of digester cracking statistic failed to reveal differences in digester design or operation that would account of differences in cracking susceptibility (Ref 68). As shown in Fig. 41 postweld heat treatment significantly reduced, but did not eliminate, susceptibility to severe cracking.

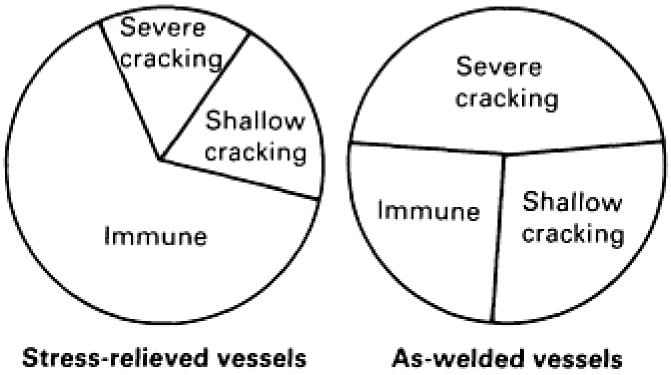

Fig. 41 Effect of stress relief on SCC susceptibility of continuous digesters

Cracking similar digester cracking was reproduced in the laboratory by using accelerated slow strain rate and fracture mechanics test (Ref 69). These tests indicated that the caustic concentration in cooking liquors at the impregnation zone was sufficient for caustic cracking of pressure vessel weldments. Furthermore, caustic cracking occured only when the potential of the digester steel was within a 100-mV range centered close to digester potentials. Figure 42 shows the dependence of cracking susceptibility on potential as determined in slow strain rate tests performed on welded specimen in simulated impregnation zone liquor (Ref 70). Potential measurements are made on an operating digester indicated that the digester rest potential remained above the cracking range, except for a few days following upset in operating routine (Ref 71).

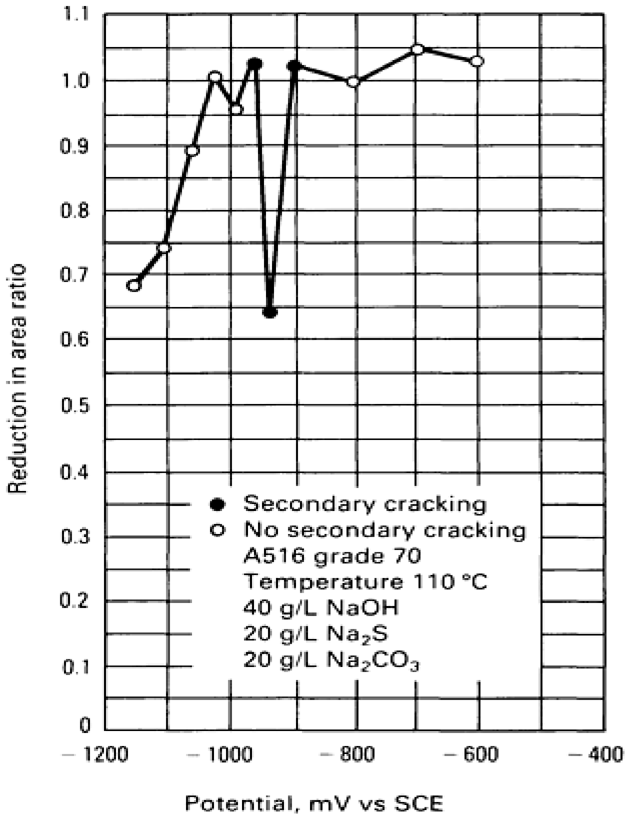

Fig. 42 Plot showing the effect of potential on cracking severity in controlled-potential slow strain rate testing of digester steels exposed to a simulated impregnation zone liquor. SCE, saturated calomel electrode

Two measures have been successful in controlling digester weld cracking: high alloy barrier coatings placed over susceptible welds and anodic protection. Other remedial measures, such as shot peening, temper-bead weld repair, *in situ* stress relief, and unsealed thermal spray coatings, have not been uniformly successful in preventing recracking.

Weld overlays and thermal sprayed coatings have both been successfully used to control cracking. Weld overlays--primarily Inconel alloy 82 and type 309L stainless steel--have been applied in bands over structural welds to isolate them from contact with cooking liquor. The overlay bands are themselves resistant to corrosion damage, but there have been cases of cracking of the carbon steel substrate in the HAZ at the edge of the overlay band. Experience with thermal sprayed coatings has been limited, but it appears that flame-sprayed and plasma-sprayed stainless steel coatings protect underlying welds if the coating is sealed with a silicone-modified furan after application (Ref 72). Additional information is available in the article “Thermal Spray Coatings” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Anodic protection has been effective in controlling both corrosion and caustic cracking in a number of continuous digesters (Ref 73). Protection is achieved by passing a controlled direct current (dc) through an electrolytic cell consisting of the digester wall, the cooking liquor, and a special cathode installed inside the digester. Currents as high as 1000 A (at 12 V dc) may be required to passivate the vessel initially, but only a few hundred watts of electrical power is required to maintain anodic protection. The digester potential is maintained approximately 100 mV above the upper limit of the potential range required for cracking. Anodic protection has suppressed further cracking in several digesters previously susceptible to severe and chronic cracking. Additional information is available in the article “Anodic Protection” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Liquor Reheater Tubing. Corrosion and cracking have been encountered in stainless steel tubes in shell and tube heat exchangers used to heat recirculating liquors. An example of a cracked liquor reheater tube is shown in Fig. 43. In most cases, severe transgranular cracking occurs when liquor leaks onto the steam side of the tubes, where it is concentrated and heated by the steam. Caustic cracking and chloride SCC have both been implicated. Differential thermal expansion between the stainless steel tube bundle and the carbon steel shell apparently provides the stress required for cracking. Cracking has been eliminated in more than 100 kraft mills by the use of a duplex stainless steel (3RE60, see Table 13 for composition) in liquor heater tubes; Inconel heater tubes have also been successfuly used (Ref 74, 75).

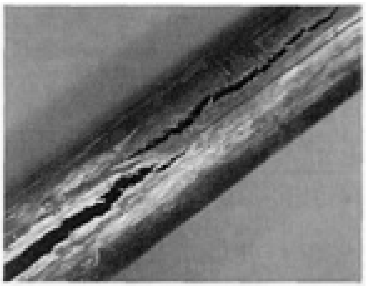

Fig. 43 Transgranular SCC of type 304L stainless liquor reheater tubing

Corrosion of stainless steel liquor heater tubing is more puzzling, because stainless steel is generally resistant to attack by kraft liquors at liquor heater temperatures. Corrosion of liquor heater tubes may actually result from improper acid cleaning--for example, by using excessive temperatures uninhibited HCI.

Corrosion in Recausticizing Equipment

The recausticizing plant provides a variety of corrosive media, including white and green liquor, lime mud slurries, lime mud wash waters, and lime kiln scrubber waters. White and green liquors attack storage tanks, clarifiers, and piping fabricated from plain carbon steel, but have little effect on stainless steel equipment (in the absence of abrasion). Erosion-corrosion is frequently seen on equipment in contact with abrasive lime mud slurries, such as clarifier rakes, lime mud slurry pump casings and impellers (Fig. 44), and lime mud discharge lines. Corrosion also occurs on lime kiln scrubber components.

Fig. 44 Erosion-corrosion of a lime mud pump impeller

Plain carbon steel storage tanks and clarifiers in white and green liquor service suffer severe corrosion attack, particularly in zones where liquor levels fluctuate frequently. Figure 45 shows the variation in corrosion rate at different elevations along the sidewall of a white liquor clarifier (Ref 76). In the zone immediately above the outlet bustle pipe, the corrosion rate approaches 0.75 mm/yr (30 mils/yr). Areas that are seldom immersed experience a much lower rate of corrosion, as do surfaces near the bottom, which are protected by a layer of lime mud sediment. In multitray clarifiers, the trays experience a similar form of attack. Little corrosion is seen on the top of the tray where lime mud settles, but severe attack occurs on the underside of the tray where air bubbles entrained in the liquor remain in contact with the tray. White liquor clarifiers and storage tanks often need extensive repair or replacement after only 10 years of service, and cases of severe corrosion in less than 2 years have been reported.

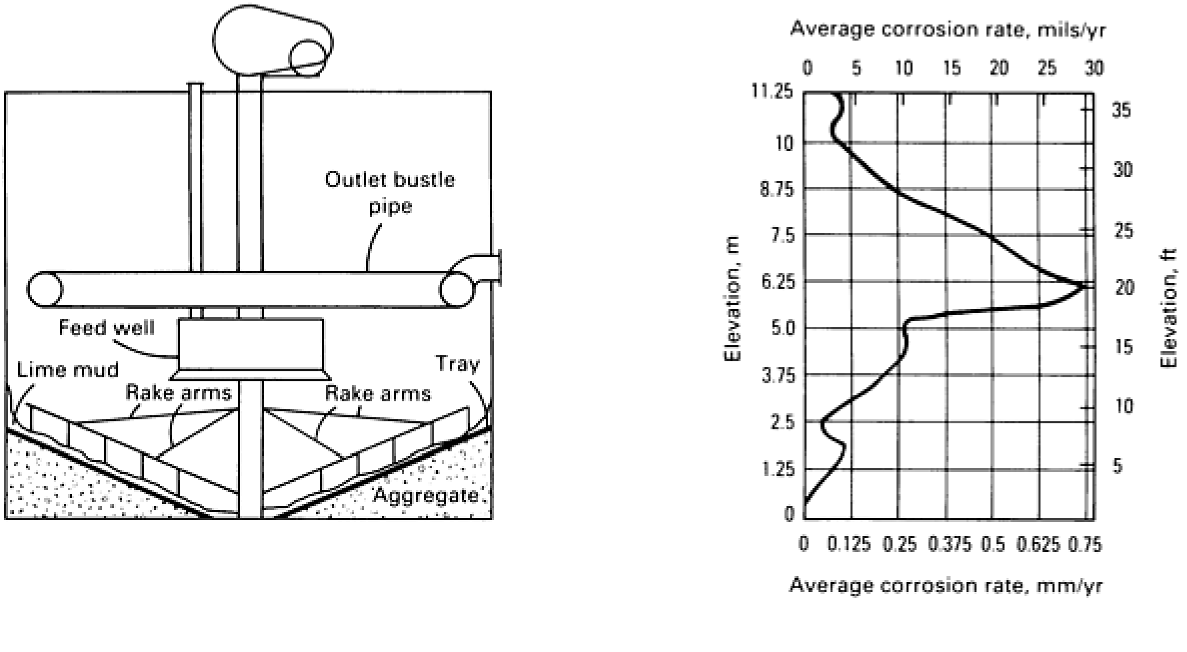

Fig. 45 Variation of corrosion rate with elevation at the wall of a white liquor clarifier

The corrosivity of white liquor is strongly influenced by the liquor composition. In simulated white liquors containing only the important pulping chemicals--NaOH and Na_2S--the rate of corrosion of carbon steel is less than 0.25 mm/yr (10 mils/yr) (Ref 77). However, the presence of thiosulfates and low concentrations of polysulfide in white liquor can increase the corrosion rate to more than 1.3 mm/yr (50 mils/yr), as shown for thiosulfate in Table 14. The effect of thiosulfate and polysulfide is greater in liquors containing high concentrations of NaOH and Na_2S. The other species typically found in white liquor--sulfates, sulfites, chlorides, and carbonates--are apparently innocuous (Ref 78). Because

the hydrosulfide in white liquor is rapidly converted to thiosulfate by air contact, the high rate of corrosion at air/liquor interfaces is probably related to the thiosulfate effect shown in Table 14.

Table 14 Effect of thiosulfate concentration on white liquor corrosivity

Duration of exposure: 8 weeks

Concentration, g/L			Corrosion rate	
NaOH	**Na_2S**	**$Na_2S_2O_3$**	**mm/yr**	**mils/yr**
80	20	0	0.18	7
80	20	2.5	0.18	7
80	20	10	0.28	11
80	20	25	0.71	28
80	20	50	1.35	53
80	40	2.5	0.15	6
80	40	5	0.51	20
80	40	10	0.53	21
80	40	25	1.09	43
80	40	50	2.21	87

Source: Ref 78

Liquor velocity relative to steel surfaces can also have a large effect on the rate of corrosion (Ref 79). As shown in Table 15, the rate of corrosion of carbon steel by white liquor is increased fivefold by a change from stagnant to laminar flow conditions. Under turbulent flow conditions, corrosion rates exceeding 3.8 mm/yr (150 mils/yr) are possible.

Table 15 Effect of liquor velocity on white liquor corrosivity of simulated liquor, 100 g/L NaOH + 33 g/L Na_2S

Velocity		Corrosion rate	
m/s	**ft/s**	**mm/yr**	**mils/yr**
0.0	0.0	0.13	5
0.14	0.46	1.65	65
0.25	0.82	2.03	80
0.30	0.98	2.51	99
0.43	1.41	3.05	120
0.50	1.64	3.63	143
0.86	2.82	3.50	138
1.32	4.33	3.81	150
2.62	8.60	3.76	148

Several corrosion control measures have been effective in recausticizing applications, including stainless steel fabrication, specification of thickwall carbon steel at critical sites, controlling thiosulfate and polysulfide levels, the use of barrier linings, and anodic protection.

Type 304L stainless steel is not affected by white or green liquor, and stainless steel recausticizing equipment will probably last for the life of the mill. The higher cost of stainless steel can be mitigated to some extent by eliminating the corrosion allowance on wall thickness. There is little justification for using more costly type 316L stainless steel in recausticizing applications; the high pH of the liquors inhibits chloride attack and precludes the need for molybdenum in the stainless steel. In vessels with corrosion at the liquid level line as shown in Fig. 45, stainless steel belly bands can be installed to prolong tank lifetime. Usually, formed stainless steel plates are seal welded to the inside wall. Careful installation is required to prevent liquor from leaking between the stainless cladding and the wall and accelerating wall corrosion.

Experience with alkali-resistant concrete and brickwork linings in recausticizing vessels has been checkered. In some cases, the lining prevents further corrosion damage. In may cases, liquor penetrates behind the barrier linings, allowing renewed attack of the wall. Installation of a protective polymeric membrane between the vessel wall and the lining may eliminate damage if the lining is breached.

Thiosulfate levels can be reduced by minimizing air contact with liquor in order to lower corrosion rates in white and green liquor systems. Thiosulfates are formed wherever dissolved sulfides in the liquors come in contact with air. Likely sites for thiosulfate formation include shatter jets (where smelt is dispersed as it falls into the dissolving tank liquor), splitter box weirs, storage tank and clarifier liquid surfaces, and leaking pump seals. Steam shatter jets are preferred over compressed air jets for reducing thiosulfate levels. In some cases, thiosulfates are generated when weak wash liquor is used to scrub lime kiln flue gases before being used as dissolving tank makeup liquor. Scrubber waters should be completely oxidized to convert thiosulfates to innocuous sulfates before use as dissolving tank makeup liquor.

Natural polysulfide levels are negligible in most white liquors. However, polysulfide-accelerated attack can occur if emulsified sulfur in added (for sulfur makeup) in the recausticizing plant, because elemental sulfur is rapidly converted to polysulfide. Makeup sulfur should instead be added to black liquor to minimize corrosion damage.

Recently, anodic protection has been shown to be an effective and economical corrosion control measure for use in white liquor storage tanks and clarifiers (Ref 76). In a prototype installation on an operating clarifier with severe corrosion damage, corrosion rates were reduced by nearly an order of magnitude by holding the rest potential of the vessel in the passive range. The anodic protection system is shown schematically in Fig. 46. Although relatively large currents were required to achieve initial protection, little power is needed to maintain protective passivation.

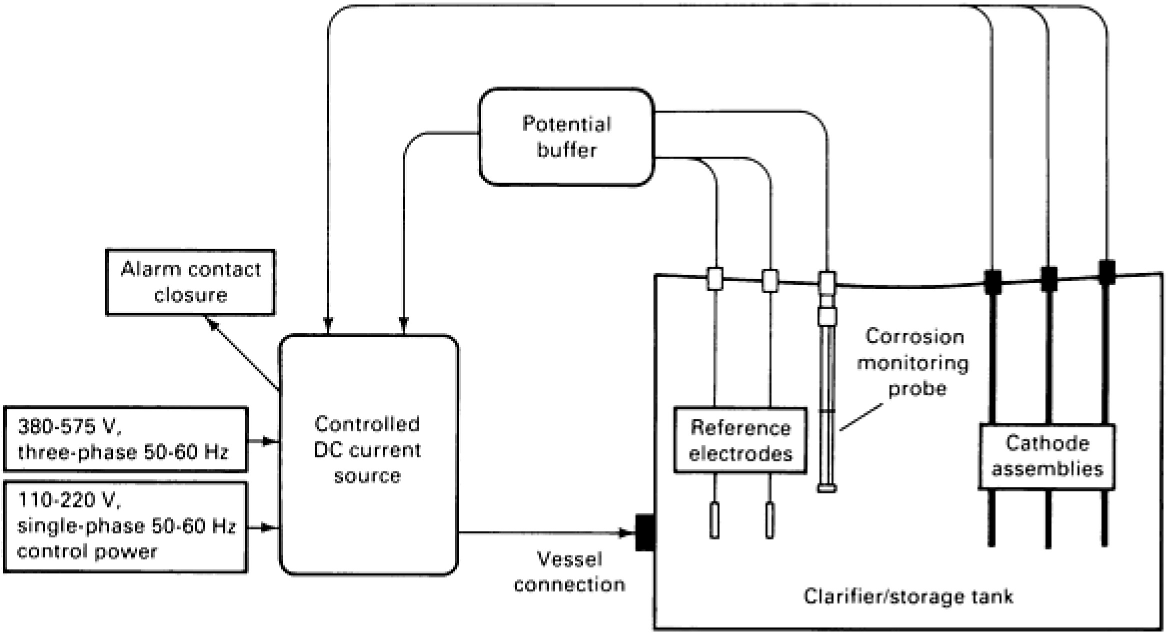

Fig. 46 Schematic diagram of an anodic protection system for recausticizing storage tanks and unit clarifiers

Erosion-corrosion is a severe problem wherever abrasive lime mud is found. Stainless steel fabrication is appropriate wherever abrasive conditions prevail, as in rakes and rake arms in while and green liquor clarifiers. In severely abrasive conditions, such as lime mud pump impellers, hard-facing overlays such as cobalt-base Stellite alloys may be effective, but periodic replacement of components is usually necessary.

Corrosion in Black Liquor Processing Equipment

Black liquor varies considerably, depending on the pulping process used, the pulping yield, and the stage of chemical recovery. Weak black liquor, the filtrate obtained from brown stock washing, contains approximately 20% solids consisting of organic compounds extracted from the wood (principally lignin compounds), inorganic salts not consumed in the pulping process, organic acids, and various hemicelluloses and sugars. The pH of weak black liquor is of the order of 12, and the residual active alkali (NaOH and Na_2S) can range from 4 to 30 g/L. The solids content of heavy black liquor is increased by evaporation into the 60 to 75% range, and heavy black liquor at room temperature is viscous and

semisolid. Black liquor oxidation can be used to convert reduced sulfur compounds in black liquor to thiosulfates and sulfates in order to reduce odorous emissions from the recovery boiler and to conserve sulfur in the process.

Corrosion of brown stock washing equipment is rarely a concern in the kraft pulp mil. Brown stock washing is usually carried out on rotary drum vacuum washers, although displacement washing is becoming more common. Washer drums are usually fabricated from carbon steel, while backing wires and face wires are usually stainless steel. The moderately high pH of weak wash filtrate, together with the low concentration of NaOH and the inhibitive effect of the dissolved organic species, generally prevent severe corrosion of brown stock washing equipment in spite of the dissimilar-metal construction. However, corrosion can become a problem if the pH of the weak wash filtrate is depressed by the use of acid bleach plant filtrate as shower water or by the addition of neutral sulfite semichemical pulping liquors. When acidic filtrates are used, it is common practice to raise the pH above 10 to reduce corrosion and to prevent odorous emission of hydrogen sulfide gas.

The details of black liquor evaporation equipment vary from mill to mill. Multiple-effect evaporators are generally used to increase the black liquor solids to the 55% level, while concentrators or cascade evaporators complete the evaporation. The shell and tube heat exchanger (rising film, long tube vertical evaporators) is the most common evaporator design, but other configurations with plates and falling films are becoming more popular. Plain carbon steel and type 304L and 316L stainless steels are common materials of construction. Stainless steel tubes are used in the higher-temperature evaporator effects (>95 °C, or 200 °F); both stainless and carbon steel tubes are used at lower temperatures. Black liquor storage tanks and oxidation equipment are usually made of plain carbon steel. Stainless steel piping is commonly used for black liquor transport.

In general, black liquor is much less corrosive toward carbon steel than the recausticizing liquors, because the concentrations of NaOH and Na_2S in black liquor have been reduced by the pulping reactions. The residual alkali in black liquor maintains the pH near 12, which stabilizes a protective film on the steel surfaces. In spite of this film, carbon steel storage tanks wetted by black liquor may experience pitting and crevice corrosion, particularly at the liquor level line and underneath sediments and scales. Pitting attack, such as that shown in Fig. 47, is often encountered on roofs and other surfaces that are exposed to vapors emanating from the black liquor. This pitting is attributed to volatile organic acids that condense on cooler surfaces but are not neutralized by direct contact with the alkaline black liquor.

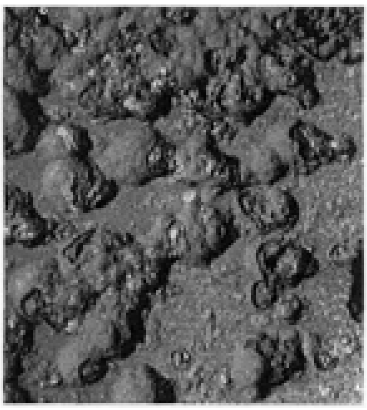

Fig. 47 Pitting of a carbon steel root section in a black liquor storage tank

Remedial measures for corrosion in black liquor storage tanks are limited. Generally, the moderate rate of attack does not justify the use of stainless steel for tanks and vessels. Although the high temperatures and organic sulfur compounds in black liquor make fiber-reinforced plastic generally unsuitable for immersion service, some mills have installed fiber-reinforced polymeric roofs on black liquor storage tanks to minimize pitting attack. Thick-wall carbon steel construction and the use of stainless belly bands may also be beneficial when attack is restricted to one area, such as the liquor level line.

Stainless steels are generally resistant to corrosion by black liquors at temperatures normally encountered in evaporation and concentration equipment. Over the years, experience has shown which evaporator components must be stainless to prevent excessive corrosion, therefore, severe evaporator corrosion is now relatively infrequent. Tubes, vapor deflectors,

and liquor boxes are generally stainless steel or stainless-chad carbon steel, particularly in the high-temperature effects. When localized corrosion does occur on carbon steel surfaces in modern evaporators, it can usually be traced to unanticipated contact between hot liquor and the steel due to foaming, excessive throughout, or other operating misadventures. In these cases, stainless steel weld overlays or thermal spray coating applied to the carbon steel surface usually forestalls continued corrosion.

Although black liquor oxidation produces high levels of thiosulfate in the black liquor, the thiosulfates are much less injurious to carbon steel in black liquor service as compared to the recausticizing situation. Oxidized black liquors have low residual alkali levels because of consumption of NaOH in the digestion process and complete oxidation of Na_2S. In the absence of significant concentrations of NaOH and Na_2S, thiosulfates are relatively innocuous toward carbon steel. Consequently, it is desirable to oxidize weak black liquor, rather than strong black liquor, so that more of the black liquor process equipment benefits from the reduced corrosion that accompanies black liquor oxidation. Carbon steel is generally adequate for oxidation equipment and oxidized black liquor storage.

Corrosion of Mechanical Pulping Equipment

C.B. Thompson, Pulp and Paper Research Institute of Canada; D.A. Wensley, MacMillan Bloedel Research

In mechanical pulping, wood fibers are separated from each other by rolling, rubbing, or teasing, either against themselves or against a harder, specially designed surface. Chemical additions or the application of heat and pressure can be used to increase the efficiency of the process, but the predominant pulping forces are mechanical. Mechanical pulping can be divided into two main areas: groundwood and disk refining. in overall terms, mechanical pulping forms an important part of the pulp and paper industry and is notable for its technological and economic expansion in recent years (Ref 80).

Mechanical Pulping Systems

Groundwood is one of the oldest commercial pulping processes and, until recently, was the predominant means of mechanical pulping. The most common version is stone groundwood, in which pulp is formed by pressing debarked logs against a rotating grindstone, as shown in Fig. 48. Water sprays are directed onto the stone to prevent the fibers from burning, and the pulp is removed in the form of a slurry. Other variations include pressurized groundwood, in which pulping occurs at elevated temperature, and chemi-groundwood, in which a chemical pretreatment is used.

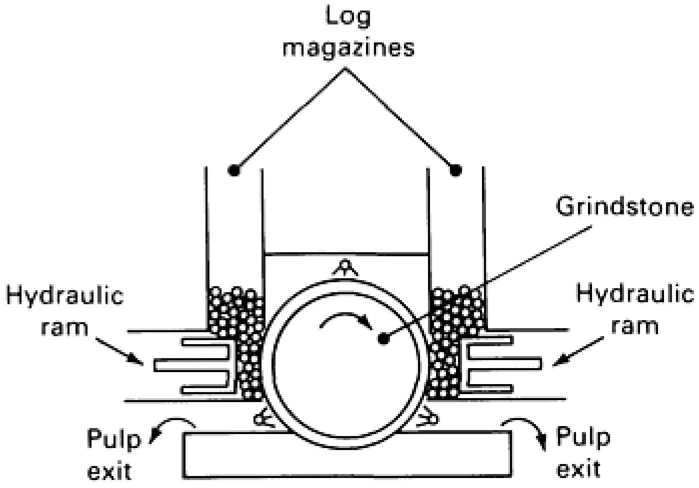

Fig. 48 Schematic sectional view of a stone groundwood machine. Cut, debarked logs are fed into magazines, from which they are pressed against a rotating grindstone to be pulped.

Corrosion is usually not of concern in these units, largely because most pulping is done by the stone groundwood method, in which water sprays are the only potentially corrosive environment. As a result, attack is limited to general wastage of exposed carbon steel.

Disk refining has overtaken groundwood in importance since the 1970s, primarily because of its ability to produce higher-strength pulps and to utilize chips or sawmill residues as feedstock. Modern disk refiners are typically large and powerful; disk diameters up to 1.8 m (70 in.) are common, with installed motor powers of 13,400 kW (18,000 HP) (Ref 80). A schematic sectional view of a refiner is shown in Fig. 49.

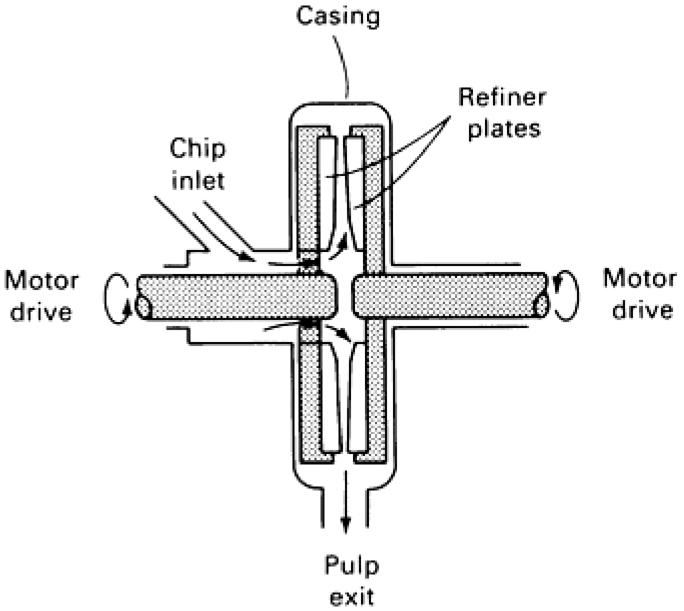

Fig. 49 Schematic sectional view of a disk refiner. Pulping takes place between rotating rings of refiner plates. In this example, the refiner plates are mounted on opposing rotor assemblies (shaded) that counterrotate at high speed. Such a unit is called a double-disk refiner. Single-disk refiners, in which only one set of refiner plates is rotated, are also common.

In operation, refiner pulp is produced by passing wood chips between two or more closely spaced serrated disks, at least one of which is being rotated at high speed by an electric motor. Each disk is made by bolting refiner plates onto a backing plate. A typical refiner plate is illustrated in Fig. 50, showing the characteristic series of raised bars. The space between two opposing sets of refiner plates is called the refining zone. As wood chips pass outward through the refining zone, they are gradually reduced to pulp by interaction with refiner plate bars. Although many plate bar patterns exist, it is common to have large bars near the inlet to cause rapid breakdown of the chips. As the pulp progresses through the outer refining zone, the bars become finer in order to impart maximum refining energy to the stock. In most cases, it is usual to have two or more refiners operating in series to obtain optimum refining efficiency.

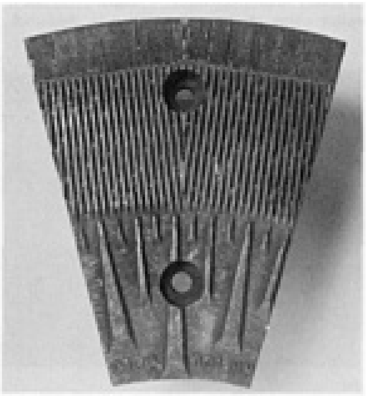

Fig. 50 General view of a refiner plate. The large bars at the bottom are called breaker bars. The bars become progressively finer towards the top edge of the plate.

A large number of refiner pulping processes have been developed, primarily as a result of the need to produce tailor-made pulps and to decrease energy requirements. The simplest process is refiner mechanical pulping, in which the chips are fed directly to the refiner with no prior use of heat or chemical dissolution. For newsprint production, this process has now been largely superceded by thermomechanical pulping, in which the chips are softened in a steaming tube before entry into the primary refiner, and by chemi-thermomechanical pulping, in which both heat and chemical additives are used in order to accelerate the pulping. In both thermomechanical and chemi-thermomechanical systems, chip presteaming and primary refining take place at temperatures above 100 °C (212 °F); in the secondary refiner, the pulp is usually discharged to atmosphere. A schematic diagram of a thermomechanical pulping system is shown in Fig. 51.

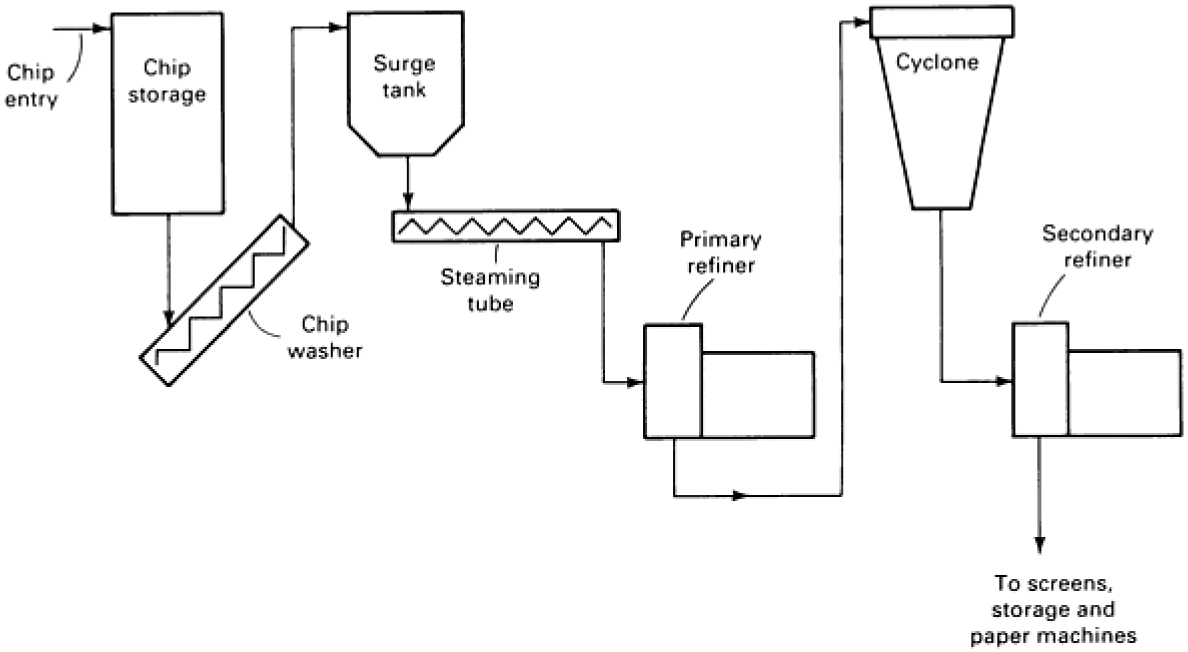

Fig. 51 Schematic of a typical thermomechanical pulping system layout

In addition to the pure mechanical pulping described above, refiners are also used in a variety of chemi-mechanical pulping methods, in which chips are typically pretreated in a digester before entering the refiners. The principal difference between the two types of pulping is the pulp yield. Chemi-mechanical pulps are in the range 55 to 90% yield; the yield for pure mechanical pulping exceeds 90%.

Corrosion is of more concern in disk refining than in stone groundwood due to the higher process temperatures and the presence of pulping chemicals. In addition, significant wear can occur because of the action of high-velocity jets of steam and water within the refiner and the presence of sand and grit entrained in the stock. Presently, the major problem areas for corrosion and wear are the refiner plates and the steaming tubes; these are discussed below in more detail.

Corrosion and Wear of Refiner Plates

Most refiner plates are cast, although wrought plate sets are available for low-consistency units. Plates are produced by either refiner manufacturers or specialist refiner plate foundries. Alloys are often of proprietary composition, although most fall into the general classes of white cast iron or cast stainless steel (Ref 81, 82). Some typical compositions are shown in Table 16. Refiner plates cast in white cast iron generally have a large volume fraction of primary carbides set in a martensitic matrix, which sometimes contains large amounts of retained austenite. Cast stainless steel refiner plates usually possess a lower concentration of carbides set in a martensitic matrix. Some typical microstructures are shown in Fig. 52.

Table 16 Typical refiner plate alloy types and compositions

Alloy type	Composition, wt%							
	C	**Cr**	**Ni**	**Si**	**Mo**	**Mn**	**P**	**S**
Martensitic white cast iron	3.3	2.4	4.0	1.2	0.3	0.6	0.03	0.02
Martensitic high-chromium	2.7	23.2	0.4	0.5	2.0	0.7	0.02	0.02
white cast irons	3.0	27.7	1.1	0.6	0.1	0.5	0.03	0.03
Martensitic cast	0.8	18.0	1.4	0.9	0.5	0.6	0.03	0.02

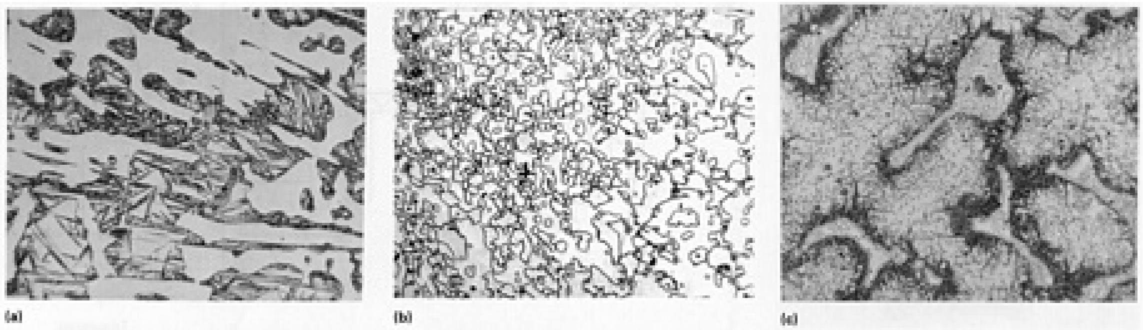

Fig. 52 Typical refiner plate alloy microstructures. (a) Low-chromium white cast iron; martensite in a eutectic matrix of martensite and iron carbide. Etched with 2% nital. (b) High-chromium white cast iron; iron-chromium primary carbides in a martensitic matrix. Depending on the heat treatment, a large amount of retained austenite may be present in the structure. Etched with 2% nital. (c) Cast stainless steel; iron-chromium primary carbides in a martensitic matrix containing secondary carbides. Etched with mixed acids. All 230×

Corrosion and Wear. Premature wastage of refiner plates by corrosion and wear adversely affects such critical pulp quality factors as burst, tear, and shives (Ref 83, 84). Worn plates can also decrease paper machine runnability; this can result in significant costs due to machine stoppages or lower speeds (Ref 85) and the need for chemical reinforcing pulps. The types of damage caused by the corrosion and wear of refiner plates are detailed below. It should be noted, however, that little systematic study has been reported in this area, and there is no consensus of opinion as to the actual mechanisms by which such wastage takes place.

Bar rounding is usually found in the outer refining zone on the bar leading edges. Severe bar rounding leads to loss of profile and a reduction in refining efficiency; a typical example is shown in Fig. 53. Bar rounding appears to take place by a combination of corrosion and low-stress abrasion due to sand and grit in the stock. Examination of rounded surfaces at high magnification shows numerous short abrasion furrows, often with associated lips or platelets, of deformed material. Typically, the primary carbides are left in relief on the surface.

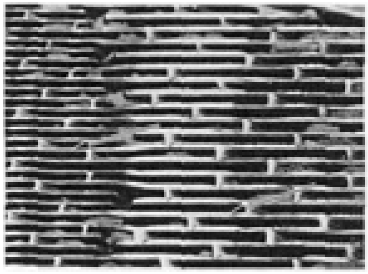

Fig. 53 Severe bar rounding (arrows) on a cast stainless steel refiner plate. Approximately $\frac{3}{5}$×

Clashing. During operation, it is common for opposing sets of refiner plates to touch each other. This is called clashing, and it can be due to loss of stockfeed or a temporary disruption of the pulp pad between the plates. Because of the high power applied during refining, clashing produces severe plate damage, commonly in the form of deep, circumferential grooves and serrations. A typical example is shown in Fig. 54. Some investigators have attributed clashing to electrochemical dissolution rather than mechanical contact, primarily because of the remarkably smooth surfaces that are often found on clashed plates (Ref 86). However, thermal cracking (Ref 87) and evidence of surface melting and smearing (Ref 82) have been observed on clashed plates, and it is probable that in most cases metal wastage due to clashing is primarily mechanical in nature. To reduce the frequency of clashing, various type of proximity sensors have been developed to monitor the gap between opposing plate sets (Ref 88).

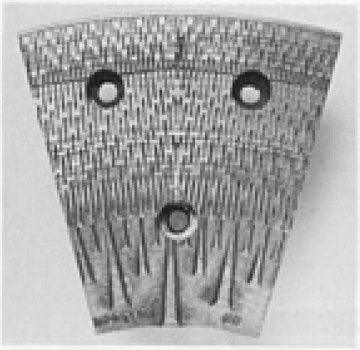

Fig. 54 Clashed surface on a white cast iron refiner plate. The circumferential serrations are typical of this type of wear.

Cavitation and Liquid Droplet Impingement Erosion. Heavy pitting at the base of breaker bars and on the edges and top surfaces of intermediate and outer zone refining bars is commonly attributed to cavitation erosion (Ref 89, 90). A typical example is shown in Fig. 55. In some cases, similar attack can be produced by liquid droplet impingement erosion, which is caused by water jets or condensing steam (Ref 91). Metal wastage due to these mechanisms is generally regarded as secondary in importance to bar rounding and clashing; plates are changed only if there is a danger of bar segments being undermined and breaking free during operation. In some cases, however, cavitation has caused such rapid loss of bar profile that plates have had to be changed after as little as 300 h of service. Such intense attack is probably due more to the design and operational characteristics of the particular refiner than to any deficiency in the cavitation resistance of the refiner plate.

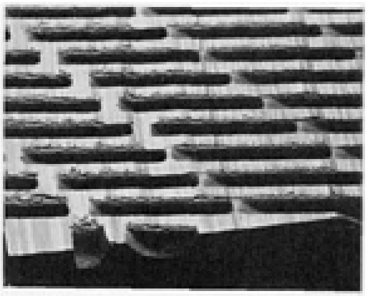

Fig. 55 Heavy cavitation attack on the intermediate refining zone bars of a high-chromium white cast iron refiner plate

Corrosion in Pressurized Equipment

Corrosion of pressurized equipment constructed from stainless alloys, such as thermomechanical or chemi-thermomechanical pulping steaming vessels and bisulfite chemi-mechanical pulping digesters, can cause serious materials

reliability problems if either chlorides or acidic sulfur compounds are present. Problems include chloride SCC, pitting, and crevice corrosion, as well as general wastage due to sulfuric acid condensation.

Thermomechanical and Chemi-Thermomechanical Pulping

Thermomechanical and chemi-thermomechanical steaming vessels may be of horizontal, vertical, or inclined configuration. Steaming is typically carried out at 130 to 150 °C (260 to 300 °F) and at 200 to 350 kPa (30 to 50 psig). Horizontal steaming tubes (Fig. 56) experience corrosion problems in areas not swept clean by the moving chip bed. Deposits can form on the vessel walls and on the lee sides of longitudinal rub bars. The rub bars are used to guide the chip mass along the vessel and to protect the vessel from accidental damage by the screw.

Fig. 56 View inside a horizontal chemi-thermomechanical pulping steaming tube with the screw removed for inspection. The vessel is of UNS NO8904 construction and has three longitudinal rub bars of the same composition stitch-welded to the shell. See also Fig. 59.

Corrosion by Chlorides. Chips from seaborne logs may introduce appreciable amounts of chloride. The liquid film surrounding damp wood chips may contain 2500 ppm NaCl and may also have an acid pH (4 to 6) due to the release of wood acids. Chlorides can concentrate beneath deposits, perhaps by evaporation of areas intermittently wetted with chloride-containing water. Chemi-thermomechanical pulping steaming tube deposits have been analyzed to contain as much as 38,000 ppm NaCl.

Chloride SCC has caused the rupture of a type 316 stainless steel steaming tube. Severe cracking was associated with the residual tensile stress fields around rub bar stitch welds (Fig. 57). Extensive cracking was also found beneath vapor space deposits in the same vessel--well removed from any welds (Fig. 58). Chloride SCC has also been observed in horizontal steaming vessels and screws constructed from UNS NO8904 stainless steel (Fig. 59 and 60).

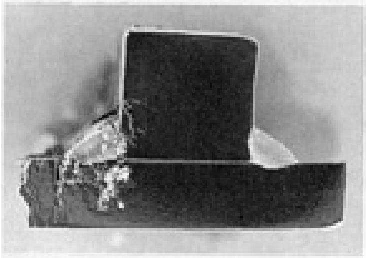

Fig. 57 Cross section of a piece cut from a type 316 stainless steel steaming vessel that failed by chloride SCC. Cracking occurred under deposits on the lee-side of a 13-mm (0.5-in.) square rub bar and progressed through

the 6-mm (0.25-in.) thick shell.

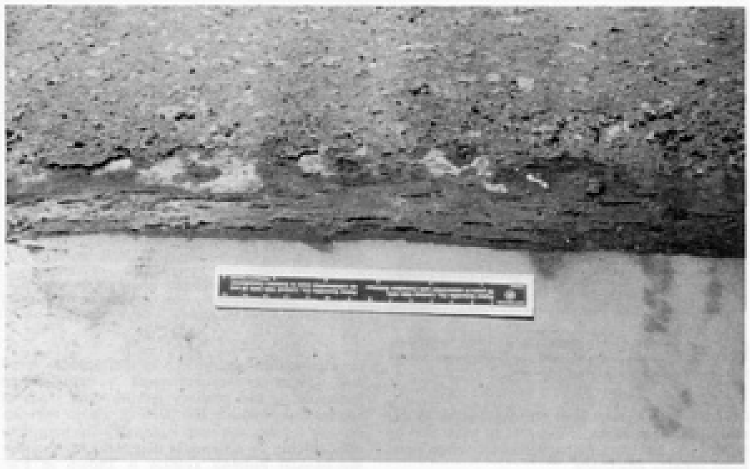

Fig. 58 Photograph of the inside surface of a failed AISI 316 steaming tube showing chloride SCC that developed beneath deposits (the cracks have been opened by subsequent deformation). The lower part of the surface was swept clean by chip movement and did not crack.

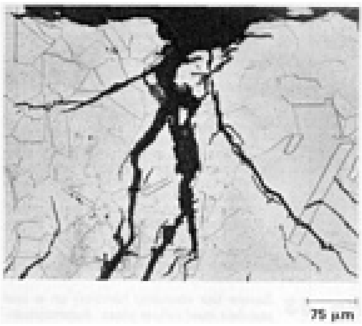

Fig. 59 Micrograph of transgranular SCC observed in a UNS NO8904 rub bar removed from the steaming tube shown in Fig. 56

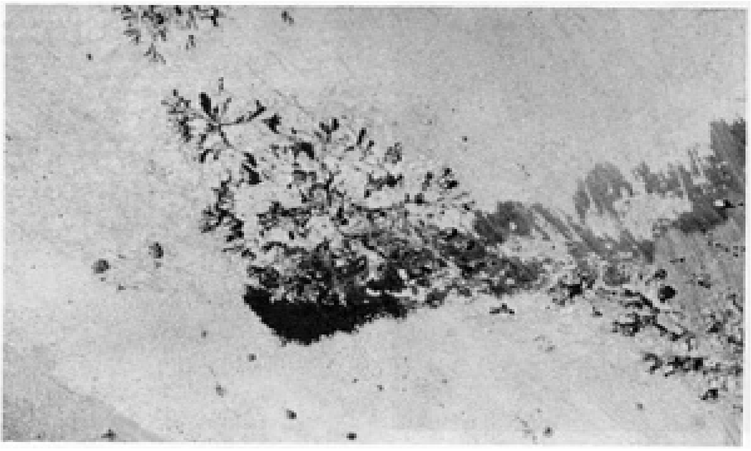

Fig. 60 Crows-foot SCC observed on the inside top surface of the shell of a UNS NO8904 steaming tube. Approximately 1×

Pitting or crevice corrosion has also been observed in steaming vessels, often in association with general attack due to condensation of acidic sulfur compounds. Chloride pitting attack tends to be particularly widespread beneath deposits that form on the screw shaft cladding and flights.

Corrosion by Acidic Condensates. Additions of Na_2SO_3 can be made prior to the steaming tube. Sulfur dioxide evolution occurs from sulfite solutions under the acidic conditions that exist naturally with damp wood chips. Sulfur dioxide is converted into the insidious sulfur trioxide in the presence of oxygen. Sulfur trioxide may condense or dissolve in condensed water films as sulfuric acid.

Stainless steels are resistant to H_2SO_4 only in either very dilute or very concentrated solutions. Condensates of intermediate concentration are therefore liable to be quite corrosive. Indeed, condensate corrosion runs have been observed on a steaming tube wall (Fig. 61). Condensate drips that form directly overhead produce circular areas of corrosion. The progress of acidic condensate corrosion in a UNS NO8904 steaming tube has been monitored by photographs taken 16 months apart (Fig. 62 and 63).

Fig. 61 Acidic condensate corrosion runs observed across a longitudinal seam weld on the wall of a UNS NO8904 steaming tube (see Fig. 56 left side wall)

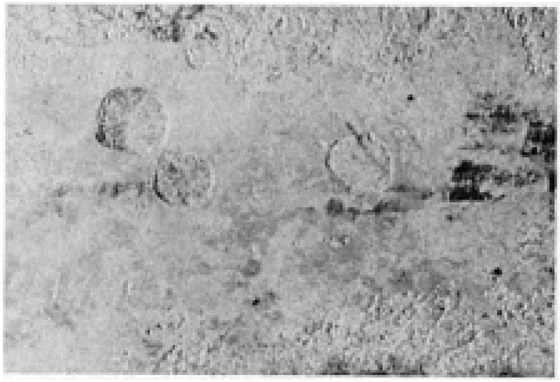

Fig. 62 Circular areas of corrosion observed directly overhead in a UNS NO8904 steaming tube due to formation of acidic condensate drips. Approximately $\frac{3}{4}$ ×

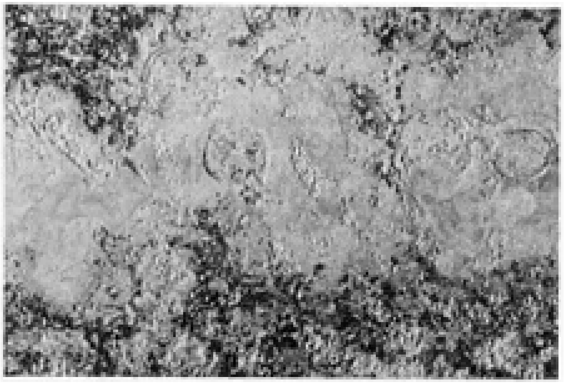

Fig. 63 Photograph 16 months later of the same area as in Fig. 62 showing the progress of corrosion from acidic condensation. Approximately $\frac{3}{4}$ ×

Bisulfite Chemi-Mechanical Pulping Digesters

Bisulfite chemi-mechanical pulping involves cooking wood chips in continuous digesters with $NaHSO_3$ liquors at 160 °C (320 °F) and at 620 kPa (90 psig). Depending on the amount of liquid in the digester, cooking may be in either the liquid or vapor phase. The conditions that promote the formation of vapor-phase condensates containing high concentrations of H_2SO_4 are the presence of air and low pH (Ref 92). If no effort is made to exclude air, the raw liquor pH must be 7.6 to prevent H_2SO_4 formation. At the optimum process pH of 6, conversely, extremely corrosive condensates containing 34.9% SO_4^{2-} and having a contact pH of 0 can be formed. Corrosion-free operation at pH 6 has been obtained by strict exclusion of air by the following means:

- Presteaming of the chips
- Plug-screw feeding into the digester, below the liquid level
- Preheating the cold blow water used to fill the digester prior to start-up
- Replacing the air in the vessel with steam prior to start-up

Corrosion in the Brewery Industry

Edgar W. Dreyman, PCA Engineering, Inc.

Introduction

BREWERIES are unique in many aspects in the food-processing industry. The product and its production, as well as cleaning procedures, storage, and bottling, all use great quantities of water. This requires a large amount of tankage and extensive hot water facilities; furthermore, the product is an acidic liquid that is aggressive to low-carbon steel. This is further complicated by the fact that the presence of iron ions in the product drastically affects its shelf life.

Wet, damp, and high-humidity conditions all contribute to plant corrosion and premature equipment failure if not properly treated. These factors make the typical brewery a challenge to the corrosion engineer.

Each brewery, whether old or modern, has a cross section of unique equipment ranging from standard power plant equipment, such as boilers, condensers, and oil-handling units, to highly sophisticated laboratory and pilot plant equipment for handling yeasts, malts, and hops essences. All types of materials are employed, from wood to glass, with many metals and special alloys used in large quantities. A brewery materials engineer must be familiar with the materials of construction for all of this equipment and must also be aware of diverse corrosion control techniques involving coatings, metals, cathodic protection, plastics, and even the use of inhibitors.

Corrosion Control Methods

As in any other industry, there are always several ways to solve a given materials problem in the brewery. The task of the materials (corrosion) engineer is to sort out the available choices and to arrive at the most cost-effective solution to the problem.

Traditionally, brewmasters, who at one time exercised complete control of all functions in a brewery, employed set conditions for plant equipment, such as wood with wax linings (tanks with slotted or perforated false bottoms used for filtering clear liquid from the grain mash) for fermentation and storage, copper for kettles and Lauter tubs, and low-carbon steel for pasteurization. This was due in part to the training programs available in Germany and later in the United States. A series of brewing academies or schools provided most of the training for brewmasters and also acted as consultants to most breweries. Their influence dictated what type of equipment was considered suitable for brewing beer.

This has changed dramatically in recent years, and many plants now have production superintendents in addition to or instead of brewmasters. With the consolidation of smaller plants into giant, multiplant brewing empires, the selection of equipment has become a staff engineering function. This group generally works out of the home offices and dictates and policy for all plants, because a major concern is that products made at any location taste alike. Some of the materials of construction used will be discussed below.

Wood. Many smaller, older plants still use wood fermentors and storage tanks. These tanks must be internally lined with an odorless wax or pitch that imparts no odor or taste to the product. Corrosion of steel hoops and rods with turnbuckles

had been a problem that required good coating systems, such as the wax or pitch used to line the barrel or food-grade enamels. The key to using wood was to keep it moist so that it remained swelled tight.

In trying to achieve longer life of the linings, several breweries switched to epoxy linings. These were completely impervious to moisture; consequently, cracking of the lining occurred as the wood staves separated from each other. Some internally pitched, wooden beer barrels are still in use, but both of these areas have yielded to the use of metals. Wood was also susceptible to dry out, which imparted an unacceptable flavor to the product.

Steel. Because iron affects the shelf life of beer, steel was not a major material of construction for tankage in contact with beer until superior linings or coatings became available to the industry. Initially, pitches or wax-type coatings were employed. These coatings had to be applied hot, and this was difficult to accomplished in the cold cellars. Some of these coatings had poor abrasion resistance and would crack and chip; therefore, they gave way to the tasteless, pure, food and drug approved epoxies.

This opened a new field for factory, epoxy-lined fermentation and storage tanks. Tank size was limited only by railroad rights-of-way; therefore, 3.7-m (12-ft) diam × 16.5-m (54-ft) long tanks became common in the industry.

Concurrently, there was an increase in the use of glass-lined steel tanks and finally thin-wall stainless steel tanks. Because the cost of nickel has decreased, new construction is virtually all stainless steel tankage.

Stainless Steel. Most of the brewery equipment currently being installed is fabricated from AISI type 304 stainless steel and includes kettles, tanks, tubs, plate coolers, and even some pasteurizers. Stainless steel hot water tanks have been a problem; there has been some major stress-corrosion cracking of heavy-wall vessels holding up to 500 barrels. The problem has been one of chloride ion (Cl^-) concentration due to evaporation under hot conditions and cracking of shaped plate sections at the bottom of the tanks. Remedial measures have consisted of treated water plus complete drainage and flushing.

Stress-corrosion failures in stainless steel thin-wall piping have been common (Fig. 1). Stress-corrosion cracking has taken place where low-chloride insulation and concentrated at temperatures as low as 70 °C (160 °F). Remedial measures have consisted of replacing the piping, coating the exposed stainless steel with a chloride-free coating, and maintaining better valve maintenance.

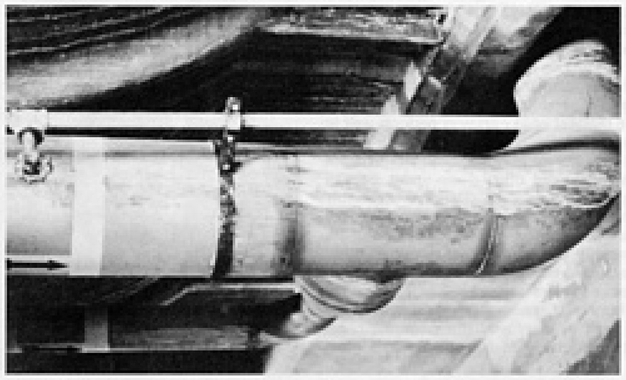

Fig. 1 Stress-corrosion cracking of thin-wall stainless steel hot water piping

Stress-corrosion cracking has also been observed where heavy scaling has occurred because of hard water conditions, with chloride concentration in the hardness salt deposits. Remedial action has involved acid treating the water to remove carbonates.

Another problem area has been contact knobs in plate-type coolers. Where deposits have collected, cracking has occurred because of vibration during operation. Remedial action has consisted of using special cleaning compounds to keep surfaces clean.

Special Alloys. Type 444 ferritic stainless steel has been successfully used where SCC problems have occurred because of deposit formation. Monel has replaced type 316 stainless steel for beechwood-chip baskets in one proprietary application in which cracking had occurred around holes in the screening.

Copper has been the traditional metal in breweries for centuries, but with the advent of new alkaline cleaners, some corrosion problems have occurred. Large-diameter brewing kettles are joined by solder joints; these joints have been preferentially corroded and have required silver soldering repair. The use of in-place cleaning with jet sprays has resulted in metal thinning of the copper plates at points of impingement. Rotary cleaners appear to be superior to stationary jets.

Kettle floor thinning has also been observed; cleaning compounds and mechanical abrasion from brushing have been responsible for this. Stainless steels are much more resistant to this type of action.

On percolator refits using stainless steel units with stainless straps, cases of galvanic attack have been reported on bolting and strapping. Copper or brass fittings should not be used in contact with large areas of stainless steel.

Beer is a very good conductor of electricity (low resistance of 200 Ω/cm) due to high CO_2 loading. Even hot water will promote galvanic effects. Thus, precipitation of scales on kettle surfaces can be protective, but when scales are removed with cleaners such as sulfamic acid, the surfaces can become very active. Experience has shown that type 304 or 316 stainless steel will perform well in this environment.

Coatings. Breweries are large consumers of quality coatings, not only for tankage but also for structural steel, flooring, and other working areas. The coatings used range from high-heat silicones for stacks to special superresistant grouts for floor pavers. With a special emphasis on sanitation, many coatings containing antibacterial and mold-control agents are employed throughout the industry.

Bottling and canning operations have very severe conditions for most coatings. Broken bottles can spill product on the coating, and bottle washers use highly alkaline cleaners and label removers at high temperatures. High-build epoxies with inhibitive pigment epoxy primers perform well in many cases.

The water-tolerant polyamide epoxies perform better in cellars and other damp areas. Special low-temperature curing epoxies have been most successful in cellars. Considerable evaluation has been done on water-base epoxies because odors can be readily picked up by the beer or other ingredients, such as hops or malts. Because quick maintenance repairs are critical in large, high-volume breweries, many products that are user friendly must be employed (for example, products that cure quickly on damp surfaces with low odor).

Again, with the large amount of water vapor present in many areas, the use of polyurethane topcoats over epoxies is finding greater acceptance. The polyurethanes do not chalk, and they hold their gloss with good color retention. This is especially true of bright greens, blues, or reds.

Floor Materials. Considerable glazed tile is used in breweries, and special epoxies with good adhesion to very smooth surfaces have been employed to coal glazed ceramic tile in order to prevent crazing (cracking). Epoxy grouts (American Tile Council Specifications) have solved the problem of grout deterioration around kettles, syrup tanks, and other areas susceptible to acidic and microbiological attack. Finally, the problems associated with floors have been addressed by many coating producers with mixed results.

Beer, as well as corn syrup, will attack concrete; therefore, many areas have tile pavers installed. However, as previously mentioned, proper grouts must be used. Where the concrete must be coated, epoxies with embedded grit (skidproofing) are being used in many areas. Chlorinated rubber has been used on cellar floors (Fig. 2), but it generally requires more maintenance because it does not have the abrasion resistance of the epoxies.

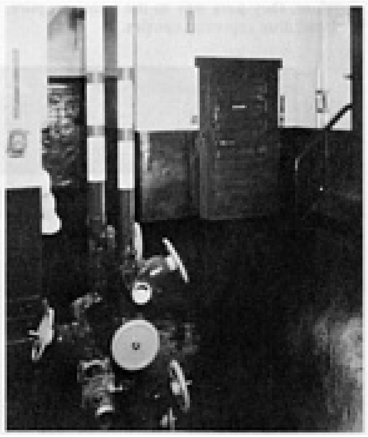

Fig. 2 Chlorinated rubber floor coating in a cellar

Proper surface preparation is most important in brewery floor work. On new floors, acid etching or a light sandblast will suffice. On old floors, removal of a minimum of 50 mm (2 in.) of concrete is mandatory; more extensive concrete removal is sometimes necessary, depending on the degree of contamination. Bacterial contamination deep in the pores of the concrete is a common occurrence. If floors are not properly sealed, corrosion of concrete rebars and structural steel can result, with eventual cracking and spalling of the concrete (Fig. 3).

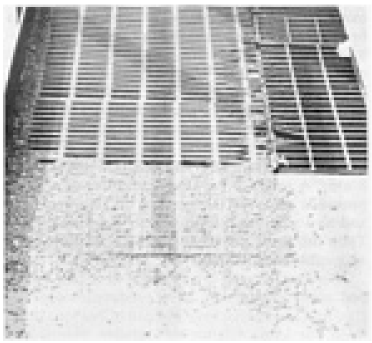

Fig. 3 Cracking and spalling of a concrete floor

Glass Linings. At one point in the evolution of the brewing industry, glass-lined tanks were introduced for fermentors, storage, and filling tanks. Glass is an excellent materials for preserving the purity of the product and is resistant to the mild acids and alkaline cleaners used to remove scales and deposits. Glass linings are applied by spraying a borosilicate glass frit on the sandblasted surface of the tank, and then firing the entire tank in a furnace until a smooth glass surface is achieved.

Glass linings were installed at thicknesses of 0.4 to 0.8 mm (15 to 30 mils) and gave good service, but were prone to maintenance problems. For example, the lining could be fractured by workmen dropping tools or hose fittings on the glass. Initially, factory pinhole repairs were made by gold filling, similar to a dental inlay. This was followed by repairs with sprayed tin; even large repairs, such as the knuckle areas on tank heads, were repaired in this manner. Tank perforations were repaired with tantalum plugs. As epoxies became available, glass repairs were performed with these materials.

In tanks with multiple pinholing, the glass lining was removed by gritblasting, and the tanks were recoated with epoxies. Cathodic protection was also employed in some cases; this will be discussed later in this article.

Because of the large capital investment required to produce glass linings and the major reduction in the number of breweries, glass linings are no longer produced commercially. Despite this, many tanks are still in use and require maintenance.

Plastics. From a corrosion control point of view, plastic materials are very useful; therefore, they have found application in breweries. Water treatment tanks, acid storage, roofing, and gutters are applications for plastics that are common to most industrial activity and as such are used by breweries. Fiberglass and polyvinyl chloride are among the plastics that have been employed. Small polypropylene tanks for yeast culture and other specialty service have some record of use.

Inhibitors. Where large volumes of water are being used, constant attention must be paid to reducing the water demand, not only because water is becoming expensive and scarce but also because wastewater must be handled in an ecologically sound manner. Brewery waste is high in bacteria and, if untreated, has a very high biological oxygen demand.

Consequently, many closed cooling systems are being employed. This necessitates cooling water treatment, and even before the current environmental regulations, breweries could not use additives containing chromates. This means that zinc/phosphate-type inhibitors and proprietary, pure, food and drug approved systems must be employed.

Even boiler water treatment must be monitored because live steam is used for heating water that goes into the product and would carry chemicals over into the product. Beer production is sensitive to most chemicals in terms of the organoleptic properties of the product and the fragility of yeast cultures.

Cathodic protection is an electrochemical method of corrosion control that impresses a direct current onto the structure to be protected. This in turn overrides the many small dc corrosion cells existing on that structure and stops corrosion (see the article "Cathodic Protection" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*).

This method of corrosion control can overcome the effects of galvanic cells due to dissimilar metals and concentration cells due to differential oxygen concentration, temperatures, or stresses. Combined with good coatings systems, cathodic protection is a most cost-effective way of controlling the corrosion of immersed and underground structures.

Breweries employ cathodic protection on waste storage tanks, fermentor tanks, beer storage tanks, hot water tanks, and underground pipelines for oil, sewerage, and, in some cases, product lines. Water treatment facilities also employ this type of corrosion control.

Equipment Problems

Air Conditioning Equipment. Humidity control in cellars will reduce paint deterioration and mold growth and will promote working safety with relatively dry floors. Lithium chloride units used for moisture control have had some deterioration problems that have necessitated the use of exotic alloys and superior coating systems.

In dusty areas, such as malt plants, the poultice corrosion of aluminum fins on cooling units has been a problem (Fig. 4). However, as with many maintenance problems, proper cleaning on a scheduled basis can prevent the failure of such components.

Fig. 4 Corrosion on air conditioner cooling fins

Cooling systems require water treatment, and water tower pans should be properly coated with such products as coal tar epoxies. On occasion, sacrificial zinc anodes have been used for cathodic protection of bare areas in coatings to prevent corrosion. As in all industrial situations, cooling towers must not be placed where they become scrubbers for stack gases. Absorption refrigeration systems use sacrificial anodes in waterboxes and require periodic eddy current inspection of the tubes to minimize corrosion failures.

Compressors. Many older breweries still use CO_2 and ammonia (NH_3) compressors, which may have intercoolers. Closed systems, if used, require water treatment and the use of sacrificial zinc anodes in cooler heads.

The brine systems associated with older breweries are gradually being phased out, but at one time, they were a major corrosion problem requiring proper inhibition. As mentioned, because chromate inhibitors are not permitted, mixed phosphate inhibitors are used for corrosion control.

Pasteurizers. A major part of a brewery is the bottling and canning operation. One of the most expensive pieces of equipment in the bottleshop is the pasteurizer. The old units were basket pasteurizers that dipped baskets of bottles into water at various temperatures to kill any residual yeast in the product. If this is not done, fermentation can occur in the bottle or can, and gushing takes place when the container is opened.

Modern pasteurizers are continuous-belt operations in which water at different temperatures is sprayed over the bottles or cans. This highly oxygenated hot water is quite corrosive, and the use of inhibitors is limited by the potential for staining of the package.

The normal pasteurizer is of stainless steel construction in the spray areas, with low-carbon steel tanks under each temperature zone. It is in these tanks that problems can be caused by broken beer bottles, which introduce trash and debris onto the tank floors.

The lower-temperature zones of a pasteurizer encourage bacterial growth, and oxygen cells can form under the biological deposits. This corrosion is further enhanced by copper heating coils in the low-resistivity water and by concentration cells produced by hot wall effects in the various compartments. Coatings have not solved this problem, because of mechanical damage from broken glass and the effects of high temperatures on the coating.

Cathodic protection has performed well. Originally, magnesium galvanic anodes were used, but the consumption rate was high; replacement was required every 2 years. High-purity zinc anodes have given 10-year service lives, but extreme care must be exercised so that water chemistry does not cause reversal problems where the steel becomes anodic to the zinc. This can be a problem in some very soft waters.

Ultimately, impressed-current systems have proved to be the most efficient corrosion control method for pasteurizers. The anode materials used include resin-impregnated carbon, high-silicon cast iron, or platinized niobium or titanium.

Current densities of about 160 to 270 mA/m^2 (15 to 25 m/A/ft^2) of bare, immersed steel or copper are used. Anodes are mounted on epoxy-coated stand-off holders that hold the anode 150 to 300 mm (6 to 12 in.) from the floor, walls, or heating coils.

A dc rectifier provides direct current through four circuits, each of which is resistorized to reflect the variance in resistivity due to water temperature. Normally, this requires anodes operating at water temperatures of 10 °C (50 °F), at 20 to 40 °C (70 to 100 °F) for preheat, at 50 to 60 °C (120 to 140 °F) for heat, at 75 °C (165 °F) (the pasteurizing temperature), and at 25 °C (80 °F) for cooling and final rinse.

Anode lives are calculated from the following rates of consumption:

- *Carbon:* 0.45 kg/A·yr (1 lb/A·yr) consumption
- *High-silicon cast iron:* 0.34 kg/A·yr (0.75 lb/A·yr) consumption
- *Platinum:* 0.006 g/A·yr (2 × 10^{-4} oz/A·yr consumption

The platinum anodes can be much smaller because the allowable current density is much higher:

- *Carbon:* 10.8 A/m^2 (1 A/ft^2) anode surface
- *High-silicon cast iron:* 27 A/m^2 (2.5 A/ft^2) anode surface
- *Platinum:* 540 A/m^2 (50 A/ft^2) anode surface

These values have been compensated for use in freshwaters. In hard waters (high in carbonates), some scaling will occur on the cathodic surfaces, and overprotection in discouraged because it will cause stripping of coatings near anodes.

Polarized potentials should not exceed -1.3 V versus a copper/copper sulfate reference electrode if epoxies are being used. Alkyd or zinc-rich coatings are not recommended. Although air-cooled rectifiers perform well as a power source, oil-cooled, sealed units are recommended because of the extensive use of water during cleanup.

Finally, some plants have pasteurizers dedicated to can pasteurization only. When tin-plated steel cans were used, the seam solder would fall to the tank floors, and galvanic pitting of the floor would take place. Most plants now use deep-drawn aluminum cans with rolled tops; therefore, this is no longer a problem.

Beer Barrels. Barrels are generally no thought of as equipment, but they represent a large brewery investment and have been a source of corrosion problems in the past. Except for the steel hoops, wooden barrels are not a problem; however, the lack of suitable wood, the few available coopers, and the heavy weight of wood has led to the use of aluminum and stainless steel barrels.

Initially, aluminum appeared to be the best material for this purpose, but shortly after it was put into use, pitting appeared in the barrels. This ultimately led to perforation, and the rough, pitted surface became hard to clean. The cause of this corrosion was found to be the tin-plated, brass tap that was commonly used. This brass tube in close proximity to the aluminum became the cathode in beer and resulted in pitting of the aluminum. This required pitching the interior of the barrels, thus negating the cost various for aluminum. Currently, the preferred material of construction for barrels is stainless steel.

Tanks. In addition to the use of coatings in tanks, some cladding with stainless steel has been employed.

Lauter Tubs. The metal cladding of Lauter tubs, especially the bottom of the tub where a perforated or slotted stainless or brass false bottom rests, has been successful. The stand-off legs of the drain plates would perforate the floor coating and cause galvanic cell corrosion action at these areas. Organic coatings were tried first, but the impact was too severe. Therefore, stainless pads or complete cladding with thin sheets of type 304 stainless steel was employed to correct the problem.

Concrete Tanks. Several breweries conceived the idea of constructing buildings in a honeycomb fashion, with concrete tanks being a part of the building support. This practice was employed in Europe and the United States.

Originally, these tanks were coated with mix, which would crack. Beer would be lost in the walls of the building, with the result being odor, corrosion of concrete rebars, and microbial contamination. Attempts were made to correct this problem with fiberglass (cloth) reinforced epoxy. This was very expensive, and failures in the lining occurred unless substantial layers of contaminated concrete were removed.

A film in the United Kingdom worked out procedures to apply thin-sheet type 304 stainless steel to concrete without expansion buckling, and this technique was used successfully in Scotland and Holland. Similar techniques were then used in the United States with acceptable performance.

The main problem in using thin type 304 stainless sheet lies in preventing movement, which can cause wrinkling and, ultimately, cracking. Proper welding techniques and support spacing are necessary to achieve a clad tank without movement of the cladding.

Another problem area was the tank doors, which today are primarily stainless steel. Coated low-carbon steel and glass-coated doors chipped readily at the edges, which are in contact with the beer; heavy pitting in these areas resulted. The solid stainless door currently provides satisfactory service.

The fermentation tank environment is more severe than that in storage tanks. Fermentation tanks fabricated of stainless steel provide good service in most plants; however, many low-carbon steel tanks still exist in working breweries and present maintenance problems. Fermentation tanks have copper heating and cooling coils inside the tank to control the rate of fermentation. The area ratio of bare steel (breaks in the coating or glass) to bare copper is very unfavorable and results in very rapid attack of the steel in the acidic CO_2-saturated product.

Repairs made to fermentation tanks using epoxies have performed well, but care must be exercised in grinding out the pits to ensure absolute cleanliness. The resin must not only conform to pure food regulations but must also exhibit low shrinkage characteristics so that it does not pull away from the edge of the pit. The resin must not be feathered over the edge onto the good coating or glass surface; if this occurs, the thin coating may fail, and the product will get into the edges of the pit with the resin coming out as a plug.

Cathodic Protection

Another method used to prevent corrosion in fermentation tanks is the use of cathodic protection to monitor the size of pinholes in coatings and linings. Galvanic anodes would introduce metal ions into the product; therefore, they cannot be used. Consequently, impressed-current systems must be employed, with anode selection becoming most important.

High-silicon cast iron anodes cannot be used, because this would introduce iron ions into the beer. Platinum would appear to be the best choice because it is the most inert. Unfortunately, oxygen is liberated at the anodic surface and this would cause deterioration of the product. Carbon, therefore, is the most logical choice for anodes because the oxygen produced combines with the carbon and produces CO_2, which occurs naturally in the beer. A second caution is that oil-impregnated carbon must not be used, because any uncarbonized oil would contaminate the product and inhibit foam formation, which is critical for a good head on the beer.

Resin-impregnated carbon anodes 75 mm (3 in.) thick and 200 mm (8 in.) in diameter have been used in fermentors. These are mounted on stand-off insulators installed in the tank floor and penetrating the tank bottom so all wiring is on the outside of the tank. This hardware has a porcelain insulator with stainless fittings. These stand-off insulators isolate each anode and provide better throwing power of the current; therefore, fewer anodes are required.

Current demand for such a tank is quite low, using 21.5 to 54 mA/m^2 (2 to 5 mA/ft^2) of bare area (including bare coil area). Typical current for an 1800-barrel tank is 0.3 to 0.5 A at 3.5 to 5 Vdc.

In order to maintain a balanced direct current load to each tank, the doors are fitted with waterproof microswitches that transfer the load to a dummy resistor when the tank is open. This prevents any current flow to the tank when workers are inside. Generally, an entire cellar is equipped with anodes from one power supply with 6 to 12 circuits. Power supplies are air cooled and are installed outside of wet cellars.

The bare steel must not be overprotected with excessive current, because coating stripping can occur. This is especially critical when phenolic coatings are used that are sensitive to alkalies. The result of the cathodic reaction is to increase the pH at the tank metal surface, which can soften phenolic resins.

In addition, hydrogen is liberated at the cathode and can be absorbed into the steel. Excessive hydrogen can cause lining failure in glass-lined tanks; therefore, excess current must be avoided. Potentials of less than -1.00 V versus a silver/silver chloride reference electrode have provided steel protection without coating or lining breakdown.

Hot Water Tanks. Many breweries using low-carbon steel hot water tanks that are bare, coated, or lined with gunited (sprayed concrete) linings have employed cathodic protection. Anodes have been resin-impregnated carbon; 75-mm (3-in.) × 1.5-m (60-in.) hanging anodes have performed well, with service lives of 7 to 10 years. These systems have been most effective where flat copper heating coils are used.

One system has been in service for 30 years in a tank that was originally scheduled for replacement. It must be remembered that only the submerged parts of a tank are protected; therefore, water tanks must be coated on the top, or dome, of the tank and down the walls to the waterline. In addition, complete coating should be considered, because this will substantially reduce the size of any cathodic protection system to be employed.

The coating used must be compatible with impressed current. Inert coatings such as epoxies, chlorinated rubbers, or vinyls will function well. Alkyds and inorganic zinc-rich coatings or primers are not recommended.

Cold Water Tanks. The same techniques employed to protect hot water tanks also are used for cold water storage and fire protection tanks. Some fire protection storage tanks are used for dual service; these may contain 3.8×10^6 L (1×10^6 gal) of water, with 950,000 to 1.9×10^6 L (250,000 to 500,000 gal) of this being used for process water. This means that the water throughput in the upper third of the tank may be substantial. This can be highly oxygenated, aggressive, agitated water; consequently, current demand for a cathodic protection system may be very high in that area (323 to 540 mA/m^2, or 30 to 50 mA/ft^2) for proper corrosion control. These design factors must be considered for such systems.

Plant Structures

Buildings. Although most structures are brick and concrete, which require good coatings and sealers (silicone), corrugated siding also is employed. Tedlar (polyvinyl fluoride) coated siding has shown good service for the costs involved. Care should be exercised to employ proper fasteners as specified by the siding vendor.

Galvanized and aluminized siding and roofing panels are commonly employed and should be specified with sufficient zinc or aluminum thickness to ensure reasonable life. If metal panels are to be recoated, special pretreatment is generally required, and coating suppliers should be consulted for the proper materials to use as primers with their top coats.

Rebar Protection. The use of epoxy-coated concrete rebars for buildings and slab construction where water intrusion may be a problem is highly recommended to prevent concrete spalling. Where deicing salt contamination is a problem, as in heated driveways or parking garages, the small additional cost is well worthwhile.

Where concrete delamination is occurring in existing structures, cathodic protection of rebars has been successfully applied. Carbon strands or platinum wire anodes or conductive polymer anodes can be successfully used for rebar protection. Anodes for this purpose must be used with conductive coatings to distribute a low dc current density over the salt-impregnated areas.

Buried Tanks and Piping. Buried steel fuel and product storage tanks, such as solvent tanks for can coatings, can be readily protected with a combination of coatings, isolation from electrical contact with other structures, and cathodic protection. The Steel Tank Institute has specifications and designs for applying protection during tank manufacturing, with 30-year warranties against corrosion. Steel fuel storage tanks for large truck fleets, when these are a part of the brewery operation, can be readily protected. Fiber-glass tanks are an alternative choice, but require more stringent installation procedures than steel.

Underground fire protection lines, gas lines, water lines, and waste lines are all readily protected with coatings and cathodic protection. If cast iron bell-and-spigot pipe (Fig. 5) is being employed, it must be bonded across the joints. Thermit bonds are preferred to brass wedges, which can loosen and fall out.

Fig. 5 Corrosion failure of an underground cast iron pipe

An alternative to cathodic protection is the use of polyethylene, plastic sleeve encasement. This technique was developed by the Cast Iron Pipe Research Institute, and it has performed well in the United Kingdom as well as in the United States.

Miscellaneous Structures. Depending on the brewery location, the type of subsoils, and the proximity to rivers and lakes, other structures, such as steel bearing piles or sheet piling, must be protected. When cosmetic requirements are not a consideration, such coatings as black coal tar epoxies or polyurethanes can be used in conjunction with cathodic protection.

Water and waste treatment plants require protection for the steel structures, such as settling basins, flocculators, and clarifiers, and for the concrete. Superior concrete protection must be employed if soils are high in sulfates, with coal tar epoxies giving good performance. The selection of corrosion control materials and systems must be predicated upon the expected life of the structure, the expected difficulty of future maintenance, and the overall cost to the owner.

Corrosion in the Pharmaceutical Industry

Ralph J. Valentine, VAL-CORR

Introduction

THE PREVENTION AND MITIGATION of corrosion in the pharmaceutical industry presents a demanding challenge to materials engineers. In most cases, they are working with processes that require equipment and piping systems to be fabricated from material having extremely low corrosion rates when exposed to a wide variety of corrosive media and operating conditions. The substances produced by corrosion reactions contaminate the product being manufactured. This contamination must be removed in one of the subsequent process steps so that the product can pass the quality control tests required for compliance with the stringent purity and quality demands established by the applicable government regulatory agencies.

Materials of Construction

The materials of construction found in pharmaceutical production facilities include:

- Metals and alloys, both solid and clad
- Thermosetting plastics and thermoplastics, both solid and as linings
- Ceramics, both solid and as linings
- Impregnated carbon

Stainless Steels

The austenitic stainless steels, especially the low-carbon and stabilized grades, have been the workhorse alloys in the pharmaceutical industry for many years. These alloys exhibit good corrosion resistance in many media, are readily fabricated, have excellent strength over a wide temperature range, offer good availability, and are relatively inexpensive. The surface condition of the austenitic stainless steels is critical where the pharmaceutical product must not be contaminated and where the stainless steel is required to resist an aggressive environment. The highly protective chromium oxide film that gives stainless steel its corrosion resistance is tenacious, durable, and self-healing in the presence of oxygen; however, this film can be damaged during equipment fabrication and postfabrication cleanup practices. Fortunately, serious problems can be minimized by following good procurement, handling, design, fabrication, and cleanup practices.

The austenitic stainless steels are widely used in oxidizing environments, high-purity water service, and in fine chemical and pharmaceutical production equipment and piping. They are not suitable for use in chloride-containing environments, particularly at high chloride concentrations and at high temperatures.

In recent years, stainless steel producers have developed the so-called super austenitic stainless steels having excellent resistance to general corrosion and pitting/crevice attack in chloride-containing environments. These alloys are highly resistant to intergranular corrosion and stress-corrosion cracking (SCC); this makes them useful in oxidizing chloride solutions, oxidizing acids, and brines. The high molybdenum (2.5 to 6.5%) content and increased chromium and nitrogen give the super austenitics good resistance to pitting and crevice corrosion. The relatively high nickel content (18 to 31%) and the high chromium and molybdenum levels give the alloys excellent SCC resistance. The presence of copper in the alloys improves resistance to sulfuric (H_2SO_4), phosphoric (H_3PO_4), and acetic acids.

The super stainless alloys are less costly than the nickel-base alloys and are readily available in a wide range of product forms, such as pipe and tubing, sheet, plate, and forgings, as well as a full range of welding consumables. In addition, the super austenitic stainless steels are more workable and have better weldability than high-alloy ferritic steels. When the

super austenitics are specified, the welding specifications of alloy producers should be followed explicitly so that the full chemical and cracking resistance of the alloy is maintained.

The duplex stainless steels are, as the name implies, duplex in structure. At room temperature, their equilibrium structure is a mixture of austenite and ferrite phases. The compositions of these alloys are carefully controlled to maintain the proper balance of austenite to ferrite. Most of the physical properties of the duplex stainless steels are between those of the austenitic and ferritic stainless alloys. The thermal conductivity of the duplex stainless alloys is less than half that of carbon steel, but about 25% higher than that of the austenitic stainless steels.

The coefficient of expansion of carbon steel is similar to that of the stainless duplex alloys and is about 40% less than that of the austenitic stainless alloys. The duplexes have excellent toughness as well as high strength. Compared with the ferritic stainless steels, the ductile-to-brittle transition of the duplex alloys is more gradual and occurs at a lower temperature, thus allowing the production of a wide range of product forms.

The duplex alloys are not suitable for cryogenic service the austenitic grades are preferred in this application. The duplex grades have good resistance of chloride SCC; however, the various alloys can show variability in pitting and crevice corrosion susceptibility because of the segregation of the ferrite and austenite phases. The high chromium content of the duplex stainless steels makes them strongly resistant to oxidation. However, prolonged exposure at elevated temperatures (above 345 to 370 °C, or 650 to 700 °F) can affect toughness and corrosion resistance in aqueous media and should be avoided.

All commonly used duplex stainless steels are included in a variety of specifications for sheet, strip, plate, and seamless and welded tubing and pipe issued by the American Society for Testing and Materials (ASTM). Many duplex stainless steels are also included in Section VIII, Division 1, of the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code, in which they are identified by their UNS designations.

The best corrosion resistance and mechanical properties in welded duplex stainless steels are achieved when the welding practice encourages the formation of a 50-50 austenite-ferrite phase in both the weld metal and the heat-affected zone (HAZ). Welding practices are required that emphasize cleanliness, the avoidance of carbon contamination, and the use of dry inert gas shielding. Because of the sensitivity of ferrite to hydrogen embrittlement, shielding gases containing hydrogen should not be used. Readily available duplex alloys include alloy 2205 (UNS S31803), 44LN (UNS S31200), and Ferralium 255 (S32550).

High-Purity Ferritic Stainless Steels. The super ferritic stainless steels were introduced in the United States during the past decade. The oldest and best known is E-Brite 26-1, an alloy containing 26% Cr and 1% Mo. E-Brite was electron beam refined to reduce carbon and nitrogen to very low levels. This process is no longer in use because of manufacturing problems; E-Brite is now made by vacuum melting. Other super ferritic alloys with approximately the same chromium and molybdenum contents with stabilizing additions of titanium have been introduced to the industry. The 26-1 alloy generally has corrosion resistance equal to or better than that of AISI types 304 and 316 stainless steel, the workhorse alloys of the pharmaceutical industry. In addition, the 26-1 alloy is resistant to SCC, a major shortcoming of the austenitic stainless steels. Because of the resistance of the high-purity ferritic alloys to a wide variety of aggressive environments, many compositions have been developed, such as 18Cr-2Mo, 29Cr-4Mo, 29Cr-4Mo-2Ni, and 27Cr-3.5Mo-2Ni.

As-welded super ferritic stainless steels typically have poor weld zone ductility and are notch sensitive in the HAZ. If these alloys are heated to between 400 and 480 °C (750 and 900 °F) for prolonged times or are slowly cooled within this temperature range, notch toughness is further reduced, and the material becomes brittle. The use of the super ferritics at low temperatures is limited because of their high ductile-to-brittle transition temperatures. If the corrosion resistance of the super ferritic alloys is to be maintained, extreme care must be taken to avoid contamination with nitrogen or carbon during welding. Special welding procedures developed by the alloy producer should be used. Because of problems with welding and controlling the ductile-to-brittle transition temperatures, these alloys are generally used in sheet thicknesses under 3.2 mm ($\frac{1}{8}$ in.) and for tubing. More information on the corrosion of all types of stainless steels is available in the article "Corrosion of Stainless Steels" in this Volume.

Nickel and Nickel-Base Alloys

Commercially pure nickel (Nickel 200) is highly resistant to many corrosive media. It is most useful in reducing environments, and it can be used under oxidizing conditions that cause the development of a passive oxide film. Nickel has poor corrosion resistance in H_2SO_4, HCl, HNO_3, and H_3PO_4. Pure nickel has outstanding resistance to alkalies, the

exception being ammonium hydroxide (NH_4OH), which rapidly corrodes nickel. Oxidizing acid chlorides such as ferric, cupric and mercuric are very corrosive. Nickel is used for containing very reactive chlorides, such as phosphorus oxychloride, phosphorus trichloride, nitrosyl chloride, benzyl chloride, and benzoyl chloride. Pure nickel resists anhydrous chlorine, anhydrous hydrogen chloride, phenol, and bromine.

Nickel-Copper Alloys. Monel alloy 400 is more resistant than nickel to corrosion under reducing conditions and more resistant than copper to corrosion under oxidizing conditions. As a solid-solution alloy, Monel 400 is free from the corrosion that can result from local galvanic action between the phases of multiphase alloys. Monel is generally resistant to SCC; exceptions are mercury and solutions of its salts, fluorosilicates, concentrated caustic soda (NaOH), and potassium hydroxide (KOH). Monel 400 is resistant to all common dry gases at room temperatures. it is not resistant to chlorine, bromine, nitric oxides, ammonia, sulfur dioxide, and hydrogen sulfide in the presence of moisture. Monel is useful in handling H_2SO_4 under air-free reducing conditions. Aeration causes a sharp increase in the corrosion rate. Monel 400 can handle aerated HCl at 10% concentration at room temperature; above room temperature, applications are usually limited to 3 to 4% HCl. In unaerated hydrofluoric acid (HF), Monel 400 is resistant to all concentrations up to the boiling point. Monel 400 has very poor corrosion resistance in HNO_3. Monel 400 has good resistance to HaOH up to about 50% concentration and to NH_4OH up to 3% concentration.

Nickel-Chromium Alloys. The high nickel content of these materials gives them considerable resistance to corrosion under reducing conditions and in strong alkaline environments. Also, because of the high nickel content, the alloys are virtually immune to chloride SCC. However, at high temperature and in contact with concentrated alkalies, they are subject to SCC. Mercury will also cause SCC at elevated temperatures.

Nickel-molybdenum alloys were developed to be resistant to HCl at all temperatures and concentrations. The nickel-molybdenum alloys have good corrosion resistance to other nonoxidizing environments, including boiling 60% H_2SO_4, pure H_3PO_4 at most concentrations and temperatures, wet hydrogen chloride gas hydrogen chloride to 455 °C (850 °F), and wet halogenated organics. The presence of ferric or cupric salts or other oxidizing agents will cause rapid corrosion of these alloys.

Nickel-Chromium-Molybdenum Alloys. The addition of chromium to the nickel-molybdenum alloys increases the resistance to oxidizing environments, giving them good resistance to HNO_3 and H_3PO_4, as well as to most chloride salts. The alloys are very resistant to pitting and crevice corrosion because of the molybdenum content. The nickel-chromium-molybdenum alloys are the most versatile corrosion-resistant alloys available. They are some of the few alloys that are resistant to wet chlorine gas, hypochlorite, and chlorine dioxide solutions. They have good resistance to ferric and cupric chlorides and other oxidizing salts, alkalies, and acids.

Nickel - chromium - molybdenum - copper alloys were developed to resist H_2SO_4 and HNO_3 over a wide range of concentrations and temperatures. They are resistant to H_3PO_4 even when the acid contains fluorides or oxidizing compounds. The article "Corrosion of Nickel-Base Alloys" in this Volume contains more information on corrosion of nickel and nickel-base alloys.

Titanium

Titanium forms a tight, adherent oxide film that makes it resistant to many oxidizing reagents, including HNO_3 and chromic acid (H_2CrO_4). Titanium is attacked by reducing acids such as H_2SO_4 and H_3PO_4. It is useful in moist chlorine gas and hypochlorite at ambient and elevated temperatures; most organic acids; and water, seawater, and brine solutions at temperatures to the boiling point. At elevated temperatures, titanium is subject to pitting and crevice corrosion in a chloride environment. Titanium will not resist red fuming HNO_3 or HF in any concentration or temperature and will ignite at very low temperatures in dry chlorine gas. More information on the corrosion of titanium and its alloys is available in the article "Corrosion of Titanium and Titanium Alloys" in this Volume.

Zirconium

The two zirconium-base alloys used most frequently in the pharmaceutical and chemical-processing industries contain some hafnium, which is metallurgically and chemically similar to zirconium and does not reduce its corrosion resistance. The alloy UNS R60702 contains a minimum of 99.2% Zr + Hf, with a maximum hafnium content of 4.5%. The second alloy, UNS R60705, contains a minimum of 95.5% Zr + HF, with a maximum of 4.5% HF and 2 to 3% Nb. Both are approved for use in the construction of pressure vessels according to the ASME Boiler and Pressure Vessel Code, Section VIII.

Zirconium has excellent resistance to HCl at all concentrations up to temperatures of 120 °C (250 °F). It resists HNO_3 in all concentrations up to 90% and temperatures to 150 °C (300 °F); however, SCC may occur above 70% concentration if high tensile stresses are present. Zirconium is corrosion resistant in H_3PO_4 in concentrations up to 55% at temperatures of 175 °C (350 °F). Above 55% concentration, the corrosion rate increases with temperature, but even in 85% H_3PO_4 at 60 °C (140 °F) the corrosion rate is still less than 0.13 mm/yr (5 mils/yr). If there are fluoride ion impurities present at any concentration of H_3PO_4, zirconium may be subject to rapid corrosion attack. Zirconium alloys are resistant to H_2SO_4 up to 75% concentration and at temperatures to boiling. Ferric, cupric, and nitrate ion impurities cause corrosion of zirconium in H_2SO_4 concentrations above 65%. Fluoride ion concentrations as low as 1 ppm in 50% H_2SO_4 will cause corrosion of zirconium alloys. Zirconium has no corrosion resistance to HF and is rapidly attacked at concentrations as low as 0.001%

Zirconium is resistant to virtually all alkaline solutions, either fused or in solution to boiling temperature. Zirconium has excellent resistance to corrosion in most organics and organic acids. It should be noted that SCC of zirconium occurs in ferric and cupric chloride solutions, concentrated HNO_3, methanol-hydrochloric acid and methanol-iodine solutions, and liquid mercury or cesium. Detailed information on the corrosion of zirconium and its alloys is available in the article "Corrosion of Zirconium and Hafnium" in this Volume.

Impervious Graphite

Impervious graphite is made of impregnating, under pressure, raw graphite with phenolic, furan, or fluorocarbon resins. The resulting nonporous graphite is impermeable to gases and liquids and is highly corrosion resistant in acids and many solvents. Impervious graphite is dimensionally stable, does not fatigue, and will withstand thermal shock. The phenolic and furan impregnants leach out from the graphite when exposed to ammoniacal compounds. NaOH and KOH, wet halogens, hydrogen peroxide (H_2O_2), strong HNO_3, hypochlorites, and some solvents.

The introduction of the fluorocarbon impregnants to graphite has markedly increased corrosion resistance in solvents, acids, and alkalies. The maximum service temperature for the phenolic and furan impregnants is 170 °C (340 °F), for the Teflon impregnant, 205 °C (400 °F).

Fluoropolymers

All fluorocarbons have high molecular weights, high melting points, and excellent chemical resistance. They have found wide application in chemical and pharmaceutical plants as pipe liners, nozzle liners, gaskets, expansion joints, valve liners, diaphragms for valves and pumps, seals and seal components, and barrier linings for vessels.

Polytetrafluoroethylene (PTFE) has a service temperature of 245 to 260 °C (475 to 500 °F) and is immune to most corrosive environments. Among the materials that attack PTFE are molten alkali metals and free fluorine. This material is rapidly permeated by bromine and oxides of nitrogen, and low molecular weight amines tend to plasticize the polymer. It can also be used at cryogenic temperatures, giving it the widest temperature range of any polymer.

Perfluoroalkoxytetrafluoroethylene (PFA) is a copolymer of tetrafluoroethylene and a perfluorovinyl ether. This material has a service temperature of 195 to 230 °C (425 to 450 °F) and is similar in corrosion resistance to PTFE. It has a lower permeability to most chemicals than PTFE, which is always helpful for lining/barrier applications, and possesses higher tensile properties at elevated temperatures.

Fluorinated Ethylene Propylene (FEP) is a copolymer of tetrafluoroethylene and hexafluoropropylene. It is a fully fluorinated thermoplastic with a service temperature of 175 °C (350 °F). Like PTFE and PFA, this material is chemically inert, with a slightly lower permeability than that of PTFE. The uses for FEP are similar to those for PFA and PTFE.

Ethylene-Chlorotrifluoroethylene (ECTFE) is the result of a 1:1 alternating copolymer of ethylene and chlorotrifluoroethylene having a service temperature of 160 °C (320 °F). Because ECTFE is not completely fluorinated, there are sites along the polymer chain at which chemical attack may occur. This material is attacked by aromatic solvents above 120 °C (250 °F), chlorinated hydrocarbons, ethers, methanol, butanol, and ketones above 65 °C (150 °F), acetic acid above 95 °C (200 °F),and H_2SO_4 and aromatic amines above 65 °C (150 °F). It resists mineral acids up to 120 °C (250 °F), inorganic alkalies, inorganic salts, and oxidizing acids at room temperatures.

Polyvinylidene fluoride (PVDF) is a crystalline, high molecular weight, partially fluorinated polymer of vinylidenedifluoride having a service temperature of 135 °C (275 °F). If is attacked by hot alkalies, hot H_2SO_4, solvents, and warm organic acids. This material has good resistance to chlorine, bromine, and their compounds; however, it will

exhibit cracking when subjected to stress in the presence of nascent halogens. Virgin unplasticized PVDF has been successfully used for high-purity water piping as a replacement for electropolished type 316L stainless steel.

Glass-Lined Steel

This material offers the corrosion resistance of glass combined with the strength of steel, making it useful for process equipment operating at elevated pressure and temperature. Glass-lined steel has excellent resistance to corrosion over a wide range of pH and environments. Most glass-lined steel applications will not adversely affect product purity, flavor, or color. Glass-lined steel has an extremely smooth surface that resists fouling and is easily cleaned, which makes it attractive for use in pharmaceutical and fine chemical manufacture.

Material and Corrosion Failures Encountered

The types of failures experienced in the pharmaceutical industry are similar in many ways to those seen in the chemical-processing industries (see the article "Corrosion in the Chemical Processing Industry" in this Volume). Three primary causes of failure in the manufacture of pharmaceuticals--embedded iron, failures of glass linings, and corrosion under thermal insulation--will be discussed in this section.

Embedded Iron

A common problem during the fabrication of stainless steel equipment is the embedding of iron in the stainless steel surface. The iron corrodes when exposed to moist air or when wetted, leaving rust streaks. Larger embedded iron particles can also initiate crevice corrosion attack in the stainless steel. Embedded iron cannot be tolerated in a fabrication destined for an application in the pharmaceutical industry in which the stainless steel is used to prevent contamination.

Fabrication Practices. The following practices are recommended for minimizing embedded iron in fabrication. First, sheet, strip, and pipe are usually purchased in a surface finish known as AISI 2B (a bright, cold-rolled finish; see the article "Surface Engineering of Stainless Steels" in *Surface Engineering,* Volume 5 of *ASM Handbook*). Plate is normally hot rolled, annealed, and pickled and is furnished with a 2B mill finish. If a plate having a better surface finish is required, it should be specified during the procurement stage. When cleanliness is very important, sheet and plate can be ordered with a protective adhesive paper that can be left in place during storage and fabrication. Pipe and tubing can be ordered with protective end covers, especially if the pipe and tubing is to be stored outdoors.

Second, sheet and plates should be stored indoors and upright in racks, not horizontally on the floor. The dragging of sheets and plates over each other and worker foot traffic are often primary causes of embedded iron and deep surface scratches.

Third, care should be exercised in handling the sheet and plate on layout tables, forming roll aprons, and benches. This will minimize iron contamination.

Lastly, equipment design plays an important role in iron contamination. Equipment and piping should be free draining. If internal attachments are needed, they should not interfere with free drainage. Bottom connections should be completely free draining. Vessel bottoms used as a work area during construction collect debris, and the foot traffic grinds the debris into the surface. It is suggested that the vessel bottom be flushed down and drained completely at the end of the workday to remove collected dirt and debris. If the vessel is a large flat-bottom unit, a slatted wood floor should be installed to reduce the grinding of contaminants into the vessel bottom by foot traffic.

Testing new fabrications for embedded iron is relatively easy. The surfaces should be washed which clean water,drained completely, and after a 24-h waiting period, inspected for rust streaks on the surface. Water testing of the fabrication as a minimum should definitely be part of the equipment purchase order. For items to be used in a pharmaceutical plant, a more sensitive test--the ferroxyl test (ASTM A 380) for free iron--should be called for in the purchase order. This test can be easily performed in the field as well as in the fabricator's shop.

Removal of Embedded Iron. Pickling is the most effective method of removing embedded iron. The surfaces must be cleaned of all surface oil, grease, and other organic materials so that the surface becomes wet by the pickling solution. The pickling solution is a mixture of HNO_3 and HF at 50 °C (120 °F). The solution removes the embedded iron and other metallic contaminants and leaves the surface clean and in its most corrosion-resistant condition. It should be noted that HNO_3 alone will remove only superficial iron contamination and will leave the deeply embedded particles. Small items

are usually pickled by immersion. Piping and vessels that are too large for immersion can be pickled by circulating the pickling solution through them. It is recommended that a competent chemical cleaning contractor be employed for the pickling operation. If the ferroxyl test shows only spotty patches of iron contamination, then it is recommended that these be removed by the use of an HNO_3-HF pickling paste, rather than a complete pickling bath.

Another method of cleaning the stainless steel surfaces is the use of glass bend blasting. The beads should be clean and of a proper size to abrade the surface slightly and remove the contamination. Gritblasting and sandblasting are not recommended; they leave a rough profile that makes the stainless steel prone to crevice corrosion.

Organic contamination on stainless steel surfaces increases crevice corrosion. Contaminants include grease, oil, marking crayons, paint, and adhesive tape. Removal of organic contaminants is best accomplished by the use of a nonchlorinated solvent. It is important that nonchlorinated solvents be used. If a proprietary degreasing solvent is used, it should be tested to ensure that it does not contain chlorides. Residual chlorides remain in crevices and cause chloride SCC of austenitic stainless steels.

Weld Defects. Austenitic stainless steel surfaces can be affected by slag from coated welding electrodes, arc strikes, welding stop points, grinding marks, and weld spatter. These factors have initiated corrosion in aggressive environments that normally do not attack stainless steels. Arc strikes damage the protective oxide film of the stainless steel and create crevicelike imperfections in or near the HAZ. Weld stops create pinpoint defects in the weld metal. Arc strikes and weld stop points are actually more damaging than embedded iron, because they occur where the protective film has been weakened by the heat of welding.

Weld stop defects can be avoided by using runout tabs, by beginning the arc immediately ahead of the stop point, and by welding over each intermediate stop point. Arc strikes are more difficult to eliminate. Initially, the arc can be struck on a runout tab. It can also be struck on the weld metal when the filler metal will tolerate arc strikes. If the metal will not tolerate arc strikes, the arc must be struck alongside the filler metal in or adjacent to the HAZ.

Weld spatter creates a small weld in which the molten glob of metal touches and adheres to the surface. The protective oxide film is penetrated, and small crevices or pits are formed where the film has been weakened.

Heat tint formation also weakens the oxide film. The weakening is greater for some degrees of heating than for others, as indicated by the extent of color change. The necessity of removing heat tint in greatest where the environment is very aggressive and the stainless steel approaches the limit of its corrosion resistance. Pickling by immersion in the standard HNO_3-HF solution is the simplest and preferred method of heat tint removal when size permits. Glass bead blasting, using beads the are clean and of proper size in order to prevent overroughening of the surface, can also be employed to remove the heat tint.

Small slag particles from coated electrodes resist cleaning and tend to collect in slight undercuts or other irregularities. To remove slag from 300-series stainless steel, wire brushes fabricated from 300-series stainless steel should be used. For critical service, brushing should be followed by local pickling or glass bead blasting. Grinding is frequently used to remove slag, arc strikes, weld spatter, and other imperfections. Grinding wheels and continuous-belt grinders can overheat the surface and reduce corrosion resistance; therefore, they have limited usefulness. Abrasive disks and flapper wheels are not as harmful to the metal surface. Disks must be kept clean and replaced frequently. These procedures are good commercial fabrication practices and should be specified during the bidding and procurement stages in an effort to eliminate cost overruns and poor service performance.

Failures of Glass-Lined Steel Equipment

Most glass-lined equipment failures are not related to chemical deterioration of the lining, but rather to mechanical and thermal influences. The typical failures encountered in the use of this type of equipment in the pharmaceutical and fine chemical industries usually involve mechanical shock, corrosion, abrasion, thermal shock, and thermal stress.

Mechanical shock is the most common cause of glass failure in pharmaceutical production facilities. It accounts for approximately 70% of the failures in glass-lined steel process equipment and is frequently the result of human error.

The most obvious cause of glass failure due to mechanical shock is objects falling on either the exterior or interior of the vessel. Care must be observed at all times when working near glass-lined equipment because a shock to the outside of a vessel may cause damage to the glass lining.

Lifting lugs are normally supplied on glass-lining equipment and should be used for lifting the equipment and setting it in place. The lugs are specifically designed for this purpose and should be used in accordance with manufacturer's recommended procedures for handling and rigging. Shortcuts in rigging, such as using a nozzle as a lifting lug, can easily subject the glass lining to undue stress and cause damage to the lining. If mechanical shock has occurred or is suspected, the equipment interior should be inspected immediately and, if necessary, repaired.

Entering the interior of glass-lined steel equipment always creates a potential for mechanical damage. In addition to compliance with the routine safety precautions, the mechanic should wear clean, soft rubber soled shoes or sneakers to prevent scratching of the lining and should remove all loose objects from his pockets prior to entering the lined equipment. Even metal belt buckles should be removed to prevent accidental scratching of the glass on the entry manway. Tools can be lowered to the mechanic when he is safely inside.

If it becomes necessary to remove product or by-products from the walls of glass-lined steel equipment, care must be taken to avoid scratching of the glazed surface. Metal tools should never be used. Plastic or wood scrapers can be used; high-pressure water jets are preferable.

The introduction of nucleated glass linings by fabricators of glass-lined steel equipment has reduced the damage caused by impact and, to some extent, has lessened its occurrence. Nucleated or partially nucleated glass linings have higher tensile strength and fracture energy than conventional glassed steel linings. These properties have lessened the tendency toward spalling from mechanical shock, the releasing of internal stresses, or thermal shock. Nucleated glass linings cannot prevent cracking entirely, but they tend to limit the extent of the damage by restricting it to a small area, usually requiring only a tantalum plug for repair.

Corrosion Failures of Glass Linings. Glass-lined steel is not completely inert and is constantly undergoing local chemical reactions at the glass surface. Glass-lined steel can be used with corrosive materials because of the low rate of reaction; the slower the rate, the longer the useful life of the glass lining.

Acids. Except for HF, concentrated H_3PO_4, and phosphorous acid (H_3PO_3) above 85%, glass lined steel is resistant to corrosion by acids. Generally, the corrosion rate decreases with concentration, but accelerates with increasing temperature. Acid attack is more severe in the vapor phase than in the liquid phase, especially in more dilute solutions, because of the water vapor in the vapor phase. Usually, acid attack will result in a gradual loss of the fire-polished surface, but the lining will generally retain a dull, smooth finish.

Hydrofluoric acid will completely destroy glass-lined steel equipment. Even with concentrations as low as 20 ppm, fluorides in an acid environment corrode glass severely, especially in continuous reactions in which the fluorides are repeatedly replaced. Hydrofluoric acid reacts with silicon dioxide, the primary ingredient in glass, and destroys the silicon dioxide structure, forming silicon tetrafluoride and water vapor. The silicon tetrafluoride then hydrolyzes into silicon dioxide and hydrofluorine silicic acid, which are absorbed by the condensing water vapor. When this contaminated condensate reaches the heated vessel wall in the vapor space, it evaporates, depositing silicon dioxide and liberating the hydrofluorine silicic acid, which then disintegrates into silicon tetrafluoride and HF. The chain reaction keeps repeating itself with continuous replenishment of HF. The corrosion occurs both in the liquid phase and in the cooler areas of the vapor space in which the fluoride vapor can condense.

Glass is not attacked by fluorine and its compounds in an alkaline environment, nor is it attacked by anhydrous hydrogen fluoride gas. The prerequisite for HF attack in the vapor space is the formation of water; thus, the corrosion rate will be greatly reduced if the vapor area is heated. In the liquid phase, fluorides will severely etch the glass and produce a roughened surface with a complete loss of the fire-polished surface. In the vapor phase, the attack is more localized and concentrated; chipping and pinholes will be seen, but with considerably less loss of the fire-polished glass surface.

Reagents that contain fluoride impurities must be carefully analyzed to determine the fluoride level before they are used. Frequently, technical grade H_3PO_4 and its salts are often contaminated with fluoride, as are other mineral acids. It is important to realize this when using these chemicals in recovery operations.

Alkaline attack of glass linings is much more severe than acid attack. The attack takes place only in the liquid phase in the case of nonvolatile alkalies. The greater the concentration and pH of the alkali, the greater the amount of corrosion. Corrosion by alkalies is evidenced by pinholes, chipping, and a severe loss of the fire-polished surface.

Many glass-lined steel reactors have been lost prematurely in service by improper charging of reactants into the vessels. Caustic reactants charged into a vessel should always be fed directly into the liquid phase. If fed through a nozzle, the alkali will run down the side wall of the reactor in the vapor space and cause severe alkaline attack, especially if the reactor is being heated.

Water can cause severe corrosion of glass-lined steel, and the severity increases with water purity and temperature, becoming greatest above the boiling point. When water droplets condense on the relatively cool surface of the glass-lined equipment in the vapor space, they leach out alkali ions from the glass and form an alkaline solution that attacks the glass. A small amount of acid added to the water usually slows the corrosion caused by condensation in the vapor space. This addition of acid is frequently useful in steam distillations.

Abrasion Failures. Failure of glass linings by abrasion alone is not very common. It is evidenced by a loss of fire polish of the glazed surface and results in a rough, sandpaperlike finish. Abrasion in conjunction with acid corrosion results in severe failure. The abrasive action weakens the silica network mechanically, allowing acid corrosion to accelerate rapidly.

Thermal shock failure occurs because of abrupt changes in the temperature of the glass lining and results in relatively small but thick pieces of glass spalling off in rigid fractures. There are four operations in which sudden temperature variations can cause thermal shock:

- Sudden cooling of a glass-lined surface by subjecting a preheated surface to a cold liquid
- Sudden heating of a glass-lined steel wall by rapidly circulating a very hot fluid through the jacket of a cold vessel
- Sudden heating of the glass-lined steel surface by introducing a hot fluid into a cold vessel
- Sudden cooling of the vessel wall by rapid circulation of a cold fluid through the jacket of a preheated vessel

Thermal shock is strictly an operational problem and can be eliminated by adequate process controls. Unlike failure due to mechanical shock, thermal shock usually damages the glass lining so that repairs with tantalum plugs are not practical or possible. Reglassing of the vessel is then required.

Failure due to thermal stress is caused by differential heating or cooling that is not instantaneous. Thermal stress may occur on the vessel wall just below the area at the top jacket closure ring or in the area where the bottom jacket closure ring is welded to the vessel. In either case, the inside of the jacket can be heated or cooled, while the unjacketed area is not. At temperatures approaching 205 °C (400 °F), sufficient strain can be developed in the glass lining at these areas to cause the glass to crack.

Thermal stress can be reduced by careful control of heating or cooling operations. Also, insulation of the unjacketed areas will help to reduce the extreme temperature variations.

Water hammer has also been known to cause shock waves that add to the thermal stresses at the area of the jacket closure. If these stresses are allowed to persist for long periods of time, cracks can develop with or without chipping.

Overstressing of Nozzles. Glass is strong in compression, but a concentrated point load can damage a glass-lined nozzle. The convex radius at the top of the nozzle also makes it susceptible to damage due to overstressing. The two situations that can cause overstressing of the nozzle and lead to possible failure are overtorquing and overstressing by the attached piping.

Overtorquing of bolts or clamps used to secure nozzles on glass-lined vessels to piping can cause glass lining to spall in large segments that may include a considerable area of the nozzle. Overstressing of nozzles through external piping can break the glass lining on the nozzle face. The design of external piping systems should include expansion joints or bellows as close as possible to the nozzles to minimize accentric loads and moments and to allow for thermal expansion of the piping and the vessel. Cold springing when connecting pipe to a nozzle cannot be tolerated. Supporting heavy gear drives on a nozzle can also create an unsafe condition with regard to the glass lining.

Failures of Repair Plugs. Tantalum is the most commonly used repair material for glass linings. Its corrosion resistance is very close to that of glass, except in fuming H_2SO_4 above 65 °C (150 °F), H_2SO_4 above 98%, free sulfur trioxide (SO_3) above 65 °C (150 °F), or nascent hydrogen.

A repair made with tantalum will protect a glass-lined vessel for its useful life if the repair plug is installed in accordance with the recommendations of the manufacturer. However, the repair plug must be inspected periodically to ensure that it is secure.

Galvanic corrosion can cause hydrogen embrittlement of tantalum repair plugs, because the tantalum is in contact with the steel substrate. If as second dissimilar metal is present in the vessel, such as a metallic dip tube fabricated from a material other than tantalum, a galvanic cell is produced. Tantalum, being more noble, will generally act as the cathode where hydrogen is liberated.

Failure Due to Hydrogen Damage. Acids on the exterior steel surfaces of glass-lined steel equipment will, in time, react with the steel, forming nascent hydrogen. This hydrogen diffuses through the steel behind the glass and causes the glass to spall because of pressure buildup.

To avoid this type of failure, all acid spills on the outside of a glass-lined steel vessel should be washed off immediately to avoid acid attack. The so-called acid-resistant coatings give some degree of protection, but none is completely effective against acid attack on the steels.

Jacket cleaning can create another source of nascent hydrogen. The cleaning solutions recommended by the manufacturer should be used for cleaning the inside jacket of a glass-lined vessel. Strong acid solutions, inhibited or otherwise, should never be used for descaling the jacket in order to avoid any possibility of nascent hydrogen formation.

Corrosion Beneath Thermal Insulation

Serious corrosion problems frequently occur under thermal insulation applied to vessels and piping components in pharmaceutical plants when the insulation becomes wet. Corrosion beneath insulation is an insidious that is also discussed in the article "Corrosion in the Chemical Processing Industry" in this Volume. The insulation usually conceals the corroding metal, and the situation can go undetected until metal failure occurs. The corrosion of metal components beneath insulation has led to very high maintenance costs and lost production time and has frequently required complete replacement of major components. In addition, operator and plant safety may be jeopardized.

Thermal insulation received from manufacturers and distributors is dry, or nearly so. Therefore, if the insulation remains dry, there is no corrosion problem. Possible solutions to the problem of metallic corrosion beneath wet insulation include keeping the insulation dry of protecting the metal.

Unfortunately, the application of this solution is not that simple. Insulation can become wet in storage and during field erection. Moisture or weather barriers are not always installed correctly, or they are not effective in preventing water entry. Weather barriers and protective coatings can become damaged and are often not maintained and repaired.

The problem is further complicated by the fact that the degree of corrosion by wet insulation appears to be dependent on the insulation material as well as the atmospheric contaminants and moisture entering from external sources. Water extracts from calcium silicate base insulation, fiberglass, cellular glass, and ceramic fiber are generally neutral to alkaline, with pH values in the range of 7 to 11. Cellular glass is free of soluble chloride, while calcium silicate, fiberglass, and some ceramic fibers contain chlorides. Mineral wool gives a neutral environment when wet, usually a pH value of 6 to 7 with a low chloride content (2 to 3 ppm). Water extracts from organic foams can be quite acidic, with pH values of 2 or 3. In addition, where halogenated fire retardants have been added to the foam, water extracts show high levels of free halide, depending on the degree of hydrolysis achieved.

Carbon and low-alloy steels are normally passive in alkaline environments and have minimal corrosion rates. However, chloride ions (Cl^-), either from the insulation material itself or from airborne or waterborne contaminants, tend to break down the passivity locally and initiate pitting corrosion. If penetration by acidic airborne or waterborne contaminants of sulfur or nitrogen oxides is possible or if water extracts from the insulation are acidic, such as from organic foams, then general corrosion occurs. Occasionally, airborne or waterborne contaminants, notably the nitrate anion (NO_3^-), cause external SCC of nonstress-relieved carbon and low-alloy steel systems, especially if a cyclic wetting and drying

concentration mechanism is present. Generally, plant facilities operating continuously or intermittently between 65 and 205 °C (150 and 400 °F) are subject to corrosive attack.

The most significant corrosion problem that occurs when insulated austenitic stainless steels are subjected to moisture is external SCC. The problem occurs because chlorides tend to concentrate under the insulation at the surface of the metal when the insulation becomes wet. The moisture can leach soluble chlorides out of the insulation, or the entering moisture may already contain chloride from the environment. At the warm metal surface, the moisture is vaporized, leaving behind an increasing concentration of chlorides. During operation, when the equipment or piping is in the susceptible temperature range, chloride SCC can then occur rapidly. The four factors necessary for SCC are an austenitic stainless steel, Cl^- ions, tensile stress on the metal, and temperatures between 50 and 230 °C (120 and 450 °F).

Unfortunately, thermal stress relief, which is usually effective in preventing SCC of carbon and low-alloy steels, is normally not practical for austenitic stainless steels. However, there are numerous controllable factors in the design, construction; and maintenance of insulated equipment that have a marked effect on the amount of damage caused by corrosion under thermal insulation.

Equipment Design. The design of pressure vessels, tanks, and piping generally includes numerous details for support, reinforcement, and connection to other equipment. These details may include stiffening rings, insulation support rings, gussets, brackets, reinforcing pads, ladder brackets, flanges, and hangers. The design of equipment, including these details, is the responsibility of engineers/designers utilizing construction codes to ensure reliable designs for both insulated and uninsulated equipment. Unfortunately, consideration of the problem of insulating these details and of leaving adequate room for the insulation is completely lacking in these codes and in the instructions to the engineers/designers. As a result, the items are designed as though they will not be insulated.

Undesirable geometries and design features include:

- Flat horizontal surfaces (such as vacuum rings)
- Structural shapes that trap water (H-beams, channels)
- Shapes or configurations that are impossible to weatherproof properly (structural members, gussets)
- Shapes that lead moisture and contaminants into the insulation hanger rods (angle iron brackets)
- Inadequate spacing that causes interruption of the vapor or weather barrier (nozzle extensions, ladder brackets, deck or grating supports). The weather barrier on such designs is frequently broken because of inappropriate details for insulated equipment or the lack of space for the specified insulation thickness

The consequence of an incomplete moisture barrier is that more water and contaminants get into the insulation at each exposure cycle; this increases the time required for drying, cools the insulated equipment to temperatures at which corrosion is possible, and thus increases the damage. Some equipment details, such as gussets, brackets, and hangers, actually funnel water and contaminants into the insulation. Another consideration is the increased cost of insulating equipment that was not designed for insulation. In such cases, the insulation and jacketing must be cut and fitted by installers; thus, needless man-hours are spent insulating a complicated detail, with the result being an installation that is doomed to failure. The solution to such problems is to specify the type of insulation, thickness, and weather jacketing in the design stage.

The service or operating temperature of the equipment is very important in corrosion beneath thermal insulation. Higher temperatures make water more corrosive, and paints and caulking will fail prematurely.

Generally, corrosion associated with equipment operating below freezing temperatures is corrosion outside of, not under, the insulation. Equipment operating between freezing and the atmospheric dew point is subject to continuous corrosion, and damage can occur as quickly as it does under warm insulation. However, corrosion beneath warm insulation is more difficult to control, because of the drying out of water entering the insulation and the concentration of contaminants carried in with the water drying out repeatedly in the same location.

Insulation Materials. Corrosion is possible beneath all types of insulation. The insulation material is only a contributing factor. The insulation characteristics that are most influential in the corrosion of metal beneath insulation include water absorbency, chemical contributions to the water phase (not only from the insulation but also from external sources), and service temperature. Some of the more widely used insulation materials are discussed below.

Polyurethane foam is primarily used for cold and antisweat service. It does not absorb or wick water as long as the cell structure remains intact. It is permeable to water vapor in cold service when the required vapor barrier fails. Vapor diffuses through cell walls to the temperature zone in which it condenses and diffuses further to the point at which it freezes. The maximum service temperature is 80 °C (180 °F). If used in continuously cold service, it does not corrode unprotected metal surfaces. If in intermittent service to its maximum service temperature, it can cause corrosion of unprotected wet metal surfaces from released chlorides in fire retardants and blowing agents. The ultraviolet rays from the sun will decompose this insulation.

Polyisocyanurate foam is a fire-resistant organic foam having a low flame propagation rate. It does not absorb and wick water as long as the cell structure remains intact. It is permeable to water vapor in cold service when the required vapor barrier fails. The maximum service temperature is 120 °C (250 °F).

When polyisocyanurate is exposed to heat and moisture, the cell structure in the heated zone breaks down. The decomposition products may contain chlorides from the fire retardant and blowing agent and may aggressively corrode unprotected metal surfaces.

Flexible foamed elastomer does not readily absorb or wick water, and it has a maximum service temperature of 80 °C (180 °F). Although not corrosive by itself, it will support the corrosion of unprotected metal surfaces when water is present, especially when the water contain chlorides from an external source.

Cellular glass is a rigid glass foam whose blowing agent contains carbon dioxide and hydrogen sulfide. It does not absorb and wick water. The maximum service temperature is 480 °C (900 °F). When water is present and the cell structure is damaged, release of the foam blowing agent may cause corrosion on unprotected carbon steel surfaces.

Glass fiber for insulation is usually a pure glass fiber containing various types of binders. Fiberglass will absorb and wick water; however, it drains excess moisture better than other types of insulation. The maximum service temperature is 230 °C (450 °F), with special formulations to 455 °C (850 °F).

Mineral wool is a mineral or metal slag fiber that is basically an impure glass. It readily absorbs and wicks water. Maximum service temperatures range from 650 to 980 °C (1200 to 1800 °F), depending on type and manufacturer. The fact that mineral wool will wick and hold water makes it a contributory factor in the corrosion on unprotected wet metal surfaces.

Calcium silicate insulation is a cementitious mixture and readily absorbs and wicks water. Calcium silicate insulation can hold up to 400% of its own weight in water without dripping. The maximum service temperature is 650 °C (1200 °F). Although its pH is initially high (10 average), it is aggressive in supporting corrosion on unprotected wet metal surfaces because of its moisture retention, particularly when the moisture contains chlorides from an external source.

Protective coatings are extremely important in preventing the corrosion of metal surfaces beneath thermal insulation. In the past, the attitude has been that a single coat of primer would be adequate based on the assumption that the weatherproofing never allowed water to penetrate into the insulation system. This was not the case.

Basically, service under thermal insulation is virtually an immersion service. Once the weather-or vaporproofing barrier is broken, metal surfaces under isolation are wet longer than the surfaces of most uninsulated equipment. Under warm insulation, the coating is subject to higher temperatures than most coated, uninsulated equipment. The coatings beneath thermal insulation fail because of chemical degradation and the permeability of the coating. Highly permeable coatings allow corrosion to initiate behind the coating film, even in the absence of breaks or pinholes in the coating.

In selecting a protective coating for use beneath insulation, consideration should be given to its abrasion resistance, temperature resistance, chemical resistance, and its ability to resist hot water vapors.Organic coating materials are discussed in details in the article “Organic Coatings and Linings” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook.*

In general, for carbon steel and stainless steel piping and equipment operating at -45 to 2120 °C (-50 to 250 °F) under insulation, it is recommended that the surface be abrasive blast cleaned to National Association of Corrosion Engineers (NACE) No. 2 or Steel Structures Painting Council (SSPC) SP10 Near White metal standards having a surface profile of 50 to 75 μm (2 to 3 mils). The freshly cleaned surfaces should then be coated with 305 μm (12 mils) (total dry-film

thickness) of an epoxy phenolic coating applied in two or more coats or with 305 μm (12 mils) (total dry-film thickness) of a high melting point, amine-cured, coal tar epoxy applied in one or two coats.

For carbon steel piping and equipment operating at temperatures of 120 to 260 °C (250 to 500 °F) with intermittent cycling service into the hot water range under insulation, it is recommended that the surface be abrasive blast cleaned to NACE No. 1 or SSPC SP10 Near White metal standards having a surface profile of 50 to 75 μm (2 to 3 mils). The freshly cleaned surfaces should then be coated with 150 μm (6 mils) (total dry-film thickness) of a coplymerized silicone resin applied in two or more coats.

Carbon steel piping and equipment operating continuously above 260 °C (500 °F) under insulation should have the surface abrasive blast cleaned to NACE No. 3 or SSPC SP6 Commercial Blast standards having a surface profile of 25 to 50 μm (1 to 2 mils). The freshly cleaned surfaces should then be coated with 100 μm (4 mils) (total dry-film thickness) of a black zinc-free modified silicone coating applied in two coats.

For stainless steel piping and equipment operating at temperatures from 20 to 370 °C (250 to 700 °F) under insulation, it is recommended that the surface be cleaned according to SSPC SP1 Solvent Cleaning standards. The freshly cleaned surfaces should be coated with 100 μm (4 mils) (dry-film thickness) of a black zinc-free modified silicone coating applied in two coats.

Inorganic and organic zinc-rich primers have given very poor performance under thermal insulation and should not be used. Possible reasons for this poor performance include:

- The likelihood of reversal of polarity of galvanic couples with increasing temperature
- Chemical salts carried in and deposited with the water that interfere with or destroy the effectiveness of the coating
- The environment beneath the insulation is not freely ventilated and may not have adequate oxygen or carbon dioxide for film forming reactions to occur

Weatherproofing and Vaporproofing. The outer covering of the insulation system is critical. It is the principal barrier to the water necessary for the corrosion of metals beneath thermal insulation. Also, it is the only part of the insulation system that can be quickly inspected and economically repaired.

The purpose of the weather barrier, which should be used on warm or hot equipment, is to keep liquid out but to permit the evaporation of any moisture that gets in. The purpose of a vapor barrier is to keep both liquid and vapor out of the insulation system. Vapor barriers should be used on all cold and dual-service insulation systems.

Corrosion in Petroleum Production Operations

Chairman: James E. Donham, Consultant

Introduction

THE PRODUCTION of oil and gas, its transportation and refining, and its subsequent use as fuel and raw materials for chemicals constitute a complex and demanding process. Various problems are encountered in this process, and corrosion is a major one. The costs of lost time, the replacement of materials of construction, and the constant personnel involvement in corrosion control are substantial and, if not controlled, can be catastrophic. The control of corrosion through the use of coatings, metallurgy, nonmetallic materials of construction, cathodic protection, inhibitors, and other methods has evolved into a science in its own right and has created industries devoted solely to corrosion control in specific areas.

This article will discuss the particular corrosion problems encountered, the methods of control used in petroleum production, and the storage and transportation of oil and gas to the refinery. Refinery corrosion is discussed in the article "Corrosion in Petroleum Refining and Petrochemical Operations" in this Volume.

Causes of Corrosion

Arthur K. Dunlop, Corrosion Control Consultant

The fundamentals of corrosion and the forms of corrosion are discussed in detail in the Sections so named in this Volume. Therefore, this article will concentrate on those aspects that tend to be unique to corrosion as encountered in oil and gas production.

Most unique, of course, are the environments encountered in actual production formations, which, in the absence of contamination, are devoid of oxygen. *In situ* corrosives are limited to carbon dioxide, hydrogen sulfide, polysulfides, organic acids, and elemental sulfur. Additional unique aspects are the extremes of temperature and, particularly, pressure encountered. In deep gas wells (6000 m, or 20,000 ft), temperatures approaching 230 °C (450 °F) have been measured, and partial pressures of CO_2 and H_2S of the order of 20.7 MPa (3000 psi) and 48 MPa (7000 psi), respectively, have been encountered.

Convenient access to the most important literature on H_2S corrosion (particularly with regard to sulfide stress cracking) and CO_2 corrosion is available in Ref 1 and 2. Supplemental information is provided in Ref 3 and 4.

To the initially oxygen-free geologic environment, a variety of oxygen-contaminated fluids may be introduced. Examples are drilling muds, which are used during drilling and maintenance of wells; dense brines; water and carbon dioxide injected for secondary oil recovery; and hydrochloric acid injected to aid formation permeability. Some of these fluids are inherently corrosive; others are potentially corrosive only when contaminated with oxygen.

Oxygen is also responsible for the external corrosion of offshore platforms and drilling rigs. In oil and gas production, highly stressed structural members are directly exposed to a corrosive seawater environment. This makes corrosion fatigue a particular concern.

Another unique aspect of oil and gas production operations, particularly in older fields, is the almost exclusive use of carbon and low-alloy steels. Only recently has any extensive use of corrosion-resistant alloys been justified.

Oxygen

Although it is not normally present at depths more than approximately 100 m (330 ft) below the surface, oxygen is nevertheless responsible for a great deal of the corrosion encountered in oil and gas production. However, oxygen-induced internal corrosion problems tend to be greater in oil production, where much of the processing and handling occurs at near-ambient pressure. This makes oxygen contamination through leaking pump seals, casing and process vents, open hatches, and open handling (as in mud pits during drilling, trucking, and so on) highly likely. Also, failure of oxygen removal processes (gas stripping and chemical scavenging) is a relatively common occurrence in waterflood systems (see the discussion "Corrosion in Secondary Recovery Operations" in this article).

A number of the properties of oxygen contribute to its uniqueness as a corrosive. Oxygen is a strong oxidant. This means that even trace concentrations can be harmful, and the corrosion potential of steel (almost 1.3 V) is high enough to overcome very substantial potential drops between anodic and cathodic sites. Also, the kinetics of oxygen reduction on a metal or conductive oxide surface are relatively fast. This, coupled with the low solubility of oxygen in water and brines, tends to produce conditions in which the mass transport of oxygen is the rate-limiting step in the corrosion of carbon and low-alloy steels in nonacidic environments.

Mass transport is important in a number of aspects of oxygen corrosion and corrosion control. On newly installed bare steel offshore structures, mass transport of oxygen governs current requirements for cathodic protection. Poor mass transport under deposits and in crevices promotes localization of attack. In the final analysis, limiting the mass transport of oxygen plays a critical role in much of the corrosion control in oxygenated systems.

The crucial role of mass transport can be illustrated as follows. At ambient conditions, water equilibrated with air will contain of the order of 7 to 8 ppm of oxygen. Under such conditions, mass transport limited rates of general corrosion of steel range from about 0.25 mm/yr (10 mils/yr) in a stagnant system to 15 mm/yr (600 mils/yr) in a highly turbulent one. However, by chemically scavenging the oxygen concentration down to the order of 7 to 8 ppb, the corresponding rates are reduced to less than about 0.01 mm/yr (0.4 mils/yr). Such rates are acceptable. However, under these conditions, magnetite forms as a stable protective corrosion product film and further lowers the corrosion rate by introducing a slower, anodically controlling step.

An even more fundamental role of magnetite should be acknowledged. This is the protection of the steel surface from reaction with water or the hydrogen ions contained in the water. Therefore, if an excess of a chelating agent such as ethylenediamine tetraacetic acid (EDTA) dissolves a protective magnetite film, as would normally occur in regions of high turbulence, rapid corrosion ensues, despite the absence of oxygen.

Hydrogen Sulfide, Polysulfides, and Sulfur

Hydrogen sulfide, when dissolved in water, is a weak acid and is therefore corrosive because it is a source of hydrogen ions. In the absence of buffering ions, water equilibrated with 1 atm of H_2S has a pH of about 4. However, under high-pressure formation conditions, pH values as low as 3 have been calculated.

Hydrogen sulfide can also play other roles in corrosion in oil and gas production. It acts as a catalyst to promote absorption by steel of atomic hydrogen formed by the cathodic reduction of hydrogen ions. This accounts for its role in promoting sulfide stress cracking of high-strength steels (yield strength greater than approximately 690 MPa, or 100 ksi) (Ref 5).

Hydrogen sulfide also reacts with elemental sulfur. In a gas phase with a high H_2S partial pressure, sulfanes (free acid forms of a polysulfide) are formed so that elemental sulfur is rendered mobile and is produced along with the remaining gaseous constituents. However, as the pressure decreases traveling up the production tubing, the sulfanes dissociate and elemental sulfur precipitates. Various solvent treatments are used to avoid plugging by such sulfur.

In the aqueous phase, under acidic conditions, sulfanes are also largely dissociated into H_2S and elemental sulfur. However, enough strongly oxidizing species can remain either as polysulfide ions or as traces of sulfanes to play a significant role in corrosion reactions. Oxygen contamination of sour (H_2S-containing) systems can also result in polysulfide formation.

Iron sulfide corrosion products can be important in corrosion control. Because of the low solubility, rapid precipitation, and mechanical properties of such corrosion products, velocity effects are generally not encountered in sour systems. Satisfactory inhibition at velocities up to 30 m/s (100 ft/s) has been proved.

The great range of possible iron sulfide corrosion products and their possible effects on corrosion have been extensively studied (Ref 6, 7, 8, 9), but little of immediate practical value has resulted. At lower temperatures and H_2S partial pressures, an adequately protective film often forms. The absence of chloride salts strongly promotes this condition, and the absence of oxygen is absolutely essential.

At the high temperatures (150 to 230 °C, or 300 to 450 °F) and H_2S partial pressures (thousands of pounds per square inch) encountered in deep sour gas wells, a so-called barnacle type of localized corrosion (Ref 10) can occur, resulting in corrosion rates of several hundred mils per year (Ref 11). This type of attack is strongly promoted by polysulfide-type species and requires the presence of some minimum chloride concentration. Although initially recognized in deep sour well environments, this same mechanism may operate at lower rates under much milder conditions.

In the barnacle mechanism (Fig. 1), corrosion can be sustained beneath thick but porous iron sulfide deposits (primarily pyrrhotite, $FeS_{1.15}$ because the FeS surface is an effective cathode. The anodic reaction beneath the FeS deposit is dependent on the presence of a thin layer of concentrated $FeCl_2$ at the Fe/FeS interface. This intervening $FeCl_2$ layer is acidic due to ferrous ion hydrolysis, thus preventing precipitation of FeS directly on the corroding steel surface and enabling the anodic reaction to be sustained by the cathodic reaction on the external FeS surface.

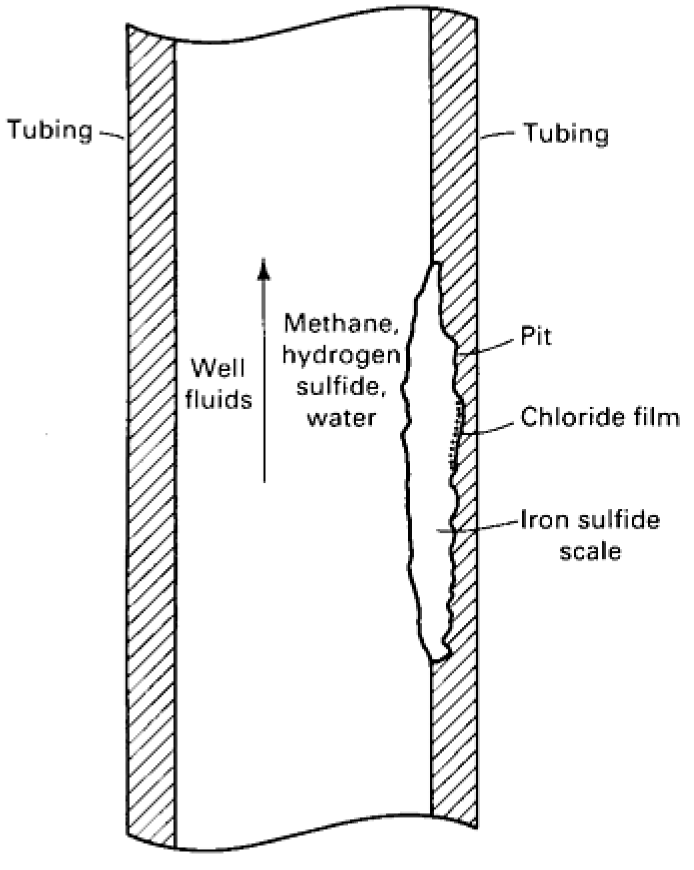

Fig. 1 Schematic showing the barnacle mechanism of sour pitting corrosion. Source: Ref 11

Carbon Dioxide

Carbon dioxide, like H_2S, is a weakly acidic gas and becomes corrosive when dissolved in water. However, CO_2 must first hydrate to carbonic acid (H_2CO_3) (a relatively slow reaction) before it is acidic. There are other marked differences between the two systems. Velocity effects are very important in the CO_2 system; corrosion rates can reach very high levels (thousands of mils per year), and the presence of salts is often unimportant.

Whether or not corrosion in a CO_2 system is inherently controlled or uncontrolled depends critically on the factors governing the deposition and retention of a protective iron carbonate (siderite) scale. On the other hand, there are the factors that determine the rate of corrosion on bare steel. These latter factors govern the importance of maintaining corrosion control.

Bare steel corrosion rates can be calculated from Eq 1, which was developed on the basis of electrochemical studies of the aqueous CO_2/carbon steel system (Ref 12):

$$\log R = A - \frac{2320}{t + 273} - \frac{5.55t}{1000} + 0.67 \log \bar{p} \quad \textbf{(Eq 1)}$$

where R is the corrosion rate, t is temperature (°C), A is a constant, and $\bar{p}$ is CO_2 partial pressure. When R is calculated in millimeters per year and $\bar{p}$ is in atmospheres, A = 7.96. When R is calculated in mils per year and $\bar{p}$ is in pounds per square inch, A = 8.78.

Corrosion rates calculated with Eq 1 reach 25 mm/yr (1000 mils/yr) at 65 °C (150 °F) and 1 MPa (150 psi) CO_2 pressure, and 250 mm/yr (10,000 mils/yr) at 82 °C (180 °F) and 16 MPa (2300 psi) CO_2 pressure. Obviously, such rates are unacceptable. An alternative, idealized condition occurs when a protective carbonate scale is present and when the corrosion rate is limited by the need to replenish the film lost due to solubility in the aqueous phase. Under such conditions, the rates calculated for a hypothetical sweet (CO_2-containing) gas well reached a maximum of about 0.15 mm/yr (6 mils/yr) as compared to calculated bare metal rates of 500 to 2000 mm/yr (20,000 to 80,000 mils/yr) (Ref 13).

Conditions favoring the formation of a protective iron carbonate scale are:

- Elevated-temperature (decreased scale-solubility, decreased CO_2 solubility, and accelerated precipitation kinetics)
- Increased pH, as occurs in bicarbonate-containing waters (decreased solubility)
- Lack of turbulence

Turbulence is often the critical factor in pushing a sweet system into a corrosive regime. Excessive degrees of turbulence prevent either the formation or retention of a protective iron carbonate film.

The critical velocity equation has been used to estimate when excessive turbulence can be expected in a CO_2 system (Ref 14). There is no doubt that the velocity effect is real, but there is some question as to whether this exact form of the equation is the appropriate one:

$$\text{Critical velocity} = \frac{K}{\sqrt{\rho}} \quad \textbf{(Eq 2)}$$

where velocity is calculated in feet per second, K is a constant, and ρ is the density of the produced fluid (liquid + gas combined). When ρ is in kilograms per cubic meter, K = 7.6; for ρ in pounds per cubic foot, K = 100.

When both H_2S and CO_2 are present, simplified calculations indicate that iron sulfide may be the corrosion product scale when the H_2S/CO_2 ratio exceeds about 1/500 (Ref 13); sour system considerations would then be expected to apply. Even in a strictly CO_2 system, iron carbonate may not always be the corrosion product. Magnetite may form instead. Figure 2 shows the stability fields expected for siderite and magnetite as a function of the redox potential (expressed here in terms of hydrogen fugacity) of the system (Ref 13). In actual experience, corrosion product scales are often found to consist of mixtures or layers of siderite and magnetite.

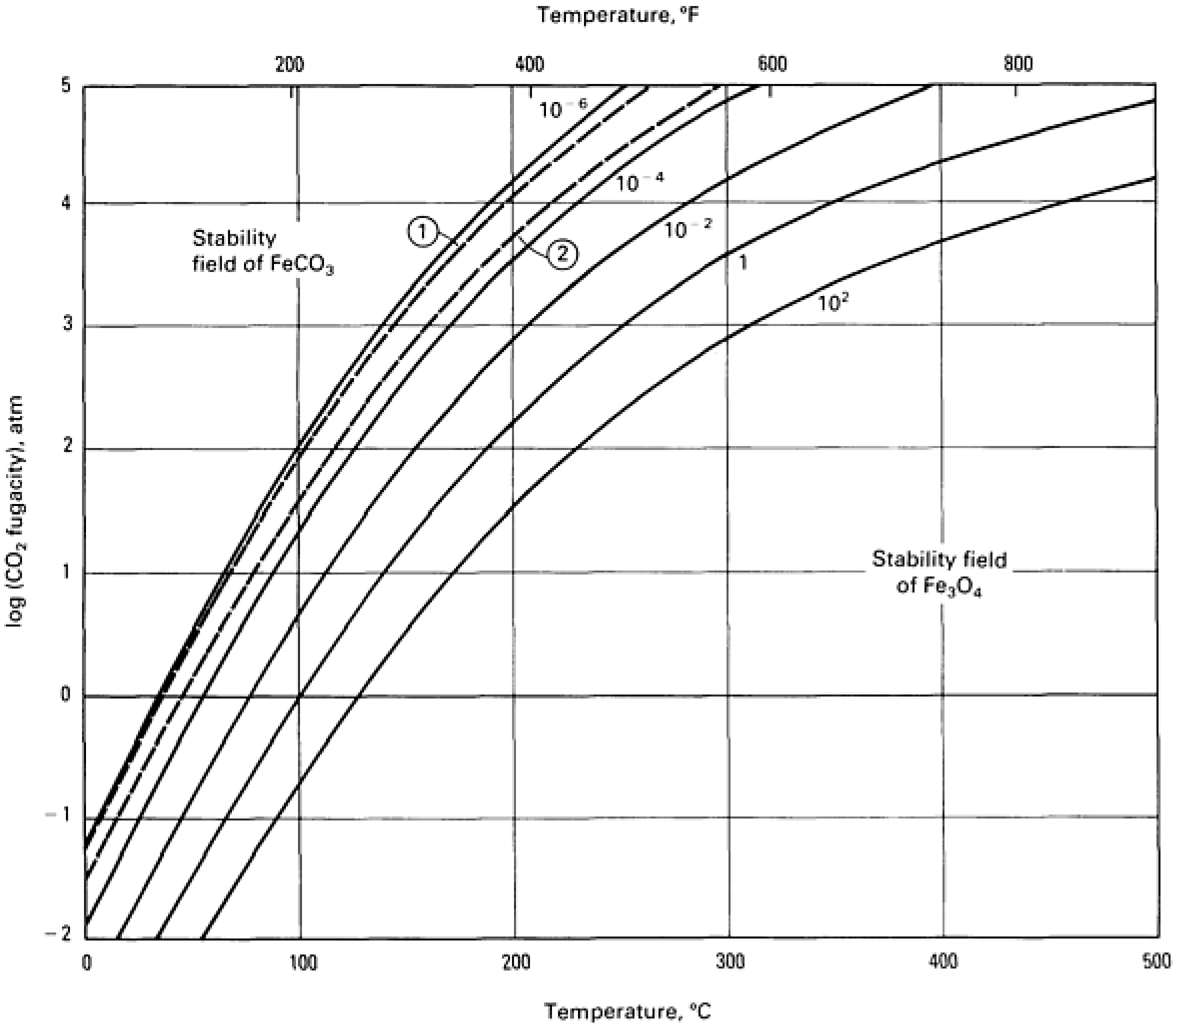

Fig. 2 Effect of temperature and hydrogen fugacity on the stability of $FeCO_3$ and Fe_3O_4 in contact with aqueous CO_2. Equilibrium calculations determine boundaries (indicated by the iso-hydrogen fugacity curves, with fugacities given in atmospheres) between $FeCO_3$ and Fe_3O_4 stability fields in the produced fluid, which contained CO_2, water, and traces of hydrogen. Curves 1 and 2 locate boundaries for locations 5180 m (17,000 ft) deep and at the wellhead, respectively, of a 170,000 m^3/day (6,000,000-ft^3/day) well corroding at a rate of 0.75 mm/yr (30 mils/yr). Source: Ref 13

Iron carbonate lacks conductivity and therefore does not provide an efficient cathode surface. Thus, the types of pitting mechanisms found in oxygenated and in H_2S-containing systems do not occur. Rather, generalized corrosion occurs at any regions not covered by the protective scale. The result is that on any bare metal the anodic and cathodic regions are so microscopically dispersed that salt--to provide conductivity--is not needed to achieve the corrosion rates predicted by Eq 1.

Strong Acids

Strong acids are often pumped into wells to stimulate production by increasing formation permeability. For limestone formations, 15 and 28% hydrochloric acids are commonly used. For sandstones, additions of 3% HF are necessary. In deep sour gas wells where HCl inhibitors lose effectiveness, 12% formic acid has been used.

Corrosion control is normally achieved by a combination of inhibition and limiting exposure time to 2 to 12 h. If corrosion-resistant alloys are present (austenitic and duplex stainless steels, and so on), concern for stress-corrosion cracking (SCC) and inhibitor ineffectiveness (respectively) may rule out the use of HCl.

Concentrated Brines

Dense halide brines of the cations of calcium, zinc, and, more rarely, magnesium are sometimes used to balance formation pressures during various production operations. All can be corrosive because of dissolved oxygen or entrained air. In addition, such brines may be corrosive because of the acidity generated by the hydrolysis of the metallic ions, as illustrated in Eq 3:

$$Zn^{2+} + H_2O = ZnOH^+ + H^+ \qquad \textbf{(Eq 3)}$$

Corrosivity due to acidity is worst with dense zinc brines. More expensive calcium bromide brines are now often used at densities above about 1.7 g/cm^3 (14 lb/gal) (attainable with $CaBr_2$ brines) to avoid long-term exposure to $ZnCl_2$ brines.

Stray-Current Corrosion

If an extraneous direct current (dc) in the earth is traversed by a conductor, part of the current will transfer to the lower-resistance path thus provided. Direct currents are much more destructive than alternating currents (ac); an equivalent ac current causes only about 1% of the damage of a dc current (Ref 15). Regions of current arrival (where electrons depart) will become cathodic, and those regions where the current departs will become anodic. With corrodible metals such as carbon and low-alloy steels, corrosion in the anodic areas is the result. For example, 1 A · yr can corrode 9 kg (20 lb) of steel.

Cathodic protection systems are the most likely present-day sources of stray dc currents in production operations. More detailed discussions are available in Ref 4 and 16. The article "Stray-Current Corrosion" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook* also contains information on the causes and mechanisms of stray-current corrosion.

Under-Deposit (Crevice) Corrosion

This is a form of localized corrosion found almost exclusively (if not exclusively) in oxygen-containing systems. Such corrosion is usually most intense in chloride-containing systems. It is essential to have some form of shielding of an area on a metal such that it is wet by an electrolyte solution but is not readily accessible to oxygen, the diffusing corrosive species.

This type of attack is usually associated with small volumes of stagnant solution caused by surface deposits (sand, sludge, corrosion products, bacterial growth), crevices in joints, and gasket surfaces. Crevice corrosion is discussed in Ref 17, and a quantitative treatment of crevice corrosion (particularly of stainless steels) is provided in Ref 18, 19, and 20.

The mechanism of crevice corrosion hinges upon the environmental conditions resulting from the loss of hydroxide production with cessation of the cathodic reaction when the initial oxygen in the shielded region is exhausted. Thus, in the shielded region, the anodic corrosion reaction continues because the corrosion potential is maintained by the reduction of oxygen on the outside surface. However, chloride or other anions now migrate into the developing anodic region to maintain electroneutrality. Thus, a relatively concentrated, essentially ferrous chloride solution accumulates in the shielded region. As a result of the hydrolysis of the ferrous ions, the pH drops to a value of 2 or 3.

At this point, the crevice corrosion type of localized attack is fully established. The anodic reaction continues in the shielded region because in the low-pH environment the ferrous ions go readily into solution and have little tendency to precipitate as an oxide or hydroxide on the surface and thus stifle the anodic reaction. Outside, the cathodic reaction continues unperturbed. Because of the large ratio of cathodic-to-anodic surface area, high rates of localized corrosion can be maintained with very modest cathodic current densities. More information on the mechanisms of crevice corrosion is available in the article "Crevice Corrosion" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Galvanic Corrosion

When two dissimilar metals are electrically coupled--both electronically by a metal bond and ionically through an electrolyte--the more active (electronegative) metal tends to become a sacrificial anode and supply cathodic protection to the more noble metal. Such situations are often encountered in heat exchangers in which carbon steel tubesheets are used

with copper alloy tubes and at junctions between piping, fasteners, or corrosion-resistant sheeting with containers of another material.

Problems with galvanic corrosion are the most acute when the cathode-to-anode area ratio is large. Such situations are often encountered inadvertently. This has happened when the normal polarity difference between zinc and steel in a galvanized pipe reversed in a bicarbonate/chloride brine so that the steel pipe walls at pinholes in the galvanizing perforated rapidly while trying to protect the extensive adjacent galvanized area. Another situation is when plastic-coated steel is coupled to more noble metal. At any pinholes in the coating, a very adverse area ratio will exist, and rapid corrosion rates can result. The article “Galvanic Corrosion” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook* contains more information on this form of attack.

Biological Effects

The most important biological effect on corrosion in oil and gas production is the generation of H_2S by sulfate-reducing bacteria (*Desulfovibrio Desulfuricans*). These are anaerobic bacteria that metabolize sulfate ions (using an organic carbon source) and produce hydrogen sulfide. They can thus introduce H_2S and all its corrosive ramifications into normally H_2S-free systems.

Colonies of sulfate-reducing bacteria can also form deposits that are conducive to under-deposit corrosion. Contrary to previous beliefs, any resultant corrosion appears to be due to a mechanical shielding action, rather than any depolarizing action resulting from the metabolic processes of the SRB. However, this is not to deny that the introduction of H_2S (whatever the source) into a crevice region could have an accelerating effect on corrosion, because H_2S is known to be an anodic stimulant. More information on biological corrosion is available in the articles “Microbiologically Influenced Corrosion” and “Evaluating Microbiologically Influenced Corrosion” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Mechanical and Mechanical/Corrosive Effects

Cavitation. This metal removal--often grain by grain--is due to high-pressure shock wave impingement resulting from the rapid collapse of minute bubbles created under certain conditions in high-velocity fluid handling equipment. It is usually found on pump impellers operating with too low a suction pressure.

Erosion. Most commonly, this is direct metal removal by the cutting action of high-velocity abrasive particles. Erosion failures (washouts) are seen in drill pipe when leaks (loose connections or a corrosion fatigue crack) allow drilling mud to flow through the wall under a high-pressure gradient. Erosion of flow lines at bends and joints by produced sand is probably the other most common occurrence of erosion in oil and gas production.

Erosion-Corrosion. Strictly speaking, in erosion-corrosion, only the protective corrosion product film is removed by erosive forces; however, with the protective film absent, corrosion can occur at a greatly accelerated rate. Erosion-corrosion may play a role in CO_2 corrosion (Ref 21), and sand, under mild flow conditions, may also cause erosion corrosion. Erosion-corrosion has also been noted in heavy anchor chains where their use in an abrasive bottom mud allowed corrosion at contact regions to proceed at a rate of many hundreds of mils per year.

Corrosion fatigue results from subjecting a metal to alternating stresses in a corrosive environment. At points of greatest stress, the corrosion product film becomes damaged during cycling, thus allowing localized corrosion to take place. Eventually, this leads to crack initiation and crack growth by a combination of mechanical and corrosive action. Because of this combined action, damage per cycle is greater at low cycling rates, where corrosion can play a larger role. Also, in corrosion fatigue, a fatigue limit does not exist; rather than leveling out as in simple fatigue, the usable stress level continues to decrease with increasing cycles.

The greatest concern for corrosion fatigue arises in connection with highly stressed, submerged, offshore structures. Welded connections on drill ships and on drilling and production platforms are particularly susceptible to this form of structural impairment. More information on attack resulting from combined corrosion and mechanical effects is available in the article "Mechanically Assisted Degradation" in this Volume.

Corrosion Control Methods*

Arthur K. Dunlop, Corrosion Control Consultant; David H. Patrick, ARCO Resources Technology; Donald E. Drake, Mobil Corporation

Materials Selection

Traditionally, carbon and low-alloy steels were virtually the only metals used in the production of oil and gas. This resulted from the fact that very large quantities of metal are required in petroleum production, and until a few years ago, crude oil and gas were relatively low-value products. In addition, insurmountable corrosion problems were not encountered.

This situation changed when gas and oil prices increased dramatically and deeper wells were drilled that encountered corrosive environments of greatly increased severity. The final factor that made the current widespread use of corrosion-resistant alloys possible was the development of high-strength forms of these alloys. This allowed thinner pipe and vessel walls and greatly reduced the amount of material required.

The result of this situation is that essentially all of the high-tonnage uses of corrosion-resistant alloys in oil and gas production involve alloys in a high-strength form. Yield strengths typically span the range of 550 to 1250 MPa (80 to 180 ksi), but can reach nearly 1750 MPa (250 ksi) in wire lines.

Metallurgical Considerations

The great majority of corrosion-resistant alloys used in oil and gas production were originally developed for other applications not requiring high strength. Therefore, many of these have an austenitic microstructure and can be strengthened only by some form of cold working. This presents no problem for the production of tubulars used underground in the well, because they are joined by threaded connections. However, for other applications, such as welded flow lines and cast and forged valves, different techniques must be used.

In addition to the problems of environmental compatibility, there are a number of difficulties of a metallurgical nature that will be briefly mentioned. For high-strength materials, particularly at the upper end of the range, adequate ductility is often difficult to achieve. Also, heat treatments developed for other applications may not be optimal for petroleum protection environments.

Environmental Considerations

There are several environmental factors that are more or less unique to oil and gas production. One factor is the general absence of oxygen in produced fluids. The dominant naturally occurring corrosives are carbon dioxide and hydrogen sulfide. However, in wells with high hydrogen sulfide concentrations, elemental sulfur--a relatively strong oxidizing agent--can also be present.

Water, which must be present to make sulfur or the acid gases (CO_2 and H_2S) corrosive, can be assumed to be present in all productive geologic formations. Therefore, liquid water is present from the bottom of the well up to the point in the flow system at which it is removed. Corrosivity is aggravated by the presence of salt in formation waters. Such brines can range from a few percent sodium chloride up to saturated solutions containing as much as 300,000 ppm of total dissolved salts.

Temperature also affects corrosivity. Deep well temperatures up to 205 °C (400 °F) are not uncommon. Therefore, temperatures from these levels down to ambient must be considered.

Corrosion

From other applications, enough is generally known to select alloys that are resistant to general corrosion. However, resistance to localized corrosion (pitting and crevice corrosion) often requires some experimental study.

Environmental Stress Cracking. In corrosion-resistant alloy selection, environmental stress cracking normally requires the greatest portion of experimental effort. This follows from the use of high-strength alloys in environments in which there is relatively little experience with these alloys.

The problem is complicated by the fact that the lowest alloy content and the maximum reliable strength level are needed to achieve an economically viable choice. Because this involves design close to the limits of the material, it is necessary to define these limits as accurately as possible.

The term environmental stress cracking was selected because it includes two different mechanisms; cathodic and anodic. The cathodic mechanism is that of hydrogen embrittlement found in sulfide stress cracking of high-strength carbon and low-alloy steels in the presence of hydrogen sulfide. Here, H_2S promotes entry of cathodically evolved hydrogen atoms into the metal.

The anodic mechanism is that involved in the chloride SCC of austenitic stainless steels at temperatures generally above about 65 °C (150 °F). Nickel-base alloys are normally immune to this type of chloride cracking. However, the presence of H_2S can induce susceptibility in normally resistant alloys by acting to promote anodic dissolution. In the most resistant alloys, such as Hastelloy alloy C-276 (Table 1), elemental sulfur and a temperature of about 230 °C (450 °F) must also be present to cause cracking. Cracking will occur only in high-strength, heavily cold worked samples.

Table 1 Compositions of corrosion-resistant alloys

Alloys	UNS designation	Composition, %[(a)]					
		C	**Cr**	**Fe**	**Ni**	**Mo**	**Other**
Hastelloy alloy C-276	N10276	0.02	14.5-16.5	4-7	bal	15-17	2.5Co, 1.0Mn, 4.5W, 0.35V
Hastelloy alloy G	N06007	0.05	21-23.5	18-21	bal	5.5-7.5	2.5Nb, 2.5Co, 2.5Cu, 2.0Mn, 1W, 1Si
Haynes No. 20 Mod	N08320	0.05	21-23	bal	25-27	4-6	2.5Mn, 1Si, Ti-4 × C min
Sanicro 28	N08028	0.03	26-28	bal	29.5-32.5	3-4	1.4Cu, 2.5Mn, 1Si
Inconel alloy 625	N06625	0.10	20-23	5	bal	8-10	0.4Al, 4.15Nb, 0.5Mn, 0.4Ti
Incoloy alloy 825	N08825	0.05	19.5-23.5	bal	38-46	2.5-3.5	0.2Al, 3Cu, 1Mn, 1.2Ti, 0.5Si
Monel alloy 400	N04400	0.3	. . .	2.5	63-70	. . .	bal Cu, 2Mn, 0.5Si

(a) Maximum unless range is given or otherwise indicated.

Effects in the Cathodic Mechanism. In corrosion-resistant alloys, environmental effects on cathodic stress cracking are generally similar to those encountered in the sulfide stress cracking of carbon and low-alloy steels. However, in extreme cases, the temperatures needed to avoid cracking susceptibility in the highest-strength materials can be as high as 120 °C (250 °F). An example is Hastelloy alloy C-276 at a hardness of 45 HRC. In contrast, the highest minimum temperature given in NACE standard MR-01-75 for high-strength low-alloy tubulars is 80 °C (175 °F).

Also, on corrosion-resistant alloys, chloride ions can have a significant deleterious effect in cathodic cracking. This results from deterioration of passivity in the presence of chloride. The resulting higher anodic corrosion rate can then support a higher cathodic rate and thus gives rise to enhanced cathodic charging of the corrosion-resistant alloy with atomic hydrogen.

Effects in the Anodic Mechanism. Determining regions of susceptibility to anodic cracking is much more complicated than defining regions of susceptibility to cathodic cracking. This is due to the multidimensional nature of the problem. Therefore, in anodic cracking, susceptibility is a strong function of such environmental factors as temperature, chloride concentration, and hydrogen sulfide partial pressure; in addition, pH, oxidants (elemental sulfur or polysulfides), and galvanic coupling can be involved. Further, alloy composition (corrosion resistance), strength level, and stress all influence cracking susceptibility.

The effect of H_2S requires some elaboration. In cathodic cracking, there is a well-established threshold for the initiation of the sulfide stress cracking phenomenon; this is not the case in anodic cracking. The effect in anodic cracking is more monotonic. Therefore, there can almost be a different critical value for every combination of alloy, strength, applied

stress, and environmental condition. However, it is safe to assume that research in this area is leading to the development of some generalized patterns.

Selection of Corrosion-Resistant Alloys

Alloy selection, from a corrosion standpoint, can be considered to be a three-step process. First, resistance to general corrosion must be ensured. This is primarily a function of the chromium content of the alloy. Second, resistance to localized attack also must be ensured. This is primarily a function of molybdenum content. Finally, resistance to environmental stress cracking is sought at the highest feasible strength level. Nickel content plays a principal role in this instance, particularly in providing resistance to anodic cracking.

The close correlation between pitting resistance and resistance to anodic cracking should be noted. This apparently results from the ease of crack initiation under the low-pH high-chloride conditions found in pits. Therefore, higher molybdenum can also increase resistance to anodic cracking.

With the procedures given below, regions for alloy applicability can be shown schematically as a qualitative function of environmental severity. This has been attempted in Fig. 3, in which an aqueous, CO_2-containing environment (hence low pH) has been assumed and the effects of temperature, chloride, and H_2S concentration are illustrated. The effect of yield strength is not shown, but if environmental cracking is the limiting factor, reducing the yield strength should extend applicability to more severe environments.

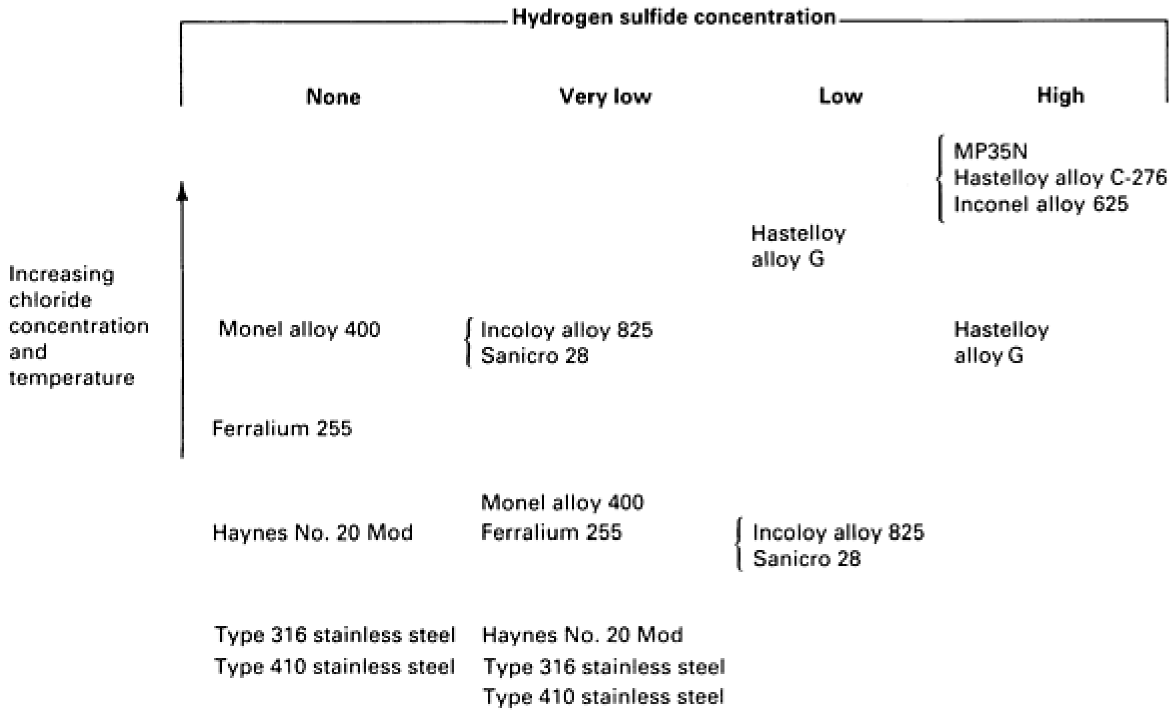

Fig. 3 Schematic showing corrosion-resistant alloy selection for production environments containing aqueous CO_2 and H_2S

The reader should be cautioned that a diagram such as Fig. 3 is really more of a guide to alloy qualification than to direct selection for a particular application. Therefore, it may aid in developing a more efficient approach to alloy testing.

Testing for Resistance to Environmental Stress Cracking

The most directly applicable results are obtained by exposing samples of commercially produced alloys to an environment simulating as closely as possible that expected in actual production operations. Fortunately, an

understanding of the principles involved allows considerable simplification to be made without significantly altering the value of the results.

Two simplifications can be readily made in the environmental parameters, as follows. First, only the CO_2 and H_2S partial pressures are usually reproduced. The overburden of methane pressure to create the actual total pressure of the environment is dispensed with. This can substantially lower the pressure ratings of test vessels. Second, only the chloride content of the brine is typically reproduced, rather than trying to simulate the total ionic spectrum of the produced fluids. Often, no reliable analysis is available. Assumption of a saturated sodium chloride solution is then a relatively conservation approach.

A wide variety of test specimens are used, but for high-strength corrosion-resistant alloy tubulars, C-rings are particularly convenient. Double cantilever beam specimens are very attractive in that they can provide a quantitative measure of fracture toughness, which can then be used in mechanical design. Slow strain rate testing can also be very useful in assessing alloy limits.

Another aspect of testing is the imposed stress level. Exposure at 100% of yield strength is the only conservative approach. However, some investigators place unwarranted reliance on design values and test at some lesser fraction of the yield strength. Detailed information on testing for resistance to environmental cracking is available in the articles "Evaluation of Hydrogen Embrittlement" and "Evaluation of Stress-Corrosion Cracking" in *Corrosion: Fundamentals, Testing, and Protection,* Volume 13A of *ASM Handbook*..

Note cited in this section

* The section on materials selection was written by A.K. Dunlop; the section on coatings was written by D.H. Patrick; and the sections on cathodic protection, inhibitors, nonmetallic materials, and environmental control were written by D.E. Drake.

Coatings

Internal protective coatings have been used to protect tubing, downhole equipment, wellhead components. Christmas trees (manifolds used to control the rate of production, receive the produced fluids under pressure, and direct the produced fluids to the gathering point), and various downstream flow lines and pressure vessels for more than 30 years. Because internal coatings are subject to damage, successful use is usually accompanied by chemical inhibition or cathodic protection as part of the entire protective program. Most of the coating use has been below 175 °C (345 °F).

Tubing. The benefits derived from coating tubing depend on the coating remaining intact. Because no coating can be applied and installed 100% holiday-free, inhibition programs are commonly employed to accommodate holidays and minor damage. The suitability of the service is dependent on specific testing and an effective quality control program.

Inhibitor and volume will not change even though an operator decides to use coated tubing rather than bare tubing. The use of coated tubing improves the protection in shielded areas that are inaccessible to inhibitors. The two greatest dangers to coated tubing are wireline damage and improper joint selection. Wireline damage can be minimized by adjusting running procedures to include wireline guides and to slow wireline speed (<0.5 m/s, or <100 ft/min). Inhibiting immediately after wireline work is good practice.

Proper joint selection involves choosing a joint that allows coating to be applied around the pin nose into the first few pin threads and from the first few coupling threads into the coupling body. The proper joint allows the coating to remain undamaged. Often, a corrosion barrier compression ring is used to accomplish this end. Metal-to-metal sealing joint designs are not joints that can be coated.

The coatings used for tubing protection are polyurethane, phenolformaldehyde, epoxized cresol novolac, and epoxy resins. Suitability for service is and should be based on laboratory testing using the specific environment proposed for the service.

The quality control parameters of concern are tubing surface finish/preparation, application techniques, coating thickness, holiday detection, joint condition, and inspection. Inspection is required to ensure the suitability of the other parameters. Quality control and surveillance are as much a part of a successful protective coating program as choosing the appropriate coating. The production coating must be applied in the same way the coating was applied to the test specimens.

Coated pipe and couplings must be carefully handled after coating, during shipping, in storage, and at the well site. The threads must be protected from impact with other pipe and objects.

Wireline work is necessary. These operations can be accomplished with a minimal amount of damage to the tubing if the wireline speeds are kept to 0.5 m/s (100 ft/min) or less, if all sharp edges are removed from the tools, if all tools are plastic coated or covered with a plastic sleeve, and if wheeled centralizers are used on all center hole jobs. Using the above precautions, many wireline trips can be made with little or no damage. The fact that coating should not be used because the wireline will cut the coating and cause accelerated corrosion in the wireline track is not true. When the wireline cuts uncoated tubing, it causes cold work. The wireline track then becomes anodic to the surrounding bare steel, and corrosion is accelerated. In coated tubing, the coating electrically insulates the cathodic areas so that the corrosion rate in the track is essentially the same as that for uncoated steel without wireline damage.

Wellheads, Christmas Trees, and Downhole Equipment. Exposed surfaces of wellhead equipment, Christmas trees, and downhole equipment must be coated or manufactured of corrosion-resistant materials. This starts with the tubing hanger, which is threaded onto the production tubing, and continues through the tubing bonnet (tubing adapter), the master valve(s), the tee or cross, and the wing and crown valve(s) and into the choke. Ring gasket grooves, valve seat pockets and other compression fitted parts must not be coated. These areas can be overlaid with corrosion-resistant alloys, and the coating can be applied over a transition area up to the corrosion-resistant alloy overlay. Valve internal cavities need not be coated.

Generally, tubing hangers are difficult to coat and are therefore made of corrosion-resistant alloys for corrosive service. Hangers without back pressure valve threads can be coated, but the cost of coating the carbon steel hanger may be equivalent to the cost of a corrosion-resistant alloy hanger.

Downhole equipment (nipples, polished bore receptacles, seal subs, tie backs, millout subs, packers, and so on) uses the same standards as tubing. Most downhole equipment is considered uncoatable because it was not designed for coating. Such equipment is usually coated as an assembled unit, rather than as individual pieces. If installation is below the packers, both internal and external surfaces should be coated.

Coated surface flow lines usually employ flanges or threads and couplings to join them. Joining by welding damages the coating, and field-applied repair coating is not recommended.

Vessels. The vessel must be designed as a coated vessel. Coating a vessel that was not designed for coating is rarely successful. Vessel design for coating involves welded hangers for anodes in the fluid zone, flanged access, removable internals, smooth internal surfaces, and good access to all internal surfaces to be coated. As a general rule, coating over bolted assemblies is not successful.

Cathodic Protection

Corrosion occurs when an anode and a cathode are electrically connected in the presence of an electrolyte, and electrical currents leave a metal and go into an electrolyte. If another power source can be used to oppose these corrosion currents sufficiently, the metal will be protected from corrosion. This technique is known as cathodic protection. The entire metal surface is converted into a cathode, while the corrosion currents are transferred to an auxiliary anode in which corrosion can proceed. Cathodic protection has been used in the oil field to protect pipelines, well casings, tanks and production vessels, and offshore platforms. More information on principles and applications of cathodic protection is available in the article “Cathodic Protection” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*.

Types of Cathodic Protection Systems

There are two methods of applying cathodic protection: the sacrificial anode method and the impressed-current method. Because some metals are less noble (more electronegative) than the most common oil field material--steel--in the galvanic series, they will become the anode (site of corrosion attack) when coupled to steel in the presence of an electrolyte. The

most common of these materials are magnesium, zinc, and aluminum; these are called sacrificial anodes. These types of anodes are used when:

- Current requirements are relatively low
- Electric power is not readily available
- Short system life dictates a low capital investment

The anode is usually electrically connected by a wire or steel strap to the structure to be protected. Magnesium and zinc are usually used in soils, while zinc can also be used in brine environments.

In the impressed-current method, an external energy source produces an electric current that is sent to the impressed-current anodes. The most common types of these materials include graphite, high-silicon cast iron, lead-silver alloy, platinum, and even scrap steel rails. These types of anodes are used when:

- Current requirements are high
- Electrolyte resistivity is high
- Fluctuation in current requirements will occur. These types of systems can be adjusted to compensate for varying current requirements
- Electrical power is readily available, although this is not now as severe a limitation as it was in past years.

In a typical impressed-current system, alternating current from a power line flows into a rectifier where it is converted into direct current. The dc current then flows to the anode groundbed. Other means of supplying this electrical current include solar energy and thermoelectric generators. These methods are applicable at locations where conventional electric power is not economically available.

Solar energy has powered cathodic protection for well casings in Kansas (Ref 22) and Saudi Arabia (Ref 23); segments of a 480-km (300-mile) long, 0.8-m (32-in.) pipeline in Libya (Ref 24); and segments of a natural gas distribution system in Washington (Ref 25). In these systems, silicon semiconductor devices convert sunlight directly into dc electricity, which is then used for the anode groundbed and to charge batteries. These batteries provide current to the anode groundbeds during periods of little or no sunlight. The batteries must be checked periodically for proper electrolyte levels. Solar panels can be easily replaced or increased to attain a higher current output because they are fabricated in modules.

One oil company uses solar energy to protect about 800 well casings in western Kansas. The solar panels consist of individual silicon solar cells connected in series to form modules. These modules are then connected in parallel to form a panel that is rated at about 12 A and 4 V. Because casing in this field requires 1 to 2 A for cathodic protection, 2-V, 500-A · h lead-acid batteries are used. A rheostat controls the rate of current flow from the batteries, and the voltage regulator controls the battery charge rate. The batteries can provide electrical current to the anodes for 10 days even if the sun is completely blocked.

Another unconventional electrical current source is the thermoelectric generator. One type of thermoelectric generator is a system that uses a burner to heat an organic liquid in a vapor generator. This vapor then expands through a turbine wheel, thus producing power to a shaft to drive an alternator, where ac power is produced. The vapor then passes through a condenser where it is cooled and condensed back into a liquid to start the cycle again. Once the ac power is produced by the alternator, it is then sent to the rectifier to be converted to dc. Figure 4 shows an illustration of this type of thermoelectric generator. These systems can produce a maximum of 80 A at 21 V (Ref 26).

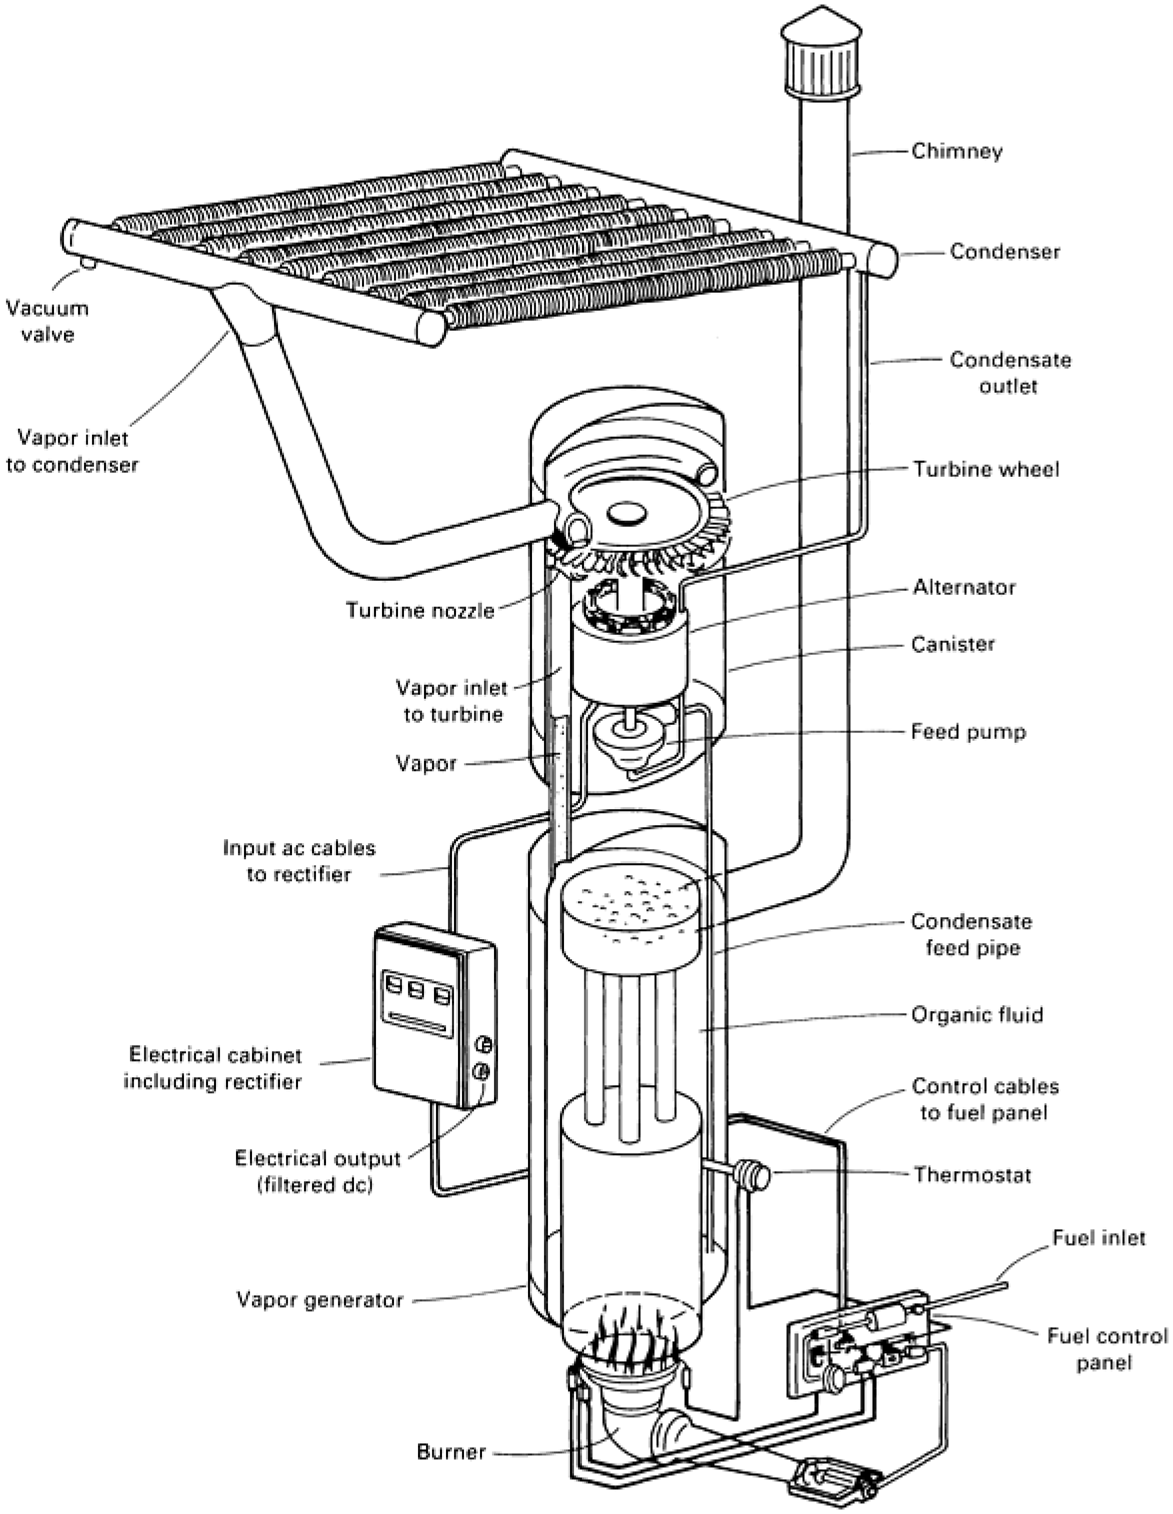

Fig. 4 Thermoelectric generator used to power cathodic protection systems in remote locations. Source: Ref 26

Application of Cathodic Protection to Oil Field Equipment

Pipelines. Cathodic protection of pipelines is very common in oil field operations. As discussed earlier in this article, sacrificial anodes or impressed current can be used for cathodic protection (Fig. 5). If the pipeline is well coated and not very long, the current requirements will probably be achieved with sacrificial anodes. If bare, a steel pipeline could require 1.1 mA/m^2 (0.1 mA/ft^2) in soil, while a very well coated pipeline could require only 0.003 mA/m^2 (0.0003 mA/ft^2) or less for cathodic protection (Ref 27).

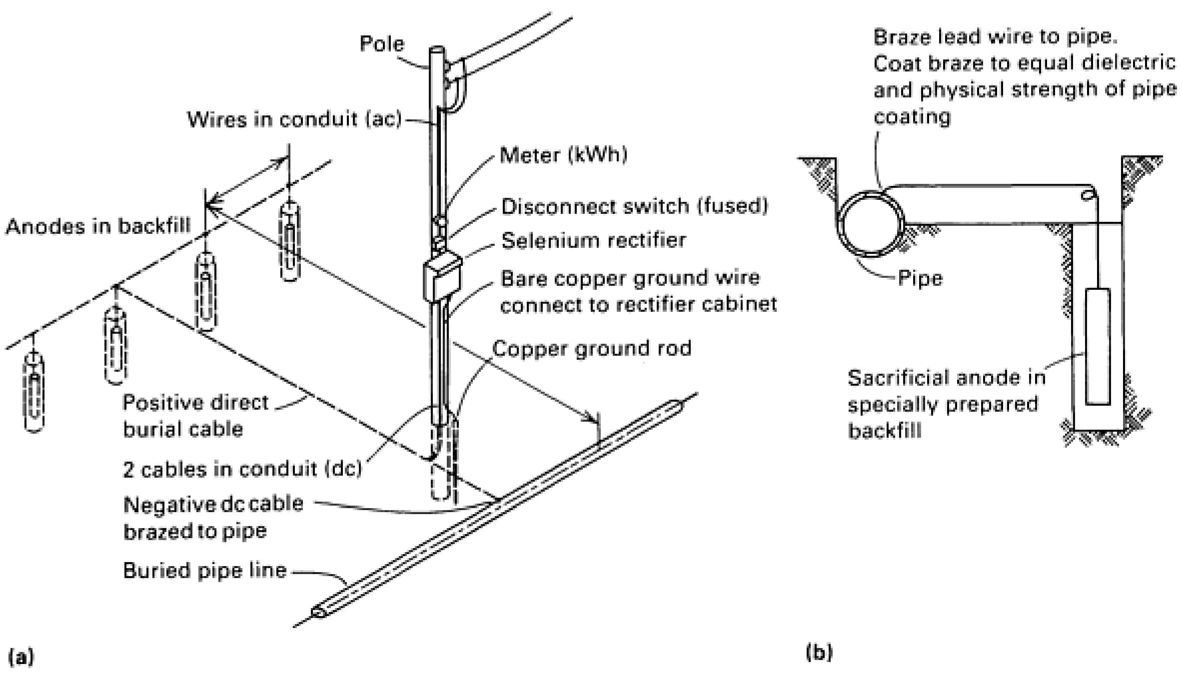

Fig. 5 Typical cathodic protection installations. (a) Impressed current. (b) Sacrificial anode

The resistivity of soils (and therefore their corrosivity) will also vary with location. Differences in aeration, soil composition (sand or clay), and the presence of chemical spills are just a few of the factors that will affect the corrosivity of the soil. Sometimes, the resistivity of the surface soils is so high that conventional groundbeds (1.8 m, or 6 ft, deep) cannot be used. Conventional groundbeds are normally used when the soil resistivities near the surface of the ground are less than 5000 $\Omega \cdot$ cm (Ref 28).

In high-resistivity soils, deep groundbeds can be used where the anodes are installed vertically in holes at depths of 15 m (50 ft) or more. Deep groundbeds (Fig. 6) are normally used to provide a better distribution of current than conventional groundbeds. These types of groundbeds also minimize right-of-way problems and are essentially unaffected by seasonal moisture variations. They are more expensive to install than conventional groundbeds, and it is usually impossible to repair any damage to the cable insulation. These systems use the same type of anodes as the conventional groundbeds. The major difference is that a perforated vent pipe can be installed to prevent chlorine gas from accumulating around the anodes. If these gases collect around the anodes, they form an insulating barrier that increases the resistance of the groundbed and eventually causes the groundbed to become ineffective.

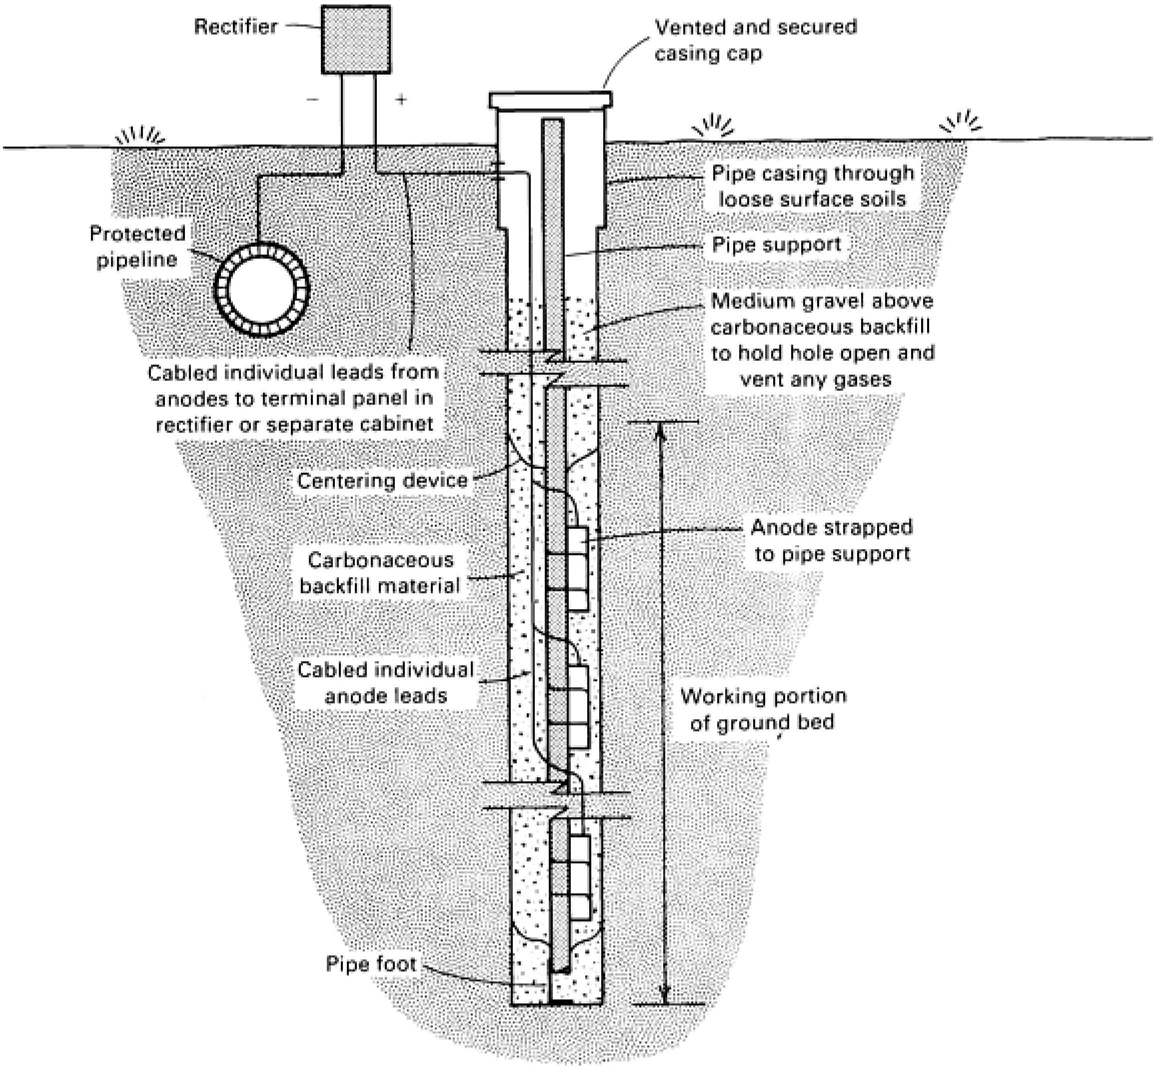

Fig. 6 Typical deep groundbed cathodic protection installation. Source: Ref 29

Well Casings. The first step in externally protecting well casing is to cement through any corrosive zones. Cement acts as a coating and will significantly reduce, but not completely stop, corrosion of the casing. Therefore, cathodic protection is needed to supplement the cement (Fig. 7). The experience of one company with the cathodic protection of well casings showed an 88% success rate in preventing predicted casing failures (Ref 31). Although a single anode bed for a buried pipeline may protect as much as 80 km (50 miles), the maximum amount of casing that needs to be protected usually does not exceed 2.4 to 3.2 km (1.5 to 2 miles). One company coated nine casing strings in 3500-m (11,500-ft) wells with fusion-bonded epoxy in Florida (Ref 31). The coating was used to reduce current requirements and to improve current distribution. Uncoated casing strings were protected with 22 to 25 A, and even then there was incomplete corrosion control. Only 10 A were needed to protect the coated casing. Some of these casing strings were pulled because of other operational problems, and the coating was found to be in excellent condition.

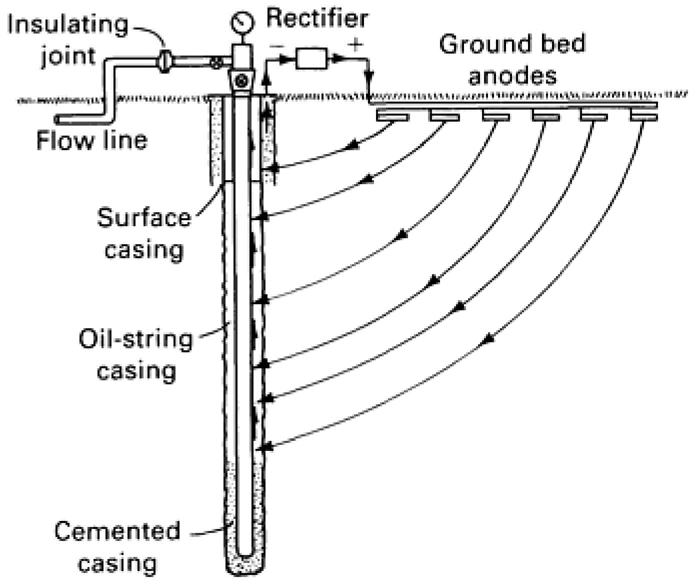

Fig. 7 Cathodic protection installation for a well casing. Source: Ref 30

Another method of reducing the current requirement is to place an insulating joint in the flow line at the wellhead. This joint prevents current from the flow line from flowing into the wellhead and down the casing. This current would leave the casing at low-resistivity zones (Ref 30).

Two methods are generally used to determine current requirements for well casing: casing potential profile and *E*-log *I*. The casing potential profile is measured by using a tool that consists of two spring-loaded probes approximately 7.6 m (25 ft) apart. This tool is pulled through the casing, and voltage readings are taken between the probes as they contact the casing every 15 or 30 m (50 or 100 ft). A plot of potential versus depth is made (Fig. 8). A slope upward and to the left indicates an anodic area, while a slope upward and to the right indicates a cathodic area. Current from a temporary groundbed is then applied to the casing for protection, and another potential profile is taken. Current is increased until the profile slopes are upward and to the right. Providing a profile slope to the right does not necessarily mean that all of the casing is protected, but it does mean that all gross corrosion areas have been eliminated.

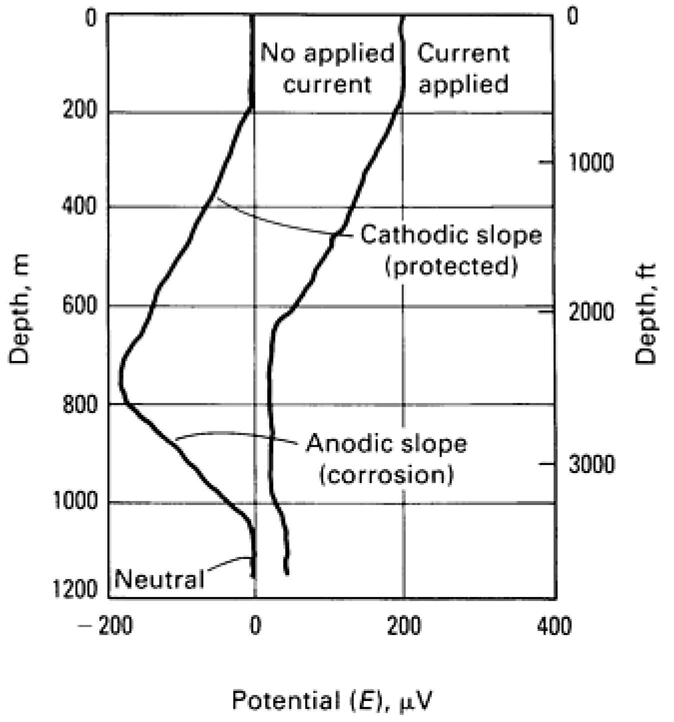

Fig. 8 Casing potential profile curve. Source: Ref 32

Another technique for determining the required current is the *E*-log *I* curve. It is less expensive and does not require the disturbance of subsurface equipment. The flow line to the well, however, must be isolated from the well casing. The pipe-to-soil potential relative to the Cu-$CuSO_4$ reference electrode is measured, and a small amount of current from a temporary groundbed is applied. The current is then interrupted, and the pipe-to-soil potential is measured as quickly as possible. The current is then increased a small amount, and the process is repeated to obtain a curve similar to that shown in Fig. 9. Generally, the current required corresponds to the break in the curve.

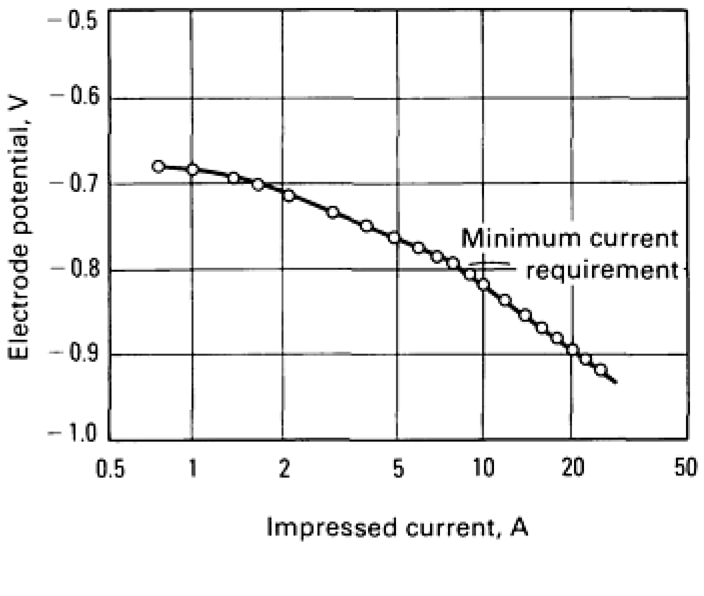

Fig. 9 Typical *E*--log *I* curve. The break in the curve indicates the minimum cathodic protection current requirement. Source: Ref 32

Tanks and Production Vessels. Internal corrosion of water-handling tanks and vessels can be controlled by the use of cathodic protection. Even if a coating has been applied to the interior of a water storage tank, there will always be imperfections where corrosion can occur; therefore, cathodic protection is needed. Sacrificial anodes can be suspended from the top of the tank as shown in Fig. 10 to offer protection to the portion of the tank that is covered with water. Cathodic protection will not help in the vapor area of the tank. Coatings must be used to protect this area. Sacrificial anodes have also been placed on concrete blocks in tanks. These blocks insulate the anode from the tank and allow decomposition products to fall away from the anode. In most cases, a lead wire is brought outside of the tank and welded to the tank. These anodes should also not be allowed to touch the sides of the tank and should be uniformly distributed within the tank to give uniform current distribution.

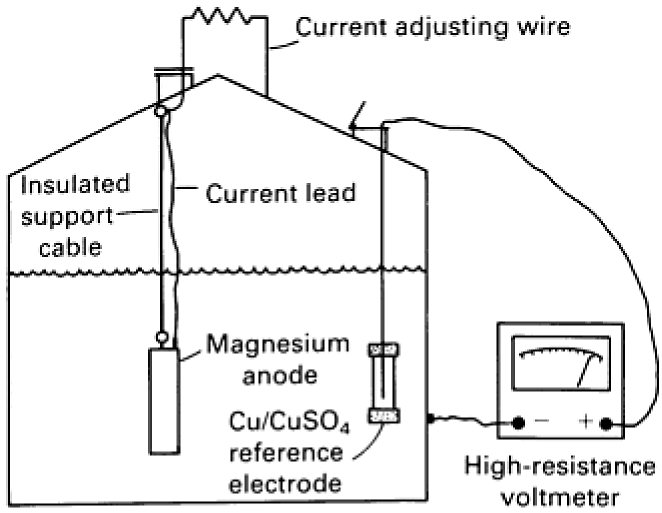

Fig. 10 Cathodic protection system for a water storage tank. Source: Ref 33

In vessels that have several sections separated by steel plates, the anodes might be shielded from protecting all of the vessel. In these cases, the only safe procedure is to install an anode in each compartment. Fire tunes in similar tanks without cathodic protection in one southern Texas field failed from corrosion in 3 months (Ref 34). When ac power is available, impressed-current systems using high-silicon cast iron, graphite, or platinized titanium anodes in through-the-wall mounts have also been used. Crude oil and some oil field chemicals have tended to stifle the flow of current from these anodes.

Offshore Platforms. The subsea zone of an offshore platform includes the area from the splash zone to and including the pilings below the mudline. Cathodic protection is the principal means of preventing corrosion in this zone, but some companies also use coatings in conjunction with cathodic protection (Ref 35). The amount of electric current required to protect the bare steel varies with location. Typical current density values range from 54 to 65 mA/m^2 (5 to 6 mA/ft^2) in the Gulf of Mexico, 86 to 160 mA/m^2 (8 to 15 mA/ft^2) in the North Sea, and as high as 375 to 430 mA/m^2 (35 to 40 mA/ft^2) in the Cook Inlet (Ref 27). Current densities in the Cook Inlet are high because of the 8-knot tidal currents experienced there. In the mud zone, current densities of 10.8 to 32 mA/m^2 (1 to 3 mA/ft^2) are needed for protection, and an allowance of 3 A per well is customary for well casings (Ref 36). Environmental factors, such as oxygen content, water salinity, temperature, velocity, erosive effects, marine growth, and calcareous deposits, are largely responsible for the differences in current densities. It is very important that the current demand be conservatively estimated.

Partial protection of the steel in seawater usually means that the area of corrosion is reduced, while the unprotected areas continue to corrode at a high rate. Some companies report pits as deep as 13 to 16 mm (0.5 to 0.625 in.) and, in many cases, holes in platform members after less than 5 years on location without adequate cathodic protection. This result corresponds to a corrosion rate of 2.5 to 3.2 mm/yr (100 to 125 mils/yr) (Ref 37).

As in all applications of corrosion control on offshore platforms, the first step for cathodic protection in the subsea zone is design. Tubular members should be used whenever possible. Recessed corners in channels and I-beams are difficult to protect. Even crevices formed by placing channels back-to-back and noncontinuous welded joints cannot be protected. Bolted and riveted fittings should be avoided. Piping such as grout lines, discharge lines, water supply casings, and

pipeline risers, if clustered around a platform leg, can cause shielding and interfere with the flow of cathodic protection current. If economically feasible, piping that is not necessary for platform operations should be removed. A minimum clear spacing of 1 $\frac{1}{2}$ diameters of the smaller pipe should be provided, and coatings on the pipe can also be used to minimize shielding. Corrosion will be negligible on the internal surfaces of structural members that are sealed and have no contact with either the atmosphere or the seawater. During launch, some structural members are flooded for the life of the platform. To prevent any internal corrosion, the flooding valves should be closed to isolate the flooded chambers from contact with fresh seawater or oxygen in the atmosphere.

Sacrificial Anode Systems. The early offshore platforms installed in the late 1940s and early 1950s used 45- and 68-kg (100- and 150-lb) magnesium anodes supported from horizontal braces. A low-carbon steel wire rope connected the anode to the brace. These anodes had a 2-year design life, which was normally shortened to 1 year or less because of hurricane or rough weather losses. These swinging anodes tangled with subsea braces, shorted, and rubbed the conductor wires to failure. A variable resistor was also connected in series with the anode and the connection at the brace. This resistor was used to regulate the current output of the anode to achieve maximum efficiency. Unfortunately, this system could never be maintained. Magnesium anodes in seawater have a high current output and corrode rapidly; therefore, they must be replaced frequently. This type of system has been discontinued for offshore use.

Zinc anodes have been used since the early nineteenth century. However, impurities, such as iron, were responsible for erratic performance. Virtually all zinc anodes are now fabricated from high-purity zinc meeting the military specification MIL-A-18001-H. More efficient aluminum anodes have also been developed. A mercury-zinc-aluminum alloy anode provides 2 $\frac{1}{2}$ times more current output than a zinc anode on a pound-for-pound basis. An anode weight of 330 kg (725 lb) is common for the initial system, while 150 kg (325 lb) is common for the replacement system. Control of impurities in the anode is essential for best performance.

The number of anodes needed depends on the size of the anode and its useful life. A design life of 20 years is common. The distribution of anodes is also important, because poor distribution and the use of too few anodes will result in underprotection, particularly at welded joints. Individual anodes should be mounted at least 0.3 m (12 in.) from the structure, or a dielectric shield should be used beneath them to improve the current distribution. Anodes should not be located in either the splash zone or on bottom bracings. The anode will not function properly if it is intermittently in and out of the seawater, and mercury-containing aluminum anodes will passivate and not function if covered by mud. Some of the earliest anodes used were prone to being knocked off of the platform during installation because the standoff posts were either too small or did not provide adequate area for contact welding of the anode to the member. Gussets and doubler plates can help obtain better anode attachment. A large fraction of premature cathodic protection failures have been traced to an inadequate number of anodes installed or excessive losses during pile driving. Some of these losses during pile driving are due to poor weld quality in attaching the anodes to the members.

Impressed-Current Systems. In an impressed-current system, the three essential components are the rectifier, the anodes, and the cable joining them together. The anode materials include graphite, high-silicon cast iron, lead-silver, and platinum wound on a niobium rod. Permanently mounted anodes, retrievable anodes, and remote anode sleds have all been successfully used. Because anodes in impressed-current systems generally produce considerably more current than sacrificial anodes, there may be only 6 or 8 impressed anodes on a structure that might do the same job as 50 to 70 sacrificial anodes. The location of these impressed-current anodes is very important in order to ensure that adequate current distribution is obtained to cover the entire surface. The connecting wiring is the critical part of an impressed-current system, especially in the splash zone, where the cable can be subjected to severe wave pounding if it is not housed in a protective conduit. Even these conduits can be torn away from the platform during a hurricane if they have been underdesigned. It is often necessary to protect the structural member near the anode with fiberglass coating or a wrap called a dielectric shield. This shield prevents excessive current consumption at this area.

Whether sacrificial or impressed anodes are used, cathodic protection currents will promote the formation of hydroxyl (OH^-) ions at cathodic areas (the entire platform, it is hoped) and cause a pH shift in the seawater near the platform. Also, the concentration of calcium and magnesium ions tends to increase in the film of seawater over the cathode. As a result of these changes, the solubility of calcium carbonate and magnesium hydroxide is exceeded, and a calcareous coating is deposited. These mineral deposits provide the primary corrosion control, and the cathodic protection current demand drops to a level sufficient to repair this coating when it is damaged. For example, if a current density of 540 mA/m^2 (50 mA/ft^2) is applied to a platform for the first 5 days on location, protection can be maintained with a current density of 32 mA/m^2 (3 mA/ft^2).

There appears to be less tendency for these mineral deposits to form in the deep ocean. In an experiment conducted by the U.S. Navy, sacrificial anodes were effective at providing cathodic protection to bare steel in seawater at depths of 1700 m (5600 ft) (Ref 38). However, the anodes were consumed more rapidly than if they were located near the surface. Because the pH is lower at great depths and the calcium carbonate concentration is below saturation, higher currents are required to achieve protection.

Inhibitors

Corrosion inhibitors are materials that, when present in a system in relatively small quantities, produce a reaction in metal loss due to corrosion attack. These inhibitors can interfere with the anodic or cathodic reaction, can form a protective barrier on the metal surface against corrosive agents, or can work by a combination of these actions. For oil field corrosion inhibitors, organic compounds containing nitrogen (amines) dominate because of their effectiveness and availability. These inhibitors usually contain three elements:

- One or more active inhibitor components
- A solvent base
- Certain additives, such as surfactants, dispersants, demulsifiers, and defoamers

Solvents are used to dilute inhibitors to control physical characteristics (such as viscosity and pour point), to aid in obtaining proper inhibitor concentration and placement during treating, to assist inhibition, and to maintain a reasonable cost per unit volume (Ref 39).

Physical characteristics of inhibitors must be considered when evaluating a potential application. These include:

- Physical form
- Solubility
- Emulsion forming tendencies
- Thermal stability
- Compatibility with other chemicals

Physical Form. Inhibitors may take either a solid or liquid form. Solid inhibitors have been made in the shape of a stick that will sink to the bottom of a well and then slowly dissolve and be produced back. These sticks are rarely used. Most corrosion inhibitors are liquid form and have densities that range from 840 to 1440 g/L (7 to 12 lb/gal) (Ref 40). These liquids must not freeze when exposed to the coldest of field conditions and must be stable with a minimum loss to the vapor state when exposed to the hottest of field conditions.

Solubility. The formation of an inhibitor film and its life are primarily governed by the solubility of that product in the system. There are three categories of solubility: soluble, insoluble, and dispersible.

A product is soluble in a fluid when it forms a clear mixture that does not separate. A product is insoluble in a fluid when it will separate after mixing to form an identifiable layer. Materials are dispersible in a fluid if they form a mixture that is not clear and separates slowly, if at all.

Different solubilities are required for different applications of corrosion inhibitors. An inhibitor to be added continuously to a waterflood should be water soluble or highly dispersible. Similarly, an inhibitor to be used for a squeeze treatment should be completely soluble in the carrying fluid to facilitate placement of the inhibitor without plugging the formation. On the other hand, where the only method of application is a periodic treatment, continuing protection requires some degree of insolubility of the inhibitor in the fluids to which it is exposed. In practical terms, this means that an inhibitor used in tubing displacement cannot be completely soluble in the well fluids. Also, a dispersion must be stable enough to remain intact until the inhibitor reaches the metal surface to be protected.

Emulsion-Forming Tendencies. Because of the chemical nature of most corrosion inhibitors, there is a positive tendency in water-oil systems to form emulsions. Some of these emulsions will break down quite readily, while others are

extremely stable and practically impossible to break. When squeezed, an incorrectly selected inhibitor can form an emulsion in the formation that blocks or severely restricts further production.

The inclusion of a demulsifier in a corrosion inhibitor is no guarantee against the formation of stable emulsions. Produced fluids from each field must be tested to provide reasonable assurance that no stable emulsion will be formed upon application of a specific corrosion inhibitor.

Thermal Stability. Corrosion inhibitors generally have temperature limits above which they will lose their effectiveness and change their chemical composition. This temperature may be variable for any one inhibitor, depending on such conditions as pressure and presence of water. A typical example is that of an acid-amine salt. Under atmospheric conditions, this salt will yield water and form an amide at 70 to 90 °C (160 to 190 °F). However, this chemical can be used in oil wells in the presence of water at these temperatures with no apparent degradation. Of course, exposure to high temperatures at low pressures will result in the vaporization of the solvent systems in these inhibitors.

Compatibility With Other Chemicals. The compatibility of corrosion inhibitors with other chemicals is ordinarily not troublesome when the inhibitor and the other chemicals are present in parts per million concentrations. However, chemical users frequently want to mix various chemicals so that a single chemical pump can be used for injection. Many products are not compatible with corrosion inhibitors, because of variations in solvent systems, type of chemicals (cationic versus anionic), and so on.

Most oil field corrosion inhibitors are cationic to some extent; that is, they carry a positive electrical charge. Mixing a cationic inhibitor with an anionic chemical, such as a scale inhibitor or certain surfactants, will likely produce a reaction product that can have characteristics that are entirely different from those of either of its parent products. At best, the new material may function poorly; at worst, it may not function at all or may even form deposits in the system. When the two chemicals must be used, this problem can be prevented by using separate injection points that are not closely spaced. It should probably be standard practice never to mix any two different products. This would avoid any potential problems.

A final example of operating problems can be found where a conventional inhibitor is used in a gas stream upstream of a compressor. The nonvolatile components in the inhibitor could be left behind to foul the valves of the compressor.

Selection of Inhibitors

Many factors are involved in the selection of inhibitors, including the following:

- Identification of the problem to be solved
- Corrosives present
- Type of system (which influences the treatment method)
- Pressure and temperature
- Velocity
- Production composition

Although problems such as rod breaks and flow line leaks may initially be seen as purely corrosion failures, the actual cause of the problem could be oxygen, scale, or bacteria. Rod coupling failures could be caused by poor assembly or corrosion fatigue. Overstressing of rods greatly accelerates these failures. In such cases, mechanical measures could reduce or eliminate the need for chemical treatment. If attack is due to oxygen entry, installation of gas blankets or closing of the casing valve could greatly reduce corrosion.

The presence of corrosives such as H_2S and CO_2 greatly influences the choice of an inhibitor. Some inhibitors perform best in sweet fluids, while other inhibitors work best in sour fluids. Even the concentration of NaCl has a bearing on the choice of an inhibitor. With increasing NaCl content, some inhibitors will become insoluble and deposit.

The type of system also has an effect on the selection of an inhibitor. The correct inhibitor to use is determined by whether the system is a pumping oil well, as gas-lift well, a gas well, a waterflood system, or a flow line. For example, a weighted inhibitor is seldom recommended in dry gas wells, because water is required to release the inhibitor before it becomes effective (Ref 41). Also, when a gas-lift well is treated, the inhibitor is injected into the gas-lift lines. Therefore, the inhibitor must not have any tendency to form gunky deposits.

Both temperature and pressure have an influence on inhibitor selection. Bottom hole temperatures and pressures may get so high that inhibitors polymerize and form a sludge. Pressure influences the corrosivity of CO_2 and H_2S.

Velocity is yet another factor to consider. With pipelines, low velocity might be insufficient to displace water from low areas in the line. In the case of dry gas pipelines with low velocity, a water-soluble inhibitor should be selected and should be injected continuously. If the velocity is high enough to prevent any accumulations of water in low areas of a dry gas line, then an oil-soluble inhibitor should be batch treated.

The composition of the produced water also determines the choice of inhibitor. Criteria such as water/oil ratio, salinity of water, and acidity of the water and oil are vital to the correct selection of the inhibitor.

Tests are conducted in the laboratory using the standard wheel test. Although not infallible, this test attempts to duplicate field conditions as closely as possible. Parameters such as temperature, water-cut, batch or continuous treatment, and whether the system is sweet or sour are reproduced as closely as possible to field conditions. Usually, these tests involve weight loss coupons.

The rate at which an inhibitor forms a film is completely dependent on the product and its environment. However, it can generally be said that film formation is a function of time and is not instantaneous. The concentration of inhibitor required to develop an adequate film is also directly related to the characteristics of the product and system. Many factors affect the dosage and frequency of treatment, including the following:

- Severity of corrosion
- Total amount of fluid produced
- Percentage of water
- Nature of corrodent
- Chemical selected
- Fluid level in the casing annulus

Because no laboratory test can take into account all of the conditions imposed by the oil well, the dosage and frequency of treatment must be constantly reviewed.

There are two general rules to follow for dosages. First, for continuous injection, a dosage of 10 to 20 ppm based on total produced fluid is used as a starting point. Second, for batch treatment, weekly batch frequency is used with a starting dosage of 3.8 L (1 gal) per week for each 100 barrels of daily fluid production.

Also, if the corrosivity of the system is known, the following general criteria can be used to define more accurately a treatment rate for continuous injection (Ref 42):

Mild corrosion	**10-15 ppm**
Moderate corrosion	15-25 ppm
Severe corrosion	>25 ppm

Several major problems can occur with inhibitors, including foaming, emulsions, scale removal and plugging, and safety and handling. Corrosion of other metals can also be a problem.

The most appropriate action to take in avoiding difficulty from foaming is to determine where foam-forming conditions exist in the system. These will consist of places where the inhibitor-containing fluid is agitated with a gas, such as in a gas separator, a countercurrent stripper, or an aerator. The next step is to obtain a sample of the fluid and gas from the process step, add the inhibitor in question, adjust the temperature to that corresponding to the process step, and shake vigorously. If this test produces a stable foam, a potential problem exists.

There are three alternative remedies. First, an antifoaming agent can be added (this must be tested also); second, tests can be conducted to select an inhibitor that does not cause foaming; and third, the system can be shut down periodically and

treated with a slug of persistent inhibitor. The last two remedies are the least palatable because the need for an inhibitor is at hand and there are few processes that can be shut down with sufficient frequency to maintain effective inhibition by slug treatment.

Emulsions are another problem that can occur when the wrong inhibitor is used. The use of other chemicals, heat, or both can usually break these emulsions. A great variety of chemicals are used for this purpose, but no one material has proved effective for all emulsions.

A system can be plugged as the result of an inhibitor loosening scale and suspending it in the fluid. This problem is best avoided by planning. The best preventive measure is to clean the system thoroughly, if possible, before inhibitor is applied. An alternative or supplementary method in systems that are very sensitive to suspended solids is to protect the sensitive parts with temporary filters.

As with most industrial chemicals handled in large volume on a regular basis, oil field corrosion inhibitors should be treated with respect from a safety standpoint. Although these products are not generally highly toxic (many acid corrosion inhibitor formulations are toxic), they can produce reactions because of the amines and aromatic solvents present. Reactions usually consist of skin burns from contact and dizziness from inhalation of the vapors. Repeated contact with amines will cause the development of sensitization to these products in some individuals. To avoid these problems, any contacted body areas should be washed, and contaminated clothing should be changed as soon as possible. Any accumulation of vapors should be eliminated from confined spaces.

Another possible adverse effect of inhibition is an increased rate of corrosion of a metal in the system other than the one for which the inhibitor was selected to protect. For example, some amines protect steel admirably, but will severely attack copper and brass. Nitrites may attack lead and lead alloys, such as solder. In some cases, the inhibitor may react in the system to produce a harmful product. An illustration of this is the reduction of nitrate inhibitors to form ammonia, which causes SCC of copper and brass. The only way to avoid these problems is to know the metallic components of a system and to be thoroughly familiar with the properties of the inhibitor to be used.

Application of Inhibitors

Choosing the proper inhibitor for treating a corrosion problem in the oil field is important; however, it is equally important to select the correct treating method. The best inhibitor available will not successfully control corrosion if it does not reach the trouble area. To be effective and economical, a corrosion inhibitor:

- Must be present at an initial concentration sufficient to promote complete coverage of all steel surfaces
- Must be replenished as necessary to repair washed-away portions of the protective inhibitor film

Batch treatments (Fig. 11) are commonly used in producing wells and, in some cases, in gas lines and crude flow lines. Inhibitor can be batched down the tubing-casing annulus, through the tubing, or between pigs (in the case of a pipeline). The various types of batch treatment are:

- Standard batch
- Extended batch
- Annular slug
- Tubing displacement
- Between pigs batch

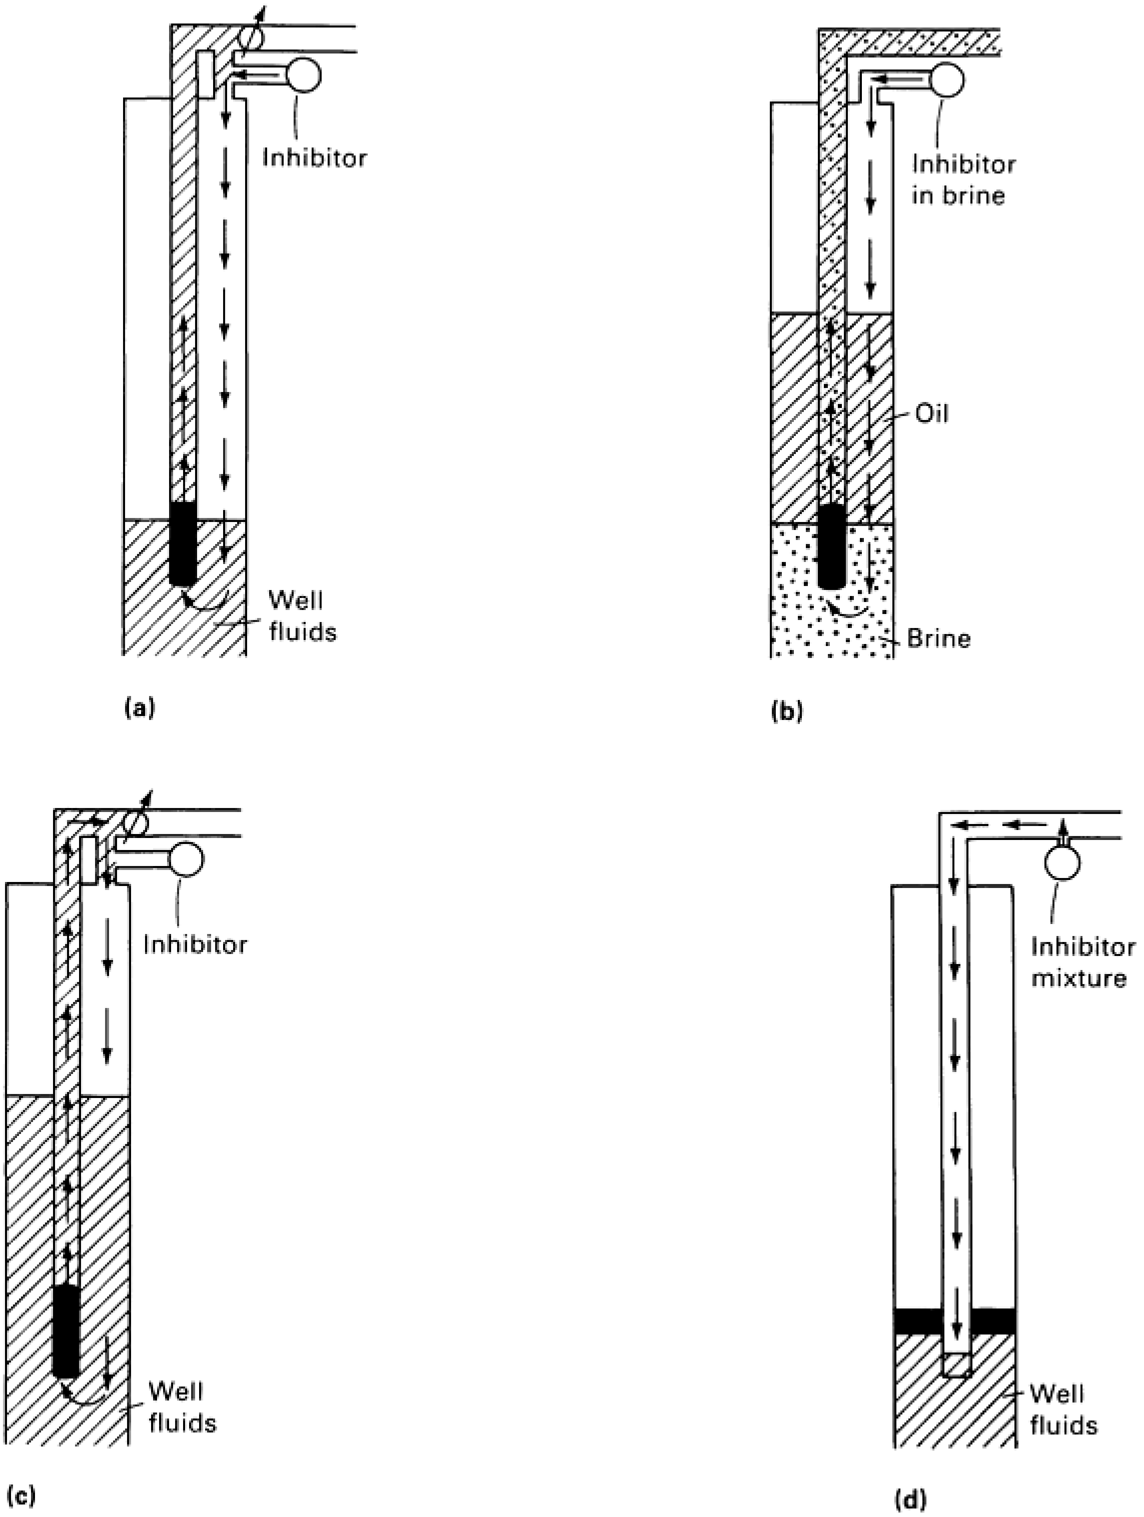

Fig. 11 Four types of batch inhibitor treating techniques. (a) Standard batch. (b) Annular slug. (c) Extended batch. (d) Tubing displacement

Standard Batch. This method is used for producing wells that are not equipped with packers. The inhibitor is put into the annulus, and the well is placed on circulation to distribute the inhibitor throughout the system. Normally, the longer the well is circulated, the better the inhibitor film. The application of this treatment in low fluid level wells depends on the fluid level maintained in the annulus. The method would not be recommended in wells that pump off. It would be estimated that a fluid level of at least 46 m (150 ft) should be maintained. In placing the treatment in operation in these

wells, it would be recommended that the initial treatment be immediately displaced into the tubing and that a second batch of inhibitor be placed in the annulus.

Extended Batch. This method is a variation of the standard batch treatment, but in this case, the inhibitor is left in the annulus. As the annular fluid level fluctuates, small amounts of inhibitor are carried in the oil into the tubing, thus giving the well periodic treatments weeks or months after the actual treatment. This type of treatment has lasted up to 6 months in some wells of Oklahoma (Ref 43). It must be remembered that this technique depends on a substantial fluid level in the annulus because the inhibitor is inventoried in the oil of the annular space.

Annular Slug. There is one technique for batch treating pumping wells that allows the well to continue full production while being treated. A water-dispersible or water-soluble inhibitor is mixed with water and placed in the annulus. This mixture will fall through the oil phase in the annulus. This technique will work if there is little or no water level in the annulus, but probably will not work if there is a substantial water level in the annulus. Frequency of treatment ranges from twice weekly to monthly.

Tubing Displacement. Wells that are set on packers or gas-lift wells are frequently treated by tubing displacement. The inhibitor is either dispersed or put in solution in water or hydrocarbon. The water may be fresh or produced. The hydrocarbon may be produced, or it may be a refined product, such as kerosene or diesel. The inhibitor is usually used at about 10% concentration in the water or hydrocarbon. The desired amount of this mixture is then introduced into the tubing. If the well is a dry gas well, the mixture will fall to the bottom if sufficient shut-in time is given (from several hours to overnight, depending on the depth of the well). If the tubing contains liquids, the mixture must be displaced to the bottom of the well by pumping liquid (usually produced fluids) in behind the mixture. The amount of displacing liquid is calculated by determining the volume of the tubing and subtracting the volume of inhibitor mixture. After the inhibitor has been displaced to the bottom, the well is usually shut in for 2 to 24 h. The well is then put into normal operation in the usual manner.

The tubing displacement technique is also known as a kiss squeeze. This type of treatment will last from a week to several months, depending on the system and the inhibitor, and is normally used on flowing oil wells.

Between Pigs Batch. This method is used to control corrosion in gas pipelines and is only used by itself in moderately corrosive systems. The volume of inhibitor mixture needed to give a 3-mil-thick coating can be calculated from an equation that takes into account the pipe diameter and length (Ref 44, 45).

Continuous treatment is used on producing wells, injection wells, pipelines, and flow lines. Continuous treatment simply involves introducing inhibitor on a continuous basis so that its concentration in the corrosive fluids is maintained at a level sufficient to prevent or reduce corrosion. This concentration may vary from a few parts per million to 50 ppm or more, depending on the severity of attack. There are many ways to continuously treat producing wells:

- Introduce inhibitor into the line that bypasses part of production into the annulus
- Inject inhibitor into the power oil of a subsurface hydraulic pump
- Inject inhibitor into a small string of tubing that is run downhole (small-bore treating string)

Squeeze Treatment. This is a combination batch-continuous method in which the inhibitor solution is placed into the formation. The inhibitor and diluent are displaced down the tubing and into formation by 25 to 75 drums of displacing fluid, which is usually clean crude, diesel fuel, or nitrogen. When the well is returned to production after a squeeze, the initial concentration of chemicals in the returned fluid is high and decreases very rapidly. The inhibitor continuously returns from the formation to repair any breaks in the inhibitor film. The second squeeze and successive treatments all give a longer treatment life than the first squeeze. Possibly, a portion of the chemical used in the first squeeze is trapped in the formation and cannot return to the well bore. This action is shown in Fig. 12. The advantages of squeeze treatment include:

- Can be used in tubingless or multiple completion wells
- Treating frequency is reduced and ranges from 6 to 18 months, depending on the inhibitor, the formation, placement technique, and the fluids being produced

The disadvantages of squeeze treatment are as follows:

- High cost
- Possible clay swelling
- Emulsion blocks that restrict production
- Injection pressure must be kept below the pressure necessary to fracture the formation

This method is used on gas-lift wells having a high-pressure, a high gas-oil ratio, and a high rate of water production. More information on the use of inhibitors in the oil patch is available in the article "Corrosion Inhibitors for Oil and Gas Production" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook.*

Corrosion in Petroleum Production Operations

Chairman: James E. Donham, Consultant

Nonmetallic Materials

In recent years, there has been an increased use of nonmetallic materials in oil field operations. These materials are being used because they do not corrode in the environments in which steel readily corrodes. They are also lightweight, suitable for rapid installation, and, in most cases, less expensive than steel. In a 1982 American Gas Association survey of 56 gas utility companies, it was found that nonmetallic pipe systems failed at only 13.2% the rate of metallic pipe systems when excavation damage is excluded (Ref 46).

Types of Nonmetallic Pipe Materials

Nonmetallic pipe can be classified into three major categories: thermoplastic materials, fiber-reinforced materials, and cement-asbestos.

Thermoplastic materials can be repeatedly heated, softened, and reshaped without destruction. The most commonly used themoplastic pipe materials are (Ref 34):

- Polyvinyl chloride (PVC)
- Chlorinated polyvinyl chloride (CPVC)
- Polyethylene (PE)
- Polyacetal (PA)
- Acrylonitrile-butadiene-styrene (ABS)
- Cellulose acetate butyrate (CAB)

Glass fiber reinforced thermoset materials are chemically set and cannot be softened or reshaped by the application of heat. There are two major classes of these materials in oil field use:

- Fiberglass-reinforced epoxy (FRE)
- Fiberglass-reinforced polyester (FRP)

Cement-asbestos is the oldest nonmetallic material in use in the oil field. It is a combination of portland cement, asbestos fibers, and silica. It can be obtained with an epoxy lining, but most of this pipe currently in use is unlined (Ref 47).

Joining Methods

The methods used to join various types of nonmetallic pipe are shown in Table 2. The heat welding method uses a heating element to soften the ends of the joints, which are then pushed together and held until the joint cools. About 25% of all thermoplastic pipe joints are made by this method (Ref 34). Solvent welding can be used on some of the thermoplastic pipe materials and on both of the thermosetting materials. This method uses both a solvent and a glue to hold the joints together. Finally, threads can be used on all nonmetallic pipe materials.

Table 2 Joining methods for nonmetallic pipe materials

Material	Joining method		
	Heat	**Solvent**	**Thread**
Thermoplastic materials			
Polyvinyl chloride	. . .	X	X
Chlorinated PVC	. . .	X	X
Polyethylene	X	. . .	X
Polypropylene	X	. . .	X
Polyacetal	X	. . .	X
Acrylonitrile-butadienestyrene	X	X	X
Cellulose acetate butyrate	X	X	X
Thermosetting materials			
Glass-reinforced epoxy	. . .	X	X
Glass-reinforced polyester	. . .	X	X
Cement asbestos	(Rubber ring seal)		X

Source: Ref 34

Advantages and Disadvantages

The advantages of nonmetallic materials include the following (Ref 34):

- They are generally immune to corrosion in aqueous systems
- They are lightweight and are therefore easier to handle
- Nonmetallic pipe is quickly joined and installed
- No external protection, such as coatings or cathodic protection, is required
- The smooth internal surface of nonmetallic pipe results in lower fluid friction loss

Among the disadvantages of nonmetallic materials are (Ref 34):

- Nonmetallic pipe has a more limited working temperature and pressure. These limits are also more difficult to predict with assurance than the limits of steel pipe
- Careful handling is required in loading, unloading, and installation
- Nonmetallic pipe should be buried to protect it from sunlight, mechanical damage, freezing, and fire
- Nonmetallic pipe has very low resistance to vibration and pressure surges

Typical Applications

Thermoplastics have seen use in flow lines, gathering lines, saltwater disposal lines, liners for steel pipe in high-pressure operations, and fuel lines for gas engines. Polyvinyl chloride has a maximum temperature limit of 65 °C (150 °F) and a maximum operating hoop stress of 27.5 MPa (4000 psi). Polyethylene has a maximum operating temperature of 40 °C (100 °F) and a maximum operating hoop stress of 4.3 MPa (625 psi) (Ref 30).

Glass fiber reinforced thermoset materials have also seen use in flow lines, gathering lines, saltwater disposal lines, liners for steel pipe in high-pressure operations, and fuel lines for gas engines. They have also been used for tubing in disposal and injection wells. Neither FRE nor FRP should be used for a well production flow line or gas gathering system at pressures above 2.1 MPa (300 psi) and temperatures of 65 °C (150 °F). These materials should not be used in vacuum systems or where repetitive vacuum surges are likely to occur and in lines handling sandladen fluid.

In addition, FRP has been used for stock tanks and barrels ranging in size from small chemical tanks of 1890 L (500 gallons) or less to 500 barrels or larger. Even sucker rods have had their bodies made of FRP.

Cement-asbestos materials have been used in low-pressure saltwater disposal lines. They have a maximum temperature rating of 95 °C (200 °F).

Environmental Control

Oxygen dissolved in oil field water is one of the primary causes of corrosion. Dissolved oxygen is needed at 25 °C (75 °F) for an appreciable corrosion rate in neutral waters, while even in high-salinity brines at 150 °C (300 °F), the corrosion rate is low once the oxygen is removed (Ref 32). This type of corrosion is usually a localized form of attack, such as pitting, rather than a uniform attack. Oxygen also causes the growth of aerobic bacteria, algae, and slime, which can create plugging and enhance pitting. Also, mixing an oxygen-containing water with oil field waters containing dissolved iron or hydrogen sulfide can cause precipitation of iron oxides, iron hydroxides, or free sulfur, thus causing serious plugging problems. In one case, some injection wells of a waterflood in west Texas were filled with as much as 23 m (75 ft) of iron hydroxides after a few months of service (Ref 48). Even if there are other corrosive agents present, air-free operation is needed in order for film-forming corrosion inhibitors to work (Ref 49); the presence of dissolved oxygen will significantly reduce the effectiveness of corrosion inhibitors.

Both mechanical and chemical means have been used to remove dissolved oxygen from oil field waters. The mechanical means are counter-current gas stripping and vacuum deaeration, while the chemical means include sodium sulfite, ammonium bisulfite, and sulfur dioxide. The choice of oxygen removal method depends on economics. Usually, the mechanical means are used when large quantities of oxygen are to be removed. Chemical removal is usually employed to remove small quantities of oxygen and even sometimes for the removal of residual oxygen after the mechanical means have been used.

Mechanical Methods

Gas stripping is performed in either a packed column or a perforated tray column. Perforated tray columns are preferred because they are not as easily fouled with suspended solids or bacterial slime as packed columns. Figure 13 illustrates a tray-type gas stripping column. Oxygenated water flows into the top of the column, while the stripping gas flows through the bottom inlet. As the gas bubbles up through the water, oxygen comes out of solution. The trays or packing in the column increases the contact area. These systems are designed to use not more than 0.06 m^3 (2 ft^3) of gas per barrel of water being stripped (Ref 30). The gas source should be free of both oxygen and H_2S. Either natural gas or exhaust gas from engines is commonly used. The principle of removal is to reduce the concentration of oxygen in the gas coming in with the water by dilution with the stripping gas.

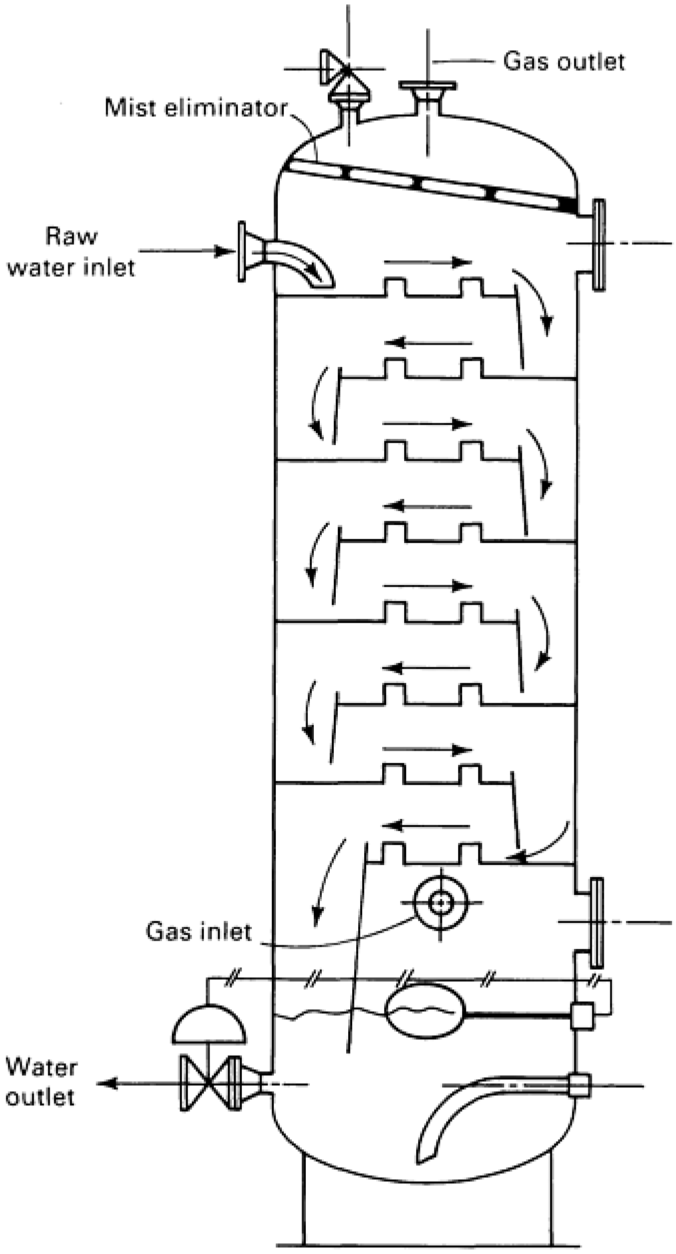

Fig. 13 Tray-type countercurrent gas stripping column. Source: Ref 33

In vacuum deaeration, a vacuum is created in a packed tower, and as the oxygenated water is passed over the packing, the low pressure causes the oxygen to bubble of solution. The vacuum pump pulls the oxygen, water vapor, and other gases from the top of the tower. The tower usually consists of several different pressure stages, as shown in Fig. 14. In a packed column, each stage consists of a height of packing, which is sealed from the stage below by a layer of water

in the bottom of the packing (Ref 33). A single-stage tower will economically remove oxygen only to a lower limit of 0.1 ppm because of the excessive vacuum pump horsepower required to achieve lower concentrations. Therefore, multi-stage columns are needed. Dissolved oxygen concentrations as low as 0.01 ppm have been achieved in three-stage towers (Ref 33).

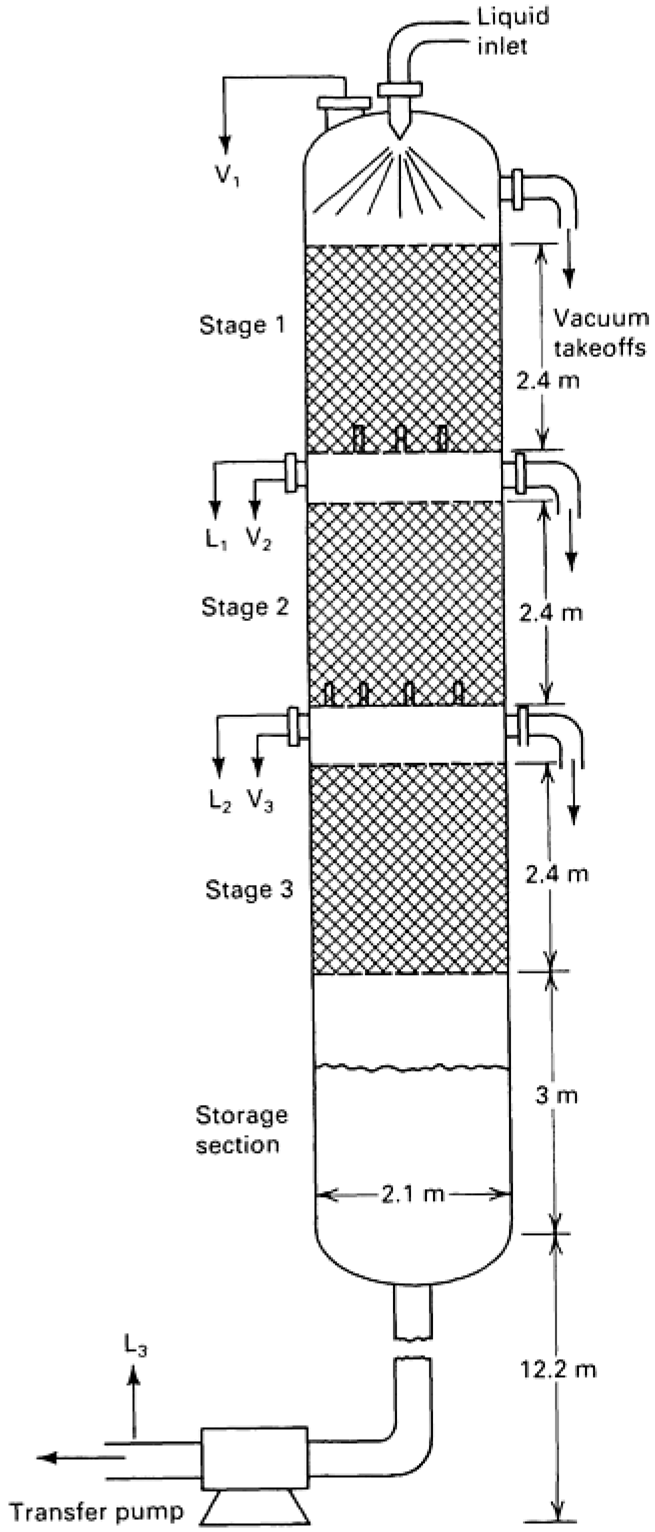

Fig. 14 Three-stage vacuum deaerator tower. L_1, L_2, L_3 and V_1, V_2, V_3 are liquid and vapor sample points, respectively. Pressure decreases as the liquid moves down the tower. Source: Ref 33

Combination Vacuum Deaeration and Gas Stripping. Vacuum deaeration with the use of 0.003 m^3 (0.1 ft^3) of natural gas has been used to reduce the oxygen content of water from 5 to 0.05 ppm or less in a 40,000 barrel per day waterflood in west Texas. Single-stage vacuum deaeration reduced the oxygen content of the water to 0.17 ppm, while the gas stripping further reduced the oxygen content to 0.05 ppm. Corrosion rates in the water were reduced from 0.36 to 0.04 mm/yr (14 to 1.6 mils/yr) (Ref 50).

Chemical Methods

Sodium sulfite is used to scavenge oxygen from water and is available as a liquid or as a powder. It reacts with oxygen according to Eq 4:

$$2Na_2SO_3 + O_2 \rightarrow 2Na_2SO_4 \qquad \textbf{(Eq 4)}$$

Approximately 8 ppm of Na_2SO_3 is required to react with 1 ppm O_2. A 10% excess is usually required for complete reaction, and a catalyst such as cobalt chloride (0.1 ppm) is needed to scavenge to acceptable levels within a few minutes. Because Na_2SO_3 solutions will react with atmospheric oxygen, an inert gas blanket is required on the storage tank.

Ammonium bisulfite is a liquid scavenger and reacts with oxygen according to Eq 5:

$$2NH_4HSO_3 + O_2 \rightarrow (NH_4)_2SO_4 + H_2SO_4 \qquad \textbf{(Eq 5)}$$

An 80% solution of NH_4HSO_3 requires a 10:1 ratio by weight for the reaction. A 10% excess is needed to complete the reaction. Ammonium bisulfite does not react with air and can be stored in open containers. A catalyst is not usually needed for oil field brines. Because the chemical is supplied as a solution with a pH of 4 to 4.5, it must be stored in a corrosion-resistant vessel. Type 304 stainless steel is commonly used (Ref 33).

Sulfur dioxide is a chemical scavenger that can be either supplied as a liquified gas under pressure in a cylinder or generated by burning sulfur. The reaction between sulfur dioxide and oxygen proceeds according to Eq 6:

$$SO_2 + H_2O + \frac{1}{2}O_2 \rightarrow H_2SO_4 \qquad \textbf{(Eq 6)}$$

A quantity of 4 ppm by weight of SO_2 is required to remove 1 ppm of oxygen. A 10% excess and a catalyst such as cobalt chloride are needed to complete the reaction. Sulfur dioxide from cylinders is applied by using a bypass line that handles approximately 10% of the total fluids, as shown in Fig. 15. The scavenger is added to the bypass fluids. The materials used in this bypass line should be resistant to acid attack because of the low pH formed from the reaction. Use of SO_2 cylinders is most advantageous in small systems (less than 10,000 barrels per day) or where small concentrations of dissolved oxygen are encountered in larger systems (Ref 52).

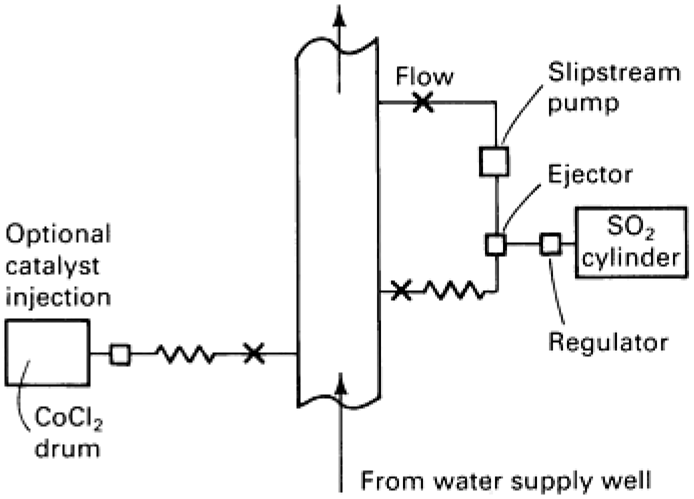

Fig. 15 Application of SO_2 through the use of a bypass line. Source: Ref 5

When larger volumes of water are to be treated, it may be more economical to produce SO_2 gas by burning sulfur. This gas is then dissolved in a sidestream of the water to be treated, pumped through the packed column, and then back into the main line.

Precautions

Some precautions involving oxygen scavengers should be noted (Ref 33):

- Oxygen scavengers will react with chlorine and hypochlorite (ClO^-), which are added to injection water for bacterial control. Therefore, these chemicals should be added downstream of the point of scavenger injection to allow completion of the scavenger-oxygen reaction
- Any organic chemicals, such as biocides, scale inhibitors, and corrosion inhibitors, can possibly interfere with the scavenger-oxygen reaction and should be selected with care
- Oxygen scavengers cannot normally be used in sour systems. If H_2S is present, it may react with the cobalt chloride catalyst to form insoluble sulfides (Ref 33)

Oxygen Exclusion

It is usually more economical to exclude oxygen from oil field equipment than to remove it after it has entered the system. The most common means of excluding oxygen is through the use of gas blankets on water supply wells and water storage tanks. Maintenance of valve stems and pump packing is also important.

All tanks handling air-free water should be blanketed with an oxygen-free gas such as natural gas or nitrogen. Most tanks require only a few ounces of pressure (Ref 49). The regulator should be sized to supply gas at a rate adequate to maintain pressure when the fluid level drops.

Oil blankets should not be used in place of gas blankets. Oxygen may be 5 to 25 times as soluble in hydrocarbons as in oil field waters (Ref 49). Oil blankets will coat precipitates in the water, which can lead to well plugging problems. Some bacteria will even thrive at the oil/water interface (Ref 33).

Even supply wells and producing wells may need to be gas blanketed to prevent oxygen entry. If these wells are operated cyclically without gas blankets, oxygenated air will be drawn into the annulus every time the well is turned on and the fluid level drops.

Oxygen can also enter a pump on its suction side if a net positive suction head is not maintained. If the seals start to leak, air can then be sucked into the pump (Ref 49).

Problems Encountered and Protective Measures**

H.E. Bush, Consultant; James E. Donham, Consultant; John D. Alkire, Amoco Corporation; S. Ibarra and T.M. Stastny, Amoco Corporation; M.C. Place, Jr., Shell Oil Company

The problems encountered and protective measures to be discussed in this section are based on the state-of-the-art as practiced daily by corrosion and petroleum engineers and production personnel. These are by no means all of the methods employed for corrosion protection, but they represent the most commonly used processes.

Drilling Fluid Corrosion

Due to the nature of drilling conditions, corrosion is a problem in water-base drilling fluids. Important considerations are the causes of corrosion and the rate and forms of corrosion attack.

Causes of Corrosion

The major environmental causes of corrosion in drilling fluids are oxygen, carbon dioxide, hydrogen sulfide, ionic concentration, and low pH. Physical conditions causing corrosion include metal composition, metal properties, string design, stress, and temperature. Combined physicochemical corrosion accelerators include stress corrosion and erosion-corrosion. Microorganisms also introduce biological causes of corrosion in drilling environments.

Combined Effects. The forms of corrosion attack will provide characteristic patterns that can be identified and used in selecting preventive methods (Ref 53). The major forms of attack are crevice corrosion under deposits, corrosion fatigue, and SCC. Erosion-corrosion, uniform attack, and galvanic corrosion are also common problems. More than one form of attack can occur, and one form can transform into a second form. For example, a pit can deepen and increase stress, initiating stress corrosion or fatigue (Table 3).

Table 3 Drilling fluid corrosion control trouble shooting chart

Corrosion cause	Primary source	Identification	Major corrosion forms	Remedies
Oxygen	Atmosphere, mud conditioning, equipment, oxidizing agents, air drilling	Oxygen test, iron oxide by-products	Underdeposit corrosion, pitting	Avoid mechanical air entrapment in mud pits or defoamers; use oxygen scavengers for normal drilling; use passivating agents for air drilling operations.
Hydrogen sulfide	Formation, bacteria, chemical or thermal degradation	H_2S analysis, iron sulfide test	Underdeposit corrosion, uniform corrosion, sulfide stress cracking	Control pH $\geqq$9.5; use sulfide scavengers or filming inhibitors, reduce stress; change to oil mud in severe H_2S environments.
Carbon dioxide	Formation, bacteria, chemical or thermal degradation	CO_2 analysis, iron carbonate by-products	Underdeposit corrosion, pitting	Control pH $\geqq$9.5; use calcium hydroxide to combine with and precipitate CO_2 products; use filming inhibitors.

Dissolved salts	Formation, chemical additives	Water analysis	Underdeposit corrosion, uniform corrosion, chloride SCC	Control pH $\geqq$9.5; remove oxygen, H_2S, and/or CO_2; use filming inhibitors.
Bacteria	Makeup water, formation	Culture tests for sulfate-reducing bacteria and/or slime forms	Underdeposit corrosion, sulfide stress cracking	Control pH $\geqq$9.5; add biocides.
Temperature	Formation heat, friction	Test	Sulfide stress cracking, pitting	Select temperature-stable chemicals; use friction/torque reducers; cool mud; use oil mud.
Abrasion (erosion-corrosion)	Formation, directional or deviated hole	Observation	Erosion-corrosion	Use lubricants, torque reducers, and filming inhibitors; Control solids; use oil muds.
Metal composition				
Carbon steels, HRC $\leqq$ 22	. . .	. . .	Underdeposit corrosion, uniform corrosion, pitting	Control pH $\geqq$9.5; control oxygen, H_2S, and CO_2; limit stress.
Carbon steels, HRC > 22	. . .	. . .	Underdeposit corrosion, sulfide stress cracking, pitting	Control H_2S to very low levels.
Stainless alloys	. . .	. . .	Chloride SCC	Limit salts and temperature exposure; control deposits.
Aluminum alloys	. . .	. . .	Underdeposit corrosion, galvanic corrosion, pitting	Limit pH to 9.5-10.5; use passivation.

Failure Analysis

Analysis of used and failed equipment can provide a means of developing corrosion prevention methods. Identification of corrosion products (Ref 54) and corrosion forms (Ref 17, 55) can be developed into cause-effect mechanisms.

Monitoring

Drill pipe corrosion coupons are used to measure the rate, form, and cause of corrosion (Ref 56). Corrosion rates of 2.4 to 9.8 kg/m^2/yr (0.5 to 2 lb/ft^2/yr) free of pitting is an acceptable range. The lower rate should be used for deviated holes, deep drilling, and/or high-stress conditions. Special monitoring using linear polarization (Ref 57) or galvanic probes (Ref 58) will provide instant detection of corrosion and changes in rates that can be related to system conditions on a real time basis.

On-site chemical and physical analyses of drilling fluid properties are conducted on a frequent basis (Ref 56). Test procedures should include oxygen, CO_2, H_2S, and bacterial analysis for comprehensive monitoring of corrosion problems. The *Drilling Manual*, published by the International Association of Drilling Contractors, presents equipment inspection methods as well as information on the care, handling, and specifications of tool joints, drill pipe, casing, and tubing. Reference is made to this manual to provide comprehensive information on drilling and production equipment.

Oxygen Corrosion Control

Oxygen causes crevice corrosion under deposits and is considered to be the most serious corrosion accelerator in drilling environments. Oxygen enters the drilling fluid system externally from the atmosphere, usually by way of solids control and mud mixing equipment (Ref 59). The operation of this equipment to reduce air entrapment into the circulating system is an effective technique for limiting oxygen levels. Foaming problems are characteristic of some mud systems and can result in high oxygen levels on the high-pressure side of the pump. Defoaming the fluid or maintaining properties to release gas quickly is required to overcome this problem.

Oxygen scavengers, such as sodium sulfite or ammonium bisulfite, are used to remove oxygen from drilling fluid (see the discussion "Environmental Control" in this article). Treatment methods involve a continuous addition of chemical at the rate of 10 mg/L sulfite ion for each 1 mg/L of oxygen present in the fluid. A residual sulfite concentration of approximately 100 mg/L is maintained in the drilling fluid as a functional means of controlling oxygen in drilling systems. Oxygen scavenger catalysts are frequently required to overcome interfering side reactions that prevent the oxygen-sulfite reaction. Calcium in the fluid can combine with sodium sulfite and form calcium sulfite precipitate, thus

preventing the sulfite ion from scavenging oxygen. Aldehydes and chlorine dioxide used as biocides in drilling fluids react with sulfite ions and may prevent oxygen removal. The addition of cobalt or nickel catalysts overcomes many of these problems by increasing oxygen-sulfite reaction rates.

Passivating compounds, such as sodium chromate or nitrite, are used to protect equipment during air, mist, or foam drilling operations. Treatment levels range from approximately 500 to 2000 mg/L of chromate or nitrite ion in fresh to slightly brackish fluid. Higher concentrations are required in high-brine solutions, and sodium nitrite is not recommended above approximately 25,000 mg/L of chloride ion concentration. A noteworthy disadvantage of using passivating agents is the tendency toward accelerated pitting attack if treatment levels are too low or if deposits exist under which the metal cannot be passivated. Zinc compounds are often combined with passivating agents to reduce pitting tendencies. Treatments for controlling deposits are recommended to mitigate under-deposit attack and are covered in the discussion "Scale and Deposit Control" in this section. Chromate or nitrite compounds are not compatible with sulfite-type oxygen scavengers.

Care should be exercised in the use and disposal of chromate compounds. These materials are classified as carcinogens, and personnel safety should be ensured. Injection of drilling fluid within deep formations has been used to dispose of excess or waste fluid.

A clear advantage is gained in the use of sodium chromate or nitrite chemicals when hydrogen sulfide is encountered in the well. These compounds oxidize and remove H_2S (see the discussion "Hydrogen Sulfide Corrosion Control" in this Section).

Atmospheric corrosion occurs on drilling equipment in urban, polluted, tropical, and marine environments. Protective coatings are commonly applied at the steel mill or storage yard and periodically between drilling operations. Many coating compositions are commercially available for both short-and long-term storage (2 or 3 years). The filming inhibitors that are typically used during drilling often provide good atmospheric protection for short periods between jobs. For long-term exposure, careful surface cleaning and selected atmospheric coating are recommended.

Hydrogen Sulfide Corrosion Control

Hydrogen sulfide causes two forms of corrosion surface attack--under-deposit (crevice) corrosion and sulfide stress cracking. Corrosion control methods include selecting resistant materials, removing the H_2S from the fluid, and reducing stress. Hydrogen sulfide enters the drilling fluid primarily from the formation, but it can also come from thermally degraded mud products, sulfate-reducing bacteria, and makeup water.

Alkaline pH control and sulfide scavengers are used to neutralize, precipitate, and/or oxidize H_2S. Film-forming amine-type inhibitors are recommended for coating the drill string. Caustic soda or calcium hydroxide treatments are used to neutralize the acid gas. Alkaline pH above 9.5 results in the production of sodium bisulfide or sodium sulfide products that are almost totally water soluble. This treatment provides both personnel safety and corrosion protection.

Compounds of iron oxide (Fe_3O_4), zinc carbonate, zinc oxide, and zinc chelates are used to precipitate sulfide ions from solution. Pretreatments of approximately 1 kg/barrel (2 lb/barrel) of one of the scavengers are commonly recommended as a precaution against a small influx of H_2S entering the mud system and causing damage. Tests are used to monitor scavenger concentrations and treatment requirements. Sodium chromate, zinc chromate, or sodium nitrite compounds are used to oxidize H_2S to sulfate or elemental sulfur. The oxidizing process is a fast and efficient method of removing H_2S from the system. There is no compatibility problem with the sulfide scavengers listed above. Formaldehyde and chlorine dioxide are compounds that are frequently used as drilling fluid biocides. These products react with hydrogen sulfide, offsetting its corrosive action; however, their biocidal properties are diminished or eliminated in the process.

Filming amine inhibitors provide protection from hydrogen sulfide surface attack and hydrogen embrittlement. Oil-soluble filming inhibitors applied directly on the drill pipe are recommended to offset corrosion fatigue and hydrogen embrittlement. Care should be taken with cationic filming inhibitors, which can damage mud properties by flocculating the anionic clays in drilling systems. Oil muds provide the most effective protection against all corrosion causes, including H_2S. The oil phase provides a nonconductive film covering exposed equipment and thus preventing the corrosion process.

Stress reduction by mechanical changes, such as rotary speed and less weight on the bit, is effective in reducing sulfide-induced embrittlement failures. Torque-reducing agents, particularly in high-angle drilling, are effective in lowering stress.

Material selection for drill pipe and casing can have a significant effect in controlling sulfide stress cracking. The brittle failures related to H_2S are linked to the hardness and yield strength of the steel. Steels with hardness levels below 22 HRC or with maximum yield strengths of 620 MPa (90 ksi) have few sulfide stress cracking problems. Cold work, such as tong or slip marks, increases the hardness of steel, and sulfide stress cracking then becomes a problem. The service stresses in drilling frequently demand materials of great strength, requiring hardness and strength levels that are susceptible to sulfide stress cracking. Because of such requirements, the primary means of avoiding sulfide stress cracking is by control of the drilling fluid. A full discussion of the metals used in sulfide environments is provided in NACE MR-01-75.

Higher temperatures (above 80 °C, or 175 °F) reduce sulfide stress cracking failures on high-strength steel. This factor can become advantageous in drilling and production operations if properly controlled. For example, an influx of H_2S while drilling may not cause damage if the fluid temperature is above 80 °C (175 °F) in the hole. If H_2S is detected, scavenging should always be completed before operations are begun that would lower the metal temperature, such as pulling the drill pipe from the hole.

Carbon Dioxide Corrosion Control

Carbon dioxide causes pitting primarily by under-deposit corrosion cell action. Corrosion control methods involve controlling the pH in the higher alkaline ranges. An effective technique is to treat the mud with calcium hydroxide to neutralize this acid-forming gas and to precipitate carbonates, thus lowering CO_2 levels. Film-forming inhibitors of the oil-soluble amine type applied by spraying the outside of the drill pipe and batch treatments for inside diameter filming are recommended to penetrate pits and deposits, stopping their corrosion action. Control of CO_2 is quite similar to H_2S corrosion control, and these two gases often enter the mud from the formation together.

Scale and Deposit Control

Mineral scale, corrosion by-products, and mud that form deposits on exposed metal are a major factor in setting up conditions that result in under-deposit pitting attack. The prevention and removal of these deposits with scale inhibitors is quite effective in offsetting this most serious drilling fluid corrosion problem. Inhibitors such as organic phosphonate, phosphate esters, and others of the acrylic, acrylamide, or maleic acid base structures have been effective. Products that exhibit threshold effect, temperature stability, and strong surface-active characteristics are useful. Treatments are variable because of environmental conditions, which differ greatly in drilling fluid compositions. As general rules apply, treatments of 15 to 75 mg/L are used on a daily basis for most mineral scale control. Treatments above this level are used to control deposits of metal corrosion by-products. Considerably higher treatment levels, up to 1000 mg/L, are used to provide corrosion protection. Care should be exercised in using the higher treatment levels, because these compounds may alter mud properties because of their dispersing characteristics.

Primary Production

There are two main types of producing oil wells: artificial lift wells and flowing wells. Artificial lift wells can be further divided according to the method used to pump the hydrocarbon to the surface. These include rod-pumped wells, wells that use downhole hydraulic pumps, and gas-lift wells. Approximately 90% of the artificial lift wells in the United States are rod pumped.

Artificial Lift Wells

Rod-pumped wells. In a rod-pumped well, the potential for corrosion damage is aggravated by the sucker rods alternately being stretched and compressed and by the abrasion of the rod couplings on the inside of the tubing. It is common for a well to have continuing sucker rod failures. Pulling and replacing the rods is a quick fix, but the problem will continue to exist until the root cause of the failure is identified and corrected. Identifying the problem is the most important step, because corrective action cannot be taken if the cause is not clear. Rod breaks should be inspected immediately after the rod string is pulled to determine if corrosion is occurring and to determine the steps that can be taken immediately to prevent a recurrence.

Corrosion in rod-pumped wells can be caused by several mechanisms, as discussed below. Galvanic corrosion is caused by dissimilar metals in contact or by the difference in metallurgy between two areas on a sucker rod. Most galvanic corrosion on rods is caused by differences in metal condition caused by hammer, wrench, or tong marks and the grooves left by rod-straightening machines. The impact area will be cathodic to the body of the rod, and corrosion will occur adjacent to the mark. Sucker rods have a soft decarburized layer or skin of low-carbon steel 0.13 to 0.2 mm (5 to 8 mils) thick. This layer can be broken by careless handling.

Bent rods are sometimes straightened and used again. This is poor practice, because a bent rod is permanently damaged and should be discarded. The rod-straightening machine will put spiral grooves around the rod, and corrosion will occur directly adjacent to the groove.

Any of these conditions will lead to pitting, and stress raisers will be set up. The cyclic stresses resulting from alternately stretching and compressing the rods during pumping operations will lead to rapid failure.

Stray current from surface equipment or leakage from a cathodic protection system will cause severe corrosion where the current leaves the rod string. It is usually seen on couplings or the part of the rod that is close to the coupling.

Damage from oxygen corrosion may take place when the rods are stored outdoors or when oxygen enters the wellbore through the annulus. Rusting of stored rods will often cause pitting, and rust deposits can set up concentration cells or under-deposit corrosion when the rods are run in the hole. Oxygen entry into the wellbore in wells that pump off or oxygen introduced during inhibitor treating operations will aggravate other forms of corrosion by depolarizing the cathodes on the metal surface during the corrosion reaction. Oxygen corrosion generally occurs in the lower part of the well: the casing, pump, tubing, and the lower part of the rod string. The effect lessens in the upper part of the well, because the oxygen is depleted by the corrosion reaction.

Carbon dioxide or sweet corrosion is caused by CO_2 from produced gases dissolving in water and forming carbonic acid. The carbonic acid ionizes to bicarbonate irons and hydrogen ions. A low pH results, and the bicarbonate and the carbonic acid will react directly with the steel rod and cause metal loss and pitting. The pits formed are usually round bottomed with sharp sides, and they may be connected in a line or will sometimes form a ring around the rod. Fatigue cracks will be initiated at the bottom of the pits.

Carbon dioxide corrosion is aggravated by the presence of oxygen and organic acids. Oxygen depolarizes the cathodes, and organic acids deplete the bicarbonate ion concentration, which dissolves protective carbonate scale. The formation of iron carbonate scale is the major limiting factor in CO_2 corrosion.

Many pumping wells are in the temperature range (<100 °C, or 212 °F) that is most conducive to CO_2 pitting. At these temperatures, the iron carbonate scale is formed mainly away from the surface, with some forming as a noncontinuous layer. Accelerated metal loss occurs in the gaps in the scale layer, and pits are formed.

Carbon dioxide corrosion may be sudden and catastrophic when breakthrough takes place in CO_2 floods. Wells that have been noncorrosive have failed within weeks after breakthrough.

Hydrogen sulfide ionizes in water to form HS^- and hydrogen ions. It is characterized by metal loss and pitting and can be quite severe. The iron sulfide formed generally does not form a protective layer and is usually cathodic to the metal surface. Even if a protective sulfide layer is formed, a break in this layer will result in pitting.

The presence of oxygen will increase the corrosion rate, and oxygen, in addition to depolarizing the cathodes, reacts with iron sulfide and forms elemental sulfur. This removes any protective sulfide layer and increases the corrosion rate. Elemental sulfur is corrosive to steel and further increases the corrosion rate.

Organic acids increase the corrosion rate by dissolving iron sulfide scale and leaving the metal bare. They also lower the pH and increase the driving force of the corrosion reaction. At pH less than 6, hydrogen sulfide reacts directly with the metal, and little or no iron sulfide is formed on the surface.

The pits formed during H_2S corrosion are generally small, round, and cone shaped. The acute angle at the bottom of the pit is a stress raiser, and it leads to cracking. Pits are usually not connected and are in a random pattern.

The amount of H_2S present has a direct effect on the time to failure or rods due to cracking. In some cases, corrosion pits are so small as to be undetectable before cracking occurs, or cracking may take place quickly at dents or nicks on the rods.

In addition to metal loss and pitting, sulfide stress cracking may occur in H_2S corrosion. The corrosion reaction generates hydrogen ions that combine to form atomic hydrogen. Atomic hydrogen penetrates the metal along grain boundaries and recombines to molecular hydrogen. The molecular hydrogen generates high pressures, and the metal cracks at grain boundaries. The microcrack acts as a stress raiser and quickly propagates.

Rod-on-tubing abrasion is common, and it aggravates corrosion reactions. Surface scale is removed, leaving bare metal. The adjacent areas covered with scale are cathodic to the bare metal and increase metal loss. Both the rod couplings and the tubing are damaged. Severe abrasion will lead to galling or removal of large portions of metal, which are literally torn away.

The flow velocities in pumping wells are generally not high enough to influence the corrosion rate, but localized areas of high velocity around rod protectors and restrictions due to scale build-up in the tubing could occur. High velocities can remove protective scale and inhibitor films. particularly if solids are present.

Elimination of Sucker Rod Corrosion. Once the cause of the corrosion has been found, corrective action is required so that the problem does not recur. The first step is to determine if the pumping program is correct. If the rod string and pumping procedure are not dynamically balanced, excessive tensile and compressive stresses are applied that will hasten fatigue failure and cracking due to corrosion.

The range of load, that is, the difference between the load of the upstroke and the downstroke, should be kept to a minimum. Long strokes at low speed will give the lowest load. The load is due to the weight of the rods and the fluid column on the upstroke and the weight of the rods on the downstroke.

The upstroke causes stretching, and the downstroke releases this stress, causing flexing of the rod. This cyclic stress induces fatigue failure; therefore, minimizing stress will reduce breaks caused by corrosion-induced cracking.

Proper rod string makeup will also reduce failures. Recommended torque loading should be followed when making up the string to be sure that the coupling is not in excessive stress or is not subject to play or movement resulting from too little torque during makeup. Hitting the rods or couplings with hammers and the use of pipe wrenches on the string should be avoided to eliminate marks that can lead to cracking.

Fluid pounding should be avoided. Fluid pounding is caused by the pump not filling completely on the upstroke and the plunger hitting the fluid on the downstroke. The sudden stop of movement causes a shock wave to propagate up the rod string. Fluid pounding can be the most damaging factor in rod failure. Rod guides can be installed to prevent rod-on-tubing wear.

Once mechanical deficiencies are corrected, an inhibition program should be initiated. Corrosion inhibitors can prevent or greatly reduce failures caused by pitting or fatigue and will ensure that the changes made in rod loading and handling will be effective.

Sucker rods are sometimes stored outdoors or in areas where internal storage is conducive to corrosion, such as coastal and industrial areas and in oil fields that produce hydrogen sulfide. Oxygen corrosion or rust is aggravated by the deposition of salt from marine environments, such as spray on offshore platforms and coastal areas. In warehouses and under sheds, the presence of sulfur dioxide, oxides of nitrogen, and H_2S will initiate corrosion attack and increase rusting.

The rod body and threads should be regularly inspected for corrosion damage. After inspection, the rods should be cleaned, and protective coatings should be applied.
